The solutions now completed will, we think, afford to the learner all the aid he can reasonably expect in his efforts to make himself acquainted with the PRINCIPLES OF ALGEBRA. Wherever his own attempts to accomplish the satisfactory solution of a question fail, he will find it of much service to him to have at his command the assistance here offered; and even when his endeavours are successful, he will often gain instruction by comparing his own work with the details thus given. In the expectation that the present collection of solutions will be consulted with a view to such instruction, we have frequently given different methods of working out the same example, and of thus exhibiting certain algebraical artifices and expedients—familiar enough to proficients, but which can be acquired by a learner only by practice, and the careful examination of illustrative models. No one can become an algebraist by *Rule:* all that rules can do is to dictate the mode of applying general principles; while, in many special cases, independent judgment and ingenuity must be exercised, in reference to the particular circumstances of the inquiry, in order to avoid an unnecessary accumulation of symbols, and a needless outlay of time and trouble—in fact, in order to give to the algebraic process that compactness of form, and neatness of finish, which constitute what is called an elegant solution. This mastery over his subject the student can acquire only by consulting the best models, and by cultivating the power, himself, of proceeding under the guidance of his own free judgment and penetration, unfettered by the shackles of *rules.* A learner should always be on the look-out for those facilitating expedients, which are often to be brought into operation in cases, in reference to which rules can afford but imperfect guidance. He would do well, however, to keep in remembrance that a *short* solution is not necessarily the *best* solution: what looks short upon paper may be the result of more mental exertion than what looks long; the art is so to manage that the expenditure of time and thought may be reduced to the smallest possible amount: a solution thus characterised is entitled to be called an elegant solution. To those merely mechanical operations—the performance of which it is the business of the early parts of algebra to teach—these remarks do not, of course, apply; they refer exclusively to the subject of problem-solving, and to the more advanced portions of algebraical research.

CHAPTER VI.

SERIES AND LOGARITHMS.

ON SERIES.

1. *The Principle of the Permanence of Equivalent Forms.*

IT was stated at page 451, that "the processes of Algebra are, for the most part, only processes of Arithmetic, extended and rendered more comprehensive by the aid of a new set of symbols, taken in combination with the well-known symbols of Arithmetic;" and in the explanations following, it is made to appear that Algebra is a generalisation of Arithmetic—that whereas 2, 5 . . . represent certain special numbers, *a*, *b* . . . represent *any* numbers. This is professedly an elementary view of the case; and, as an elementary view, is quite sufficient. But when the nature of the generalisation is more closely considered, it appears that, in what is commonly called Algebra, there are really two distinct, though closely connected sciences, which may be called respectively Arithmetical Algebra, and Symbolical Algebra. In Arithmetical Algebra, "the symbols represent numbers, whether abstract or concrete, whole or fractional, and the operations to which they are subject are assumed to be identical, in meaning and extent, with the operations of the same name in common arithmetic. The only distinction between the two sciences consists in the substitution of general symbols for digital numbers."

Thus, in arithmetic, it is impossible to subtract 7 from 5: so that $5 - 7$ is impossible; and hence in arithmetical Algebra, when we write $a - b$, we do so with the tacit assumption that $a > b$. If we generalise a step farther than this, and allow ourselves to write $a - b$ for all values of a and b, then it is clear that the negative sign has a more extended meaning than that of mere subtraction; and it remains for us to ascertain what this more extended meaning is. The science which concerns itself with this second generalisation is called *Symbolical Algebra*. Thus, then, we have, in all three sciences—

(1). Arithmetic, in which the symbols employed are *particular* in *form*, and *particular* in *value*.

(2). Arithmetical Algebra, in which the symbols employed are *general* in *form*, but *particular* in *value*.

(3). Symbolical Algebra, in which the symbols employed are *general* in *form*, and also *general* in *value*.

Thus, as the second of these sciences is a generalisation of the first, so the third is a generalisation of the second. The principle in accordance with which this second generalisation is conducted is called that of "The permanence of equivalent forms." The principle may be stated as follows:—

"Whatever algebraical forms are equivalent, when the symbols are general in form, but specific in value, will be equivalent likewise when the symbols are general in value, as well as in form."

For the full exposition of relations between these two sciences, the advanced reader is referred to a *Treatise on Algebra*, by George Peacock, D.D., to whom is due the detection of the co-existence of these two sciences in that which is generally treated as one science—Algebra. We shall have several occasions to make use of the principles above enunciated in the course of the following pages. As an example of their application, we will reconsider the Theory of Indices already treated in p. 465.

2. *On the Theory of Indices.*

We have already seen that a^m signifies $a \times a \times a \times a$, &c., to m factors, when, of course, m must be a whole number.

In like manner a^n signifies $a \times a \times a$, &c., to n factors. Hence—

$$a^m \times a^n = a \times a \times a \ldots \text{to} (m+n) \text{ factors,}$$

and therefore $a^m \times a^n = a^{m+n}$.

This is a result in *Arithmetical Algebra*. It is perfectly *general in form*, but it is *particular* in value; for m and n are, by the definition of a^m, limited to being positive whole numbers. If we suppose m and n to have negative or fractional values, this involves a generalisation of our original definition; and the question arises, what meaning we must assign to such expressions as a^{-n} $a^{\frac{p}{q}}$. To answer it, we proceed in the following manner:—By assuming m and n general in value as well as in form, we enter the domains of Symbolical Algebra; hence, by the principle of the permanence of equivalent forms, under all circumstances—

$$a^m \times a^n = a^{m+n},$$

$$\therefore a^m \times a^n \times a^r = a^{m+n} \times a^r = a^{m+n+r};$$

and so on for any number of terms. Hence—

$$a^{\frac{p}{q}} \times a^{\frac{p}{q}} \times a^{\frac{p}{q}} \times \ldots \text{to } q \text{ terms} = a^{\frac{p}{q}+\frac{p}{q}+\frac{p}{q}+\ldots \text{ to } q \text{ fraction}}$$

$$\left(a^{\frac{p}{q}}\right)^q = a^p.$$

$$\therefore a^{\frac{p}{q}} = \sqrt[q]{a^p}.$$

i.e., $a^{\frac{p}{q}}$ must (in accordance with our general principle) signify the q^{th} root of the p^{th} power of a.

Again, $a^m \times a^n \times a^{-n} = a^{m+n} = a^m$,

$$\therefore a^n \times a^{-n} = 1.$$

$$\therefore a^{-n} = \frac{1}{a^n}.$$

Hence, we see that in assigning the meaning $\sqrt{a}$ to $a^{\frac{1}{2}}$, we are doing so not arbitrarily, but in accordance with a principle which lies at the foundation of Algebra.

3. *On Impossible Expressions.*

Again, we know that $\sqrt{a^2} = a$. In like manner if we were to have $-a^2$, this is $= a^2 \times (-1)$, and $\therefore \sqrt{-a^2} = a\sqrt{-1}$. The expression $\sqrt{-1}$ is frequently spoken of as an "impossible quantity," an "imaginary expression," and so on, since -1 cannot be produced by multiplying either $+1$ by $+1$, or -1 by -1. In reality, however, $\sqrt{-1}$ is as possible or as impossible as -1; for in arithmetical Algebra a and $\sqrt{a}$ are only admissible on the supposition that a is positive. In symbolical Algebra this restriction is removed, and therefore in *that* both $-a$ and $\sqrt{-a}$ are admissible. Hence in future investigations we shall make use of $\sqrt{-1}$ just as freely as $\sqrt{a}$, whenever it may suit our purpose, quite undeterred by the circumstance of its so-called impossibility. Of course there are many differences between the symbols -1 and $\sqrt{-1}$; for instance, the interpretation of the former is a much simpler matter than the interpretation of the latter, and in some cases $a - b$ belongs to arithmetical Algebra; but $a + b\sqrt{-1}$ *never* does. We cannot enter further into the matter now; what we have said will be enough to explain that we are justified in introducing into our calculations expressions which are called "imaginary," or "impossible."

4. *To prove that if* $A_0 + A_1x + A_2x^2 + \cdots + Anx^n = a_0 + a_1x + a_2x^2 + \ldots + a_nx_n$, *for all values of* x. *Then* $A_0 = a_0$, $A_1 = a_1$, $A_2 = a_2$, $-A_n = a^n$.

For since $A_0 + A_1x + \ldots + A_nx^n = a_0 + a_1x + \ldots + a_nx^n$ are equivalent for ALL values of x; they are equivalent when $x = 0$. $\therefore Ao = a_0$, and $\therefore A_1x + A_2x^n + \ldots + A_nx^n = a_1x + a_2x^n + \ldots + a^nx^n$; $\therefore A_1 + A_2 x + \cdot\cdot + A_nx^{n-1} = a_1 + a_2x + \ldots + a_nx^{n-1}$ for all values of x: and hence when $x = o$, $\therefore A_1 = a_1$, and so on. Hence $A_2 = a_2 \ldots$ and $A_n = a_n$.

This is called the principle of Indeterminate Coefficients.

It will be seen, that in the case supposed, where the number of terms in each series is finite, the proof is quite rigid. If each series were infinite the proof would not then be conclusive; and, accordingly, we shall refrain from using this principle except in cases where no objection can be raised to its use. Such as the following:—

(1). To resolve $\frac{1-2x+3x^2}{(x-1)(x-2)(x-3}$ into partial fractions.

Assume $\frac{1-2x+3x^2}{(x-1)(x-2)(x-3)} = \frac{A_1}{x-1} + \frac{A_2}{x-2} + \frac{A_3}{x-3}$.

$\therefore 3x^2 - 2x + 1 = A_1(x-2)(x-3) + A_2(x-3)(x-1) + A_3(x-1)(x-2) = x^2(A_1 + A_2 + A_3) - x(5A_1 + 4A_2 + 3A_3) + 6A_1\ 3A_2 + 2A_3$.

This being true for all values of x, we have

$$\begin{aligned} A_1 + A_2 + A_3 &= 3. \\ 5A_1 + 4A_2 + 3A_3 &= 2 \\ 6A_1 + 3A_2 + 2A_3 &= 1. \\ \therefore 2A_1 + A_2 &= -7. \\ 4A_1 + A_2 &= -5 \\ \hline 2A_1 &= 2. \end{aligned}$$

$$\therefore A_1 = 1.$$
$$\therefore A_2 = -9.$$
$$A_2 = 11.$$

$$\therefore \frac{3x^2-2x+1}{(x-1)(x-2)(x-3)} = \frac{1}{x-1} - \frac{9}{x-2} + \frac{11}{x-3}.$$

N.B.—A fraction written in the above form is said to be resolved into its partial fractions.

(2). Resolve $\frac{x-1}{(x+1)(x^2+3)}$ into its partial fractions.

Assume $\frac{x-1}{(x+1)(x^2+3)} = \frac{A}{x-1} + \frac{Mx+N}{x^2+3}$.

$$\therefore x - 1 = x^2(A + M) + x(M + N) + 3A + N$$

$$\begin{aligned} \therefore A + M &= 0 \\ M + N &= 1 \\ 3A + N &= -1 \\ \therefore A - N &= -1 \\ \therefore 4A &= -2 \\ A &= -\tfrac{1}{2}. \\ N &= \tfrac{1}{2} \\ M &= \tfrac{1}{2}. \end{aligned}$$

$$\therefore \frac{x-1}{(x+1)(x^2+8)} = -\frac{1}{2(x+1)} + \frac{x+1}{2(x^2+3)}.$$

The student can prove the following:—

(1). $\frac{3x^2+4x-1}{(x+1)(x-1)(x-2)} = \frac{1}{x+1} + \frac{1}{x-1} + \frac{1}{x-2}$

(2). $$\frac{2x+3}{(x+2)(x-3)(x-5)} = -\frac{1}{35(x+2)} - \frac{11}{10(x-3} + \frac{79}{70(x-5)}$$

(3). $$\frac{x}{(x-a)(x-b)} = \frac{a}{a-b}\cdot\frac{1}{x-a} - \frac{b}{a-b}\cdot\frac{1}{x-b}.$$

(4). $$\frac{1}{(x-a)(x-b)(x-c)} = \frac{1}{(c-a)(b-a)}\cdot\frac{1}{x-a} + \frac{1}{(a-b)(c-b)}\cdot\frac{1}{x-b} + \frac{1}{(a-c)(b-c)}\cdot\frac{1}{x-c}$$

(5). A series is a number of algebraical expressions, each of which is connected with those which precede it in some determinate manner.

For example:—In the treatise on Elementary Algebra, we have had examples of series in the arithmetical and geometrical progressions.* In the former case, each term is derived from the one preceding it by adding a certain known number called the common difference. In the latter case, each term is derived from the one preceding it by multiplying that term by a certain known number called the common ratio. Hence,

$$a + (a+b) + (a+2b) + (a+3b) \cdots\cdots$$
$$a + ar + ar^2 + ar^3 + \cdots\cdots$$
$$\text{and } 1 + r + r^2 + r^3 + \cdots\cdots$$

are series.

Def.—A series is called a finite series when it has an assignable last term. It is called an infinite series when, if we fix on any term whatever, there are terms beyond it.

Thus, $1 + r + r^2 + \cdots\cdots + r^n$ is a finite series. But $1 + r + r^2 + \cdots\cdots$ *ad inf.* is an infinite series, because, if we take any term whatever—for instance, the 50th, or 500th, or 5000th—there are always terms beyond it.

6. *To explain what is meant by a Convergent and a Divergent Series.*

Def.—If the sum of the terms of a series has an arithmetical limit when the number of terms is infinite, that series is *convergent*; if otherwise, it is *divergent*.

If we divide 1 by $1 - r$, we shall produce $1 + r + r^2 + \cdots\cdots$ which series we can continue to produce to any number of terms whatever. Hence the fraction $\frac{1}{1-r}$, and the series, $1 + r + r^2 + \cdots\cdots$ *ad inf.* are equivalent to each other; or

$$\frac{1}{1-r} = 1 + r + r^2 + r^3 + \textit{ad infinitum}.$$

Now, it has been already proved, that if $r < 1$, by taking a sufficiently large number of terms, the numerical value of the series can be made to approach to the numerical value of $\frac{1}{1-r}$, to within any assignable limits. For instance, if $r = \frac{1}{2}$ then $\frac{1}{1-r} = 2$; and if we take four terms the series equals 1·875. If we take five terms it equals 1·9375; if six terms, it equals 1·96875; and hence in the extreme case, when we suppose the number of terms to be infinitely large, the series is actually equal to 2. And hence if r be less than 1,

$$\frac{1}{1-r} = 1 + r + r^2 + r^3 + \textit{ad infinitum},$$

where by the sign $=$ we mean that the fraction $\frac{1}{1-r}$ is arithmetically equal to the series. But if r be greater than 1, for instance, if equal to 2, the fraction equals -1; whereas if we take four terms, the series 15; if five terms, 31; if six terms, 63; and so on, where there is no trace of approximation towards arithmetical equality between the series and the fraction. In the former case the series is said to be *convergent*, in the latter *divergent*; and if we include both cases in the expression,

$$\frac{1}{1-r} = 1 + r + r^2 + \ldots \textit{ ad infinitum};$$

it must be understood that the sign $=$ signifies algebraically equivalent, not arithmetically equal. This explanation will be sufficient to enable the student to understand the meaning of the terms convergent and divergent, when applied to special series. The general questions that are suggested by series, and their convergency and divergency, belong to the higher parts of the science—and many of them are still doubtful.

7. *A test for ascertaining the Convergency of a given Series.*

We have already seen that—

$\frac{1}{1-r} = 1 + r + r^2 + r^3 + \ldots.$ is convergent when r is < 1. Hence if we have a series

$$\text{A} + \text{B} + \text{C} + \text{D} + \ldots.$$

and can show that $\text{B} < r\text{A}$, $\text{C} < r^2\text{A}$, $\text{D} < r^3\text{A}$, &c. Then—

$$\text{A} + \text{B} + \text{C} + \text{D} + \ldots < \text{A}\,(1 + r + r^2 + r^3 + \ldots.).$$

This latter is convergent if r be < 1. And if so, the former must plainly be convergent too. This gives us a test for ascertaining whether a given series is convergent, which we shall find useful hereafter. The student must remember that, though all series which submit to this test are convergent, many may be convergent which do not submit to it.

For instance, to ascertain whether the series

$\theta + \frac{\theta^3}{1\cdot2\cdot3} + \frac{\theta^5}{1\cdot2\cdot3\cdot4\cdot5} + \text{\&c.}$, *ad infinitum*, is convergent when $\theta < 2$.

The series may be written—

$$\theta\left\{1 + \frac{\theta^2}{2\,3\cdot} + \frac{\theta^4}{2\cdot3\cdot4\cdot5} + \ldots\right\}$$

$$\frac{\theta^2}{2\cdot3} = \frac{\theta}{2} \times \frac{\theta}{3} < \frac{\theta}{2}\cdot\frac{\theta}{2} \text{ or is } < \left(\frac{\theta}{2}\right)^2$$

Similarly, $\frac{\theta^4}{2\cdot3\cdot4\cdot5} < \left(\frac{\theta}{2}\right)^4$ and so on for the other terms; hence the given series is less than

$$\theta\left\{1 + \left(\frac{\theta}{2}\right)^2 + \left(\frac{\theta}{2}\right)^4 + \ldots \textit{ ad infin.}\right\}$$

and this is convergent if $\left(\frac{\theta}{2}\right)^2 < 1$, or if $\theta < 2$; and hence the given series is convergent if $\theta < 2$.

N.B. $\frac{1}{1+r} = 1 - r + r^2 - r^3 + \ldots.$ is true arithmetically when $r < 1$. Hence, the above test of convergency holds good when the terms are alternately positive and negative.

In the following pages we shall confine our attention to three series—the *Binomial*, the *Exponential*, and the *Logarithmic*.

8. *To state the Binomial Theorem.*†

If $a.\ b.\ n.$ are any numbers whatever, then—

$$(a+b)^n = a^n + n.a^{n-1}b + \frac{n(n-1)}{1\cdot2}a^{n-2}b^2 + \frac{n(n-1)(n-2)}{1\cdot2\cdot3}a^{n-3}b^3 + \text{\&c.}$$

The reader will observe that the first term is a_n, that in each term the index of a diminishes by unity, while the power of b continually increases by unity, so that the sum of the indices of each term is n.

Again, the coefficient of each term has for each denominator the continued products $1.2.3\ldots.$ up to the index of b *inclusive*; and for numerator, the continued product $n\,(n-1)\,(n-2)\ldots.$ down to the index of a

---

* See *ante*, p. 477, *et seq.*

† See *ante*, p. 462.

exclusive. Thus the coefficient of the term which involves $a^{n-r}b^{r}$ is

$$\frac{n.(n-1)\,(n-2)\,\ldots\ldots(n-r+1)}{1\cdot\ \ 2.\ \ \ 3.\ \ \ldots\ldots\ \ r}.$$

9. *To prove the Binomial Theorem when n is a positive Integer.*

(*a*) To show that $(a+b)^n = a^n + na^{n-1}b + \ldots.$

By actual multiplication,

$$\begin{aligned}(a+b)^2 &= a^2 + 2ab + \ldots.\\ (a+b)^3 &= a^3 + 3a^2b + \ldots.\\ (a+b)^4 &= a^4 + 4a^3b + \ldots.\end{aligned}$$

These results plainly suggest the assumption

$$(a+b)^m = a^m + ma^{m-1}b + \ldots.$$

Multiply both sides by $a+2$, and we have

$$(a+b)^{m+1} = a^{m+1} + (m+1)\,a^mb + \ldots.$$

which is clearly of the same form as the assumption, *i. e.*, this has $m+1$, wherever that has m. Hence, if the theorem be true for m, it must also be true for $m+1$. Now it is true for 4, ∴ it is true for 5, ∴ for 6, and so on; therefore it is always true for any positive whole number.

$$\therefore (a+b)^n = a^n + na^{n-1}b + \ldots. \qquad (a)$$

N.B.—If $a = 1$, and $b = x$, we of course have

$$(1+x)^n = 1 + nx + \ldots. \qquad (b)$$

(*β*) To show that—

$$(1+x)^n = 1 + nx + \frac{n.(n-1)}{1.2}x^2 + \frac{n\,(n-1)\,(n-2)}{1.2.3.}x^3 + \ldots$$

For suppose—

$$(1+x)^n = 1 + nx + A_2x^2 + A_3x^3 + A_4x^4 + \ldots \quad (c)$$

It is plain, since $(1+x)^n$ means $(1+x)$ multiplied into itself n times, that this series is finite, so that we may employ the principle of indeterminate coefficients.

In the series A_2, A_3, A_4, ….. do not at all depend on x, and will therefore continue the same for all values of x, so that, for instance—

$$(1+y)^n = 1 + ny + A_2y^2 + A_3y^3 + A_4y^4 + \ldots.$$

In equation (*a*), write $x = y + z$. Then—

$$\begin{aligned}(1+y+z)^n &= 1 + n\,(y+z) + A_2\,(y+z)^2 + A_3\,(y+z)^3 + \ldots.\\ &= 1 + ny + nz + A_2\,(y^2 + 2yz + \ldots) + A_3\,(y^3 + 3y^22 + \ldots.)\\ &= 1 + ny + A_2y^2 + A_3y^3 + A_4y^4 + \ldots.\\ &\quad + z\{n + 2A_2y + 3A_3y^2 + 4A_4y^3 + \ldots.\} + \&c. \ (d)\end{aligned}$$

which is true for all values of y and z.

Again, if in equation (*a*) we take $1+y = a$ and $z = b$, we have—

$$(\overline{1+y}+z)^n = (1+y)^n + n\,(1+y)^{n-1}z + \ldots.\ (E).$$

Now, (*d*) and (*e*) are the same for all values of z, ∴ the coefficient of z in each must be the same, ∴

$$n\,(1+y)^{n-1} = n + 2A_2y + 3A_3y^2 + 4A_4y^3 + \ldots.$$

for all values of y; multiply both sides by $1+y$,

$$\begin{aligned}\therefore n\,(1+y)^n = n &+ 2A_2y + 3A_3y^2 + 4A_4y^3 + \ldots.\\ &+ ny + 2A_2y^2 + 3A_3y^3 + \ldots.\end{aligned}$$

But by equation, (*c*) $n\,(1+y)^n = n + n^2y + A_2ny^2 + A_3ny^3 + A_4ny^4 + \ldots.$

$$\begin{aligned}&\therefore n + n^2y + nA_2y^2 + nA_3y^3 + nA_4y^4 + \ldots.\\ &= n + (2A_2 + n)y + (3A_3 + 2A_2)y^2 + (4A_4 + 3A_3)y^4 + \ldots.\end{aligned}$$

These expressions are true for all values of y.

$$\begin{aligned}\text{Hence } 2A_2 + n &= n^2\\ 3A_3 + 2A_2 &= nA_2\\ 4A_4 + 3A_3 &= nA_3\end{aligned}$$

$$\therefore 2A_2 = n^2 - n = n(n-1(, \ \therefore A_2 = \frac{n(n-1)}{1\cdot2}$$

$$3A_3 = A_2(n-2) \qquad A_3 = \frac{n(n-1)(n-2)}{1\cdot2\cdot3}$$

$$4A_4 = A_3(n-3) \qquad A_4 = \frac{n(n-1)(n-2)(n-3)}{1\cdot2\cdot3\cdot4}$$

Hence—

$$(1+x)_n = 1 + nx + \frac{n(n-1)}{1\cdot2}x^2 + \frac{n(n-1)(n-2)}{1\cdot2\cdot3}x^3 \ \ldots.\ (I).$$

The student will observe the manner in which each successive coefficient is derived from the one that goes before it. He will easily see that if we look in the $r-1^{th}$ and r^{th} terms—viz., $A_{r-1.}\,x_{r-1} + A_rx_r + \ldots.$ we should then have an equation—

$$\begin{aligned}rA_r - (r-1)\,A_{r-1} &= nA_{r-1},\\ \therefore rA_r &= A_{r-1}\,(n-r+1).\end{aligned}$$

so that the general term of the expansion will be—

$$\frac{n.(n-1)\,(n-2)\ldots(n-r+1)}{1\cdot\ \ 2\cdot\ \ \ 3\cdot\ \ \ldots\ \ r}x_r.$$

He will also observe that if n be a whole number when r is greater than n, there will be in the general term a factor $n - \overline{n+1} + 1 = o$; or x^n is the last term of the series, also the coef. of

$$x^n = \frac{n.n-1\ldots2\cdot1}{1\cdot2\ldots.n} = 1. \text{ Hence—}$$

$$(1+x)^n = 1 + nx + \frac{n(n-1)}{1\cdot2}x^2 + \frac{n(n-1)\,(n-1)}{1\cdot2\cdot3}x^3 + \ldots + x^n$$

(*γ*) To prove the series—

$$(a+b)^n = a^n + n.a^{n-1}b + \frac{n.(n-1)}{1\cdot2}a^{n-2}b^2 + \ldots + b^n$$

For in the last series write $x = \frac{b}{a}$. Then-

$$\left(1+\frac{b}{a}\right)^n = 1 + n\,\frac{b}{a} + \frac{n(n-1)}{1\cdot2}\frac{b^2}{a^2} + \ldots. + \frac{b^n}{a^n}.$$

$$\text{Now, } a\left(1+\frac{b}{a}\right) = a + b,$$

$$\therefore a^n\left(1+\frac{b}{a}\right)^n = (a+b)^n.$$

$$\text{But } a^n\left(1+\frac{b}{a}\right)^n = a^n + n.\frac{b}{a}\times a^n + \frac{n.(n-1)}{1\cdot2}\frac{b^2}{a^2}\times a^n + \ldots + \frac{b^n}{a^n}\times - a^n$$

$$\therefore (a+b)^n = a^n + na^{n-1}b + \frac{n.(n-1)}{1\cdot2}a^{n-2}b^2 + \ldots + b^n\ \ldots\ (II),$$

which is the Binomial Theorem when n is a positive integer.

In page 461, a table of the developments of powers of a binomial is given. These may be immediately deduced from the series we have just proved. Thus, to develop, or expand $(a+x)^8$, we have—

$$(a+x)^n = a^n + n\,a^{n-1}x + \frac{n.n-1}{1\cdot2}a^{n-2}x^2 + \ldots.$$

$$\begin{aligned}\therefore (a+x)^8 = a^8 &+ 8\,a^7x\frac{8\cdot7}{1\cdot2}a^6x^2 + \frac{8\cdot7\cdot6}{1\cdot2\cdot3}a^5x^3 + \frac{8\cdot7\cdot6\cdot5}{1\cdot2\cdot3\cdot4}a^4x^4,\\ &+ \frac{8\cdot7\cdot6\cdot5\cdot4}{1\cdot2\cdot3\cdot4\cdot5}a^3x^5 + \frac{8\cdot7\cdot6\cdot5\cdot4\cdot3}{1\cdot2\cdot3\cdot4\cdot5\cdot6}.a^2x^6 +\\ &+ \frac{8\cdot7\cdot6\cdot5\cdot4\cdot3\cdot2}{1\cdot2\cdot3\cdot4\cdot5\cdot6\cdot7}.\,ax^7 + \frac{8\cdot7\cdot6\cdot5\cdot4\cdot3\cdot2\cdot1}{1\cdot2\cdot3\cdot4\cdot5\cdot6\cdot7\cdot8}.\,x^8\\ = a^8 &+ 8a^7x + \frac{8\cdot7}{1\cdot2}a^6x^2 + \frac{8\cdot7\cdot6}{1\cdot2\cdot3}a^5x^3 + \frac{8\cdot7\cdot6\cdot5}{1\cdot2.3.4}.\,a^4x^4\\ &+ \frac{8\cdot7\cdot6}{1\cdot2.3}a^3x^5 + \frac{8\cdot7}{1\cdot2}a^2x^6 + 8ax^7 + x^8.\\ = a^8 &+ 8a^7x + 28a^6x^2 + 56a^5x^3 + 70a^4x^4 + 56a^3x^5\\ &+ 28a^2x^6 + 8ax^7 + x^8.\end{aligned}$$

The student will observe that the coefficients of a^7x and of ax^7 are the same, as also of a^6x^2 and a^2x^6 of a^5x^3 and a^3x^5.

And, in general, if we write the series, whether we begin from a or from x, we get the same coefficients. Thus—

$$x^9 + 8x^7a + 28x^6a^2 + 56x^5a^3 + 70x^4a^4 + 56x^3a^5 + 28x^2a^6 + 8xa^7 + a^9$$

$$a^9 + 8a^7x + 28a^6x^2 + 56a^5x^3 + 70a^4x^4 + 56a^3x^5 + 28a^2x^6 + 8ax^7 + x^5.$$

It can easily be seen that this must be the case, for the former of these two is $(x + a)^9$, and the latter $(a + x)^9$, which are clearly the same thing. This consideration greatly facilitates our expansion of a binomial. Thus—

$$(a + x)^{10} = a^{10} + 10\,a^9x + \frac{10\cdot9}{1\cdot2}a^8x^2 + \frac{10\cdot9\cdot8}{1\cdot2\cdot3}\,a^7x^3 + \frac{10\cdot9\cdot8\cdot7}{1\cdot2\cdot3\cdot4}\,a^6x^4 + \frac{10\cdot9\cdot8\cdot7\cdot6}{1\cdot2\cdot3\cdot4\cdot5}\,a^5x^5 + \ldots$$

$$= a^{10} + 10a^9x + 45a^8x^2 + 120a^7x^3 + 210a^6x^4 + 252a^5x^5 + 210a^4x^6 + 120a^3x^7 + 45a^2x^8 + 10ax^9 + x^{10}.$$

In like manner—

$$(a + x)^9 = a^9 + 9a^8x + 36a^7x^2 + 84a^6x^3 + 121a^5x^4 + 121a^4x^5 + 84a^3x^6 + 36a^2x^7 + 9ax^8 + x^9.$$

It will also be observed that, in the case of $(a + x)^{10}$ there is a middle term, $252a^5x^5$; but in the case of $(a + x)^9$ there is no middle term. In fact, it is plain that the expansion of $(a + b)^n$ contains $n + 1$ terms, for the expansion contains one term in which b does not appear, and also terms containing b, b^2, b^3 . . . . up to b^n. Hence, if n be even, $n + 1$ is odd, and the expansion has a middle term; if n be odd, $n + 1$ is even, and the expansion is without a middle term.

10. *To prove the Binomial Theorem for any value of n.*

Let us use the notation

$$f(n) = 1 + nx + \frac{n.(n-1)}{1\cdot2}x^2 + \ldots.$$

for all values of n.

$$\therefore f(m) = 1 + mx + \frac{m.(m-1)}{1\cdot2}x^2. + \ldots$$

and

$$f(m+n) = 1 + (m+n)x + \frac{(m+n)(m+n-1)}{1\cdot2}x^2 +,$$

&c.

Now, when m and n are positive integers, we obtain from equation (I)

$$(1+x)^m = 1 + mx + \frac{m.(m-1)}{1\cdot2}.\,x^2 + \ldots.$$

$$(1+x)^n = 1 + nx + \frac{n.(n-1)}{1\cdot2}x^2 + \ldots.$$

$$(1+x)^{m+n} = 1 + (m+n)x + \frac{(m+n)(m+n-1)}{1\cdot2}x^2 + \ldots.$$

$$\therefore (1 + mx + \frac{m.(m-1)}{1\cdot2}x^2 + \ldots) \times (1 + nx + \frac{n(n-1)}{1\cdot2}x^2 + \ldots)$$

$$= (1+x)^m(1+x)^n = (1+x)^{m+n} = 1 + (m+n)x + \frac{(m+n)(m+n-1)}{1\cdot2}x^2 + \text{\&c.}$$

Hence, when m and n are any positive integers whatever,

$$f(m)\,f(n) = f(m+n)$$

In accordance with the principle of the permanence of equivalent forms, we assume this to hold good, whatever m and n are, and then interpret the meaning we must assign to $f(m)$ consistently with this assumption.

It is plain that

$$f(m)\,f(n)\,f(p) = f(m+n)\,f(p) = f(m+n+p),$$

and so on for any number of terms.

Hence,

$$f(\tfrac{p}{q}) \times f(\tfrac{p}{q}) \times f(\tfrac{p}{q}) \text{ to } q \text{ factors} = f(\tfrac{p}{q} + \tfrac{p}{q} + \tfrac{p}{q} + \text{to } q \text{ fractions}) \therefore \left\{f(\tfrac{p}{q})\right\}^q = f(p).$$

Now p is a positive integer,

$$\therefore 1 + px + \frac{p.(p-1)}{1\cdot2}x^2 + \ldots. = (1+x)^p$$

$$\therefore \quad f(p) = (1+x)^p$$

$$\therefore \left\{f(\tfrac{p}{q})\right\}^q = (1+x)^p$$

$$\therefore f(\tfrac{p}{q}) = (1+x)^{\frac{p}{q}}$$

Let $\frac{p}{q} = n$

$$\therefore \quad (1+x)^n = f(n) = 1 + nx + \frac{n.(n-1)}{1\cdot2}x^2 + \ldots.$$

when n is a fraction.

Again, if n be negative we have

$$f(n)\,f(m)\,f(-m) = f(n+m-m) = f(n)$$

$$\therefore f(m)\,f(-m) = 1\cdot$$

$$f(-m) = \frac{1}{f(m)}.$$

Now, m is positive $\therefore f(m) = (1+x)^m$

$$\therefore \quad \frac{1}{f(m)} = (1+n)^{-m}$$

$$\therefore \quad (1+x)^{-m} = f(-m).$$

Let $n = -m$

$$\therefore (1+x)^n = f(n) = 1 + nx + \frac{n.(n-1)}{1\cdot2}x^2 + \ldots.$$

when n is negative.

And therefore, for all values of n positive or negative, integral or fractional,

$$(1+x)^n = 1 + nx + \frac{n.(n-1)}{1\cdot2}x^2 + \frac{n(n-1)(n-2)}{1\cdot2\cdot3}x^3 + \ldots. \text{ (III.)}$$

Let $x = \frac{b}{a}$

$$(1 - \frac{b}{a})^n = 1 + n.\frac{b}{a} + \frac{n.(n-1)}{1\cdot2}\cdot\,\frac{b^2}{a^2} + \ldots.$$

Now, $a^n(1 + \frac{b}{a})^n = (a+b)^n$

$$\therefore (a+b)^n = a^n + na^{n-1}b + \frac{n.(n-1)}{1\cdot2}a^{n-1}b^2 + \ldots. \text{(IV.)}$$

which is the Binomial Theorem, and we have proved it to hold good for all values of n positive or negative, fractional or integral.

N.B.—The Binomial Theorem was discovered by Newton; it is very important, and is constantly used in almost every part of mathematics; it is therefore very necessary that the student should be quite familiar with it. It will be well if he will carefully examine the following results.

(1.) To show that

$$(1-x)^n = 1 - n.x + \frac{n.(n-1)}{1\cdot2}x^2 - \frac{n(n-1)(n-2)}{1\cdot2\cdot3}x^3 + \text{\&c.}$$

We obtain this from equation (IV.) by writing $a = 1$, and $b = -x$.

(2). To show that

$$2^n = 1 + n + \frac{n\cdot(n-1)}{1\cdot2} + \frac{n\cdot(n-1)(n-2)}{1\cdot2\cdot3} + \ldots.$$

write in the series (IV.) $a = 1$ and $b = 1$, and we obtain this result.

(3). To show that

$$n + \frac{n(n-1)(n-2)}{1\cdot2\cdot3} + \text{\&c.} = 1 + \frac{n(n-1)}{1\cdot2} + \text{\&c.}$$

write in the series (IV.) $a = 1$ and $b = -1$. Then

$$0 = 1 - n + \frac{n(n-1)}{1\cdot2} - \frac{n.(n-1)(n-2)}{1\cdot2\cdot3} - \text{\&c.}$$

Whence the result.

(4). To show that

$$\frac{1}{\sqrt{1-x}} = 1 + \tfrac{1}{2}x + \frac{1\cdot3}{2\cdot4}x^2 + \frac{1\cdot3\cdot5}{2\cdot4\cdot6}x^3 + \&c.$$

For $\frac{1}{\sqrt{1-x}} = (1-x)^{-\frac{1}{2}}$.

Hence, by the general formula (IV.), this equals

$$1 + (-\tfrac{1}{2})(-x) + \frac{(-\frac{1}{2})(-\frac{1}{2}-1)}{1\cdot2}(-x)^2$$
$$+ \frac{(-\frac{1}{2})(-\frac{1}{2}-1)(-\frac{1}{2}-2)}{1\cdot2\cdot3\,(-2^3)}$$
$$= 1 + \tfrac{1}{2}x + \frac{\frac{1}{2}\cdot\frac{3}{2}}{1\cdot2}x^2 + \frac{\frac{1}{2}\cdot\frac{3}{2}\cdot\frac{5}{2}}{1\cdot2\cdot3}x^3 + \&c.$$

Whence the result.

(5). To ascertain whether the series $1 + nx + \frac{n(n-1)}{1\cdot2}x^2 + \ldots$ is convergent.

For the sake of brevity, let us write the series

$$1 + nx + \ldots\ldots + A_r x^r + A_{r+1}x^{r+1} + A_{r+2}x^{r+2} + \ldots\ldots$$

where $A_r = \frac{n.(n-1)\ldots\ldots(n-r+1)}{1\,2\quad\ldots\ldots\quad r}$

$$\therefore A_{r+1} = A_r\frac{n-r}{r+1}$$
$$A_{r+2} = A_{r+1}\frac{n-r-1}{r+2}$$

Now $\frac{n-r}{r+1} = \frac{n+1}{r+1} - 1.$

$$\frac{n-r-1}{r+2} = \frac{n+1}{r+2} - 1.$$

Now, r can be taken so large that $\frac{n+1}{r+2} < 1$; and therefore $\frac{n+1}{r+2} < 1$. So that if $\frac{n-r}{r+1} < 1$. $\frac{n-r-1}{r+2}$ is also < 1.

Also, these fractions are all negative, ∴ if A_r be positive, A_{r+1} is negative, A_{r+2} is positive, and so on. But if we neglect the consideration of the signs from what has been proved, it appears that $A_r, > A_{r+1}, A^{r+1} > A_{r+2}$, &c.

Hence, the part of the series beginning with $A_r x^r$; *i.e.*

$$A_r x^r + A_{r+1} + x^{r+1} + A_{r+2}x^{r+2} + \ldots\ldots$$

has its terms (if x be positive) alternately positive and negative, and is term by term less than

$$A_r x^r - A_r x^{r+1} + A_r x^{r+2} - \&c.\ldots\ldots$$

provided $A_r < 1$.

But this latter series equals—

$$A_r x^r (1 - x + x^2 -)\ \&c.$$

which is convergent of $x < 1$.

Hence, provided $x < 1$, the series, at all events, after a certain number of terms, converges.

(6). Hence, if $x < 1$.

$$(1+x)^n = 1 + nx + \frac{n\cdot(n-1)}{1\cdot2}x^2 + \ldots\ldots$$

is true arithmetically. We may therefore apply this formula to extracting roots of numbers. Thus to extract the 5th root of 1·1. The fifth root of 1·1, is $(1+\frac{1}{10})^{\frac{1}{5}}$.

Now,

$$(1+x)^{\frac{1}{5}} = 1 + \frac{1}{5}x + \frac{1\cdot4}{5\cdot10\cdot}x^2 + \frac{1\cdot4\cdot9}{5\cdot10\cdot15\cdot}x^3$$
$$- \frac{1\cdot4\cdot9\cdot14\cdot}{5\cdot10\cdot15\cdot20\cdot}x^4 + \frac{1\cdot4\cdot9\cdot14\cdot19}{5\cdot10\cdot15\cdot20\cdot25\cdot}x^5 - \&c.$$

$$1 \qquad = 1 \qquad\qquad \frac{4}{5\cdot10\cdot}\ \frac{1}{10^2} = \cdot0008$$
$$\frac{1}{5} + \frac{1}{10} \qquad = \cdot02$$
$$\frac{1\cdot4\cdot9}{5\cdot10\,15} + \frac{1}{10^3} \qquad = \cdot000048 \qquad\qquad \frac{1\cdot4\,9\,14}{5\,10\cdot15\,20\cdot} + \frac{1}{10^4} = \begin{array}{r}\cdot0008\\ \cdot00000336\\ \hline \cdot00080336\end{array}$$

$$\begin{array}{r} 1\cdot020048\\ 000803{,}36\\ \hline 1\cdot019245\end{array}$$

which is the 5th root of 1·1, true to 5 places of decimals.

11. *To show that* $a_x = 1 + Ax + \frac{A^2x^2}{1\cdot2} + \frac{A^3x^3}{1\cdot2\cdot3} + \ldots\ldots$ *ad infinitum.*

where $A = (a-1) - \frac{(a-1)^2}{2} + \frac{(a-1)^3}{3} - \&c.$

This is called the Exponential Theorem or series.

By the Binomial Theorem.

$$a^x = (1 + \overline{a-1})^x$$
$$= 1 + x\cdot(a-1) + \frac{x(x-1)}{1\cdot2}(a-1)^2 + \frac{x(x-1)(x-2)}{1\cdot2\cdot3}(a-1)^3 + \ldots\ldots \quad (a)$$

Now, it is plain that if we multiply the factors of the coefficients of $(a-1)^2$, $(a-1)^3$, $(a-1)^4$ . . . . together, we may re-arrange the series so that it shall become

$$a^x = 1 + Ax + Bx^2 + Cx^3 + Dx^4 + \ldots\ldots \qquad (b)$$

where A, B, C, D, ... contain $(a-1)$ and its powers in some determinate manner. For example, if we examine (a), we shall find that each term, after the first, contains the first power of x; viz., the second term contains $x(a-1)$, the third contains $-x.\frac{(a-1)^2}{2}$, the fourth contains $x.\frac{(a-1)^3}{3}$, the fifth $-x\cdot\frac{(a-1)^4}{4}$, and so on; hence the term involving the first power of x when (a) is re-arranged, must be

$$x\left\{(a-1) - \frac{(a-1)^2}{2} + \frac{(a-1)^3}{3} - \frac{(a-1)^4}{4} + \right\}\ \&c.$$

$$\therefore A = (a-1) - \frac{(a-1)^2}{2} + \frac{(a-1)^3}{3}$$
$$- \frac{(a-1)^4}{4} + \ldots\ldots \qquad (c)$$

In like manner, we might find B. C. D. . . . . in series (b). Instead of doing so, we proceed as follows: since (b) is true for all values of x, we must have—

$$a^y = 1 + Ay + By^2 + Cy^3 + Dy^4\ldots\ldots \qquad (d)$$

Now, $a^x \times a^y = a^{x+y}$.

$$\begin{aligned}\text{But, } a^x \times a^y = 1 + Ax + Bx^2 + Cx^3 + Dx^4 + \ldots\ldots\}\\ + y\,\{A + A^2x + ABx^2 + ACx^3 + \ldots\ldots\}\\ + y^2\,\{B + ABx + B^2x^2 + \ldots\ldots\}\\ + y^3\,\{C + ACx + \ldots\ldots\}\\ + y^4\,\{D + \ldots\ldots\}\end{aligned}$$

$$\begin{array}{rrrrrl} = 1 + Ax & + Bx^2 & + Cx^3 & + Dx^4 & + \ldots\ldots & \\ + Ay & + A^2xy & + ABx^2y & + ACx^3y & + \ldots\ldots & \\ & + By^2 & + ABxy^2 & + B^2x^2y^2 & + \ldots\ldots & (e)\\ & & + Cy^3 & + ACxy^3 & + \ldots\ldots & \\ & & & + Dy^4 & + \ldots\ldots & \end{array}$$

$$\begin{aligned}\text{And } a^{x+y} &= 1 + \text{A}(x+y) + \text{B}(x+y)^2 + \text{C}(x+y)^3 + \ldots\ldots \\ &= 1 + \text{A}x + \text{B}x^2 + \text{C}x^3 + \text{D}x^4 + \quad \ldots\ldots \\ &\quad + \text{A}y + 2\text{B}xy + 3\text{C}x^2y + 4\text{D}x^3y + \ldots\ldots \\ &\quad + \text{B}y^2 + 3\text{C}xy^2 + 6\text{D}x^2y^2 + \ldots\ldots \quad (f) \\ &\quad + \text{C}y^3 + 4\text{D}xy^3 + \quad \ldots\ldots \\ &\quad + \text{D}y^4 + \quad \ldots\ldots\end{aligned}$$

Now, from the early part of this article, it appears that there is *one definite expansion of* a^x, and $\therefore$ of a^{x+y}. Hence (*e*) and (*f*), which are each the expansion of a^{x+y}, are not merely equal, but are actually identical; therefore they must be, term by term, the same.

$$\therefore \text{A}^2 = 2\text{B} \qquad \therefore \text{B} = \frac{\text{A}^2}{1 \cdot 2}$$

$$\text{AB} = 3\text{C} \qquad \text{C} = \frac{\text{A}^3}{1 \cdot 2 \cdot 3}.$$

$$\text{AC} = 4\text{D} \qquad \text{D} = \frac{\text{A}^4}{1 \cdot 2 \cdot 3 \cdot 4}$$

Hence,

$$a^x = 1 + \text{A}x + \frac{\text{A}^2x^2}{1 \cdot 2} + \frac{\text{A}^3x^3}{1 \cdot 2 \cdot 3} + \frac{\text{A}^4x^4}{1 \cdot 2 \cdot 3 \cdot 4} + \ldots \text{(V.)},$$

where

$$\text{A} = a - 1 - \frac{(a-1)^2}{2} + \frac{(a-1)^3}{3} - \frac{(a-1)^4}{4} + \ldots \quad \text{(VI.)}$$

N.B.—Suppose *e* to be such a number that—

$$1 = (e-1) - \frac{(e-1)^2}{2} + \frac{(e-1)^3}{3} - \frac{(e-1)^4}{4} + \ldots\ldots$$

$$\text{Then } e^x = 1 + x + \frac{x^2}{1 \cdot 2} + \frac{x^3}{1 \cdot 2 \cdot 3} + \frac{x^4}{1 \cdot 2 \cdot 3 \cdot 4} + \ldots\ldots$$

This number *e* is very important, and is called the base of the Napierian Logarithms, for reasons to be explained hereafter. We can easily ascertain its value in the following manner:—In the above series let $x = 1$. Then—

$$e = 1 + 1 + \frac{1}{1 \cdot 2} + \frac{1}{1 \cdot 2 \cdot 3} + \frac{1}{1 \cdot 2 \cdot 3 \cdot 4} + \ldots$$

This series is convergent, since it is clearly—

$$< 1 + \left(1 + \frac{1}{2} + \frac{1}{2^2} + \frac{1}{2^3} + \ldots\right)$$

The series, therefore, gives the numerical value of *e*. This value may be calculated as follows:—

2	1·000000000
3	·50000000
4	·16666666
5	·041666666
6	·008333333
7	·001388888
8	·000198412
9	·000024801
10	·000002755
11	·000000275
12	·000000025
13	·000000002
	·000000000

These decimals are respectively $\frac{1}{1 \cdot 2}$, $\frac{1}{1 \cdot 2 \cdot 3}$, $\frac{1}{1 \cdot 2 \cdot 3 \cdot 4}$, $\frac{1}{1 \cdot 2 \cdot 3 \cdot 4 \cdot 5}$, &c. Their sum is ·718281827; and hence $e =$ 2·7182818, which is quite accurate, so far as it goes.

The student will observe, that the reasoning in the above article is founded upon the assumptions (1), that a^x can be expanded in a series of ascending powers of x; (2), that it can be expanded in only one series of that kind. These assumptions, in the present case, may be considered as resting on the fact that the expansion of a^x is simply a transformation of the binomial theorem. The same remark applies to the following article:—If we make the assumption general—viz., that every function of x can be expanded in a single series of ascending powers of x, we enter upon a question which has given rise to many discussions, which cannot be further noticed here.

Definition.—If $a^y = x$, then y is called the logarithm of x to the base a, and is generally written $y = \log._a x$ where $\log._a$ means "logarithm to base *a*."

12. *To show that* $\text{A} \log._e (1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4}$ + &c., *where* A *has the same value as in the last article.* This is called the logarithmic series.

$$\text{Let } y = \log._a (1+x).$$

$$\text{Then by definition } 1 + x = a^y.$$

$$\therefore (1+x)^n = a^{ny}.$$

$$\text{By the last article, if } k = x - \frac{x^2}{2} + \frac{x^3}{3} - \text{\&c.}$$

$$(1+x)^n = 1 + k.n + \frac{k^2n^2}{1 \cdot 2} + \text{\&c.}$$

$$\text{and } a^{ny} = 1 + \text{A}yn + \frac{\text{A}^2y^2n^2}{1 \cdot 2} + \text{\&c.}$$

Now, since $(1+x)^n$ is identically the same as a^{ny}, these two series must be identically the same.

$$\therefore \text{A}y = k.$$

$$\text{i.e., A} \log._a (1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \ldots\ldots \text{(VII).}$$

$$\text{where A} = (a-1) - \frac{(a-1)^2}{2} + \frac{(a-1)^3}{3} - \text{\&c.}$$

$$\text{N.B.—Now } 1 = (e-1) - \frac{(e-1)}{2} + \frac{(e-1)^3}{3} - \text{\&c.}$$

$$\therefore \log._e (1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \text{\&c.}$$

$$\therefore \log._e a = (a-1) - \frac{(a-1)^2}{2} + \frac{(a-1)^3}{3} - \text{\&c.}$$

$$\therefore \text{A} = \log._e a.$$

Hence, equation (VII.) may be written—

$$\log._e a \log._a (1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \text{\&c.}$$

It will be observed that if x be < 1, the series

$$x - \frac{x^2}{2} + \frac{x^3}{3} - \text{\&c.}$$

is term by term less than $x - x^2 + x^3 - \text{\&c.}$ and is therefore convergent, provided x is < 1.

ON THE CALCULATION OF LOGARITHMS.

13. *On the Calculation of the Arithmetical Values of Quantities expressed by Infinite Series.*

In the Treatise on Elementary Algebra, the method has been explained of obtaining in numbers the value of an algebraical expression, when definite values are assigned to the letters composing the expression.* For instance, if $a = 2$ and $b = 5$, then $(2a + b)(b - a) = 27$. The student may ask, how can an infinite series be reduced? Although we have already given three instances of the manner of doing this, the question is well worth a distinct consideration. We have already seen that

$$\frac{1}{1-x} = 1 + x + x^2 + x^3 + x^4 + x^5 + \ldots\ldots$$

Now, if $x = \frac{1}{2}$, the fraction is equal to 2; and we know that if we took the whole number of terms of the series we should get exactly 2. The first two terms are 1·5; the first three 1·75; the first four 1·875; the first five terms 1·9375; the first six 1·96875; each result being nearer to the truth than the one before. Thus, by taking a sufficiently large number of terms, we can get as near to the exact value as we like. The series, in fact, affords the means of *approximating* to the true value. Of course, in such a case as the above, we should not care for the approximation, since we can so readily get the real value. But in the large majority of cases we cannot get at the real value, or even the real value cannot be expressed by digits at all—*i.e.*, is not commensurable with unity; in such cases the approximate value is the only one we can get, *and the series is the means by which we get it.* For instance, we have called the base of the Napierian logarithm e. But what is e? It is such a number that

---

* See *ante*, p. 451.

$$1 = (e - 1) - \tfrac{1}{2}(e - 1)^2 + \tfrac{1}{3}(e -)^3 - \&c.$$

This is an equation we have no method—no direct method—of solving. We have seen, however, that e is expressed by the series

$$e = 1 + 1 + \frac{1}{1 \cdot 2} + \frac{1}{1 \cdot 2 \cdot 3} + \frac{1}{1 \cdot 2 \cdot 3 \cdot 4} + \&c.$$

From this, as we have already seen, we can find that $e = 2{\cdot}7182818$, *&c.* The student may think an approximation a very unsatisfactory result; but he must remember two things:—(1). That greater part of the quantities we have to deal with *cannot* be expressed in whole numbers, or in vulgar fractions—*e.g.*, so common and elementary an expression as $\sqrt{2}$ *cannot* be expressed as a vulgar fraction; and (2), that in practice no measurement is *accurate*, but is known to lie within certain limits. For instance, if a tailor measure a piece of cloth, he calls it a yard, though it may happen to be a quarter of an inch more or less. In like manner the most refined scientific measurements (the length of the second's pendulum, of an arc of the meridian, &c.), are generally the *means* of several results, and are accurate to within certain very small limits. Now, in approximating to a result by means of a series, we can always get to within any given limits that may be assigned. And thus approximations by means of series are as accurate as any, the most refined, measurements can be.

In practice, if we know a number to be true for the first six or seven places of decimals, it is generally known with sufficient or even more than sufficient accuracy. Thus, if we are certain that x. lies between 3·16754 and 3·16755, we may call it 3·16754; although if we calculated to a greater nicety we might obtain $x = 3{\cdot}1675438295$, for the error we commit is $< \frac{1}{10000000}$, *e.g.*, an error less than $\frac{1}{4}$ of an inch in one mile.

It is to be observed, that in calculating the value of a series, we must calculate each term to one or two more places of decimals than the result we wish to obtain, so as to be quite sure that we *carry* the right number to the seventh place. Thus, in finding the value of e (Art. 11), we calculated each term to nine places of decimals, to ensure that our result should be true to seven places.

It is also to be observed, that in cutting off the eight and subsequent decimal places, if the eighth place be 5, 6, 7, 8, or 9, we add 1 to the seventh place; but if 4, 3, 2, 1, or 0, we simply omit it. Thus we reckon

$2{\cdot}59716345827 = 2{\cdot}5971635$

But $2{\cdot}59716343254 = 2{\cdot}5971634$.

For it is plain that 2·59716345827 is nearer to 2·5971635 than to 2·5971634: whereas, as in the second instance, the contrary is the case.

We now proceed to consider the subject of logarithms in detail.

14. *To Explain the Principle on which Logarithms may be used to Facilitate Calculations.*

From the definition of a logarithm already given, it follows that if $M = a^x$ then x is the logarithm of M to the base a; and if $N = a^y$ then y is the logarithm of N to the base a, Now observe $M \times N = a^{x+y}$, whence it is plain that the *multiplication* of one number by another corresponds to the *addition* of their logarithms. In like manner, $M \div N = a^{x-y}$, or the division of one number by another corresponds to the subtraction of the logarithm of the dividend from that of the divisor. Again, $M^m = a^{mx}$, or the raising of a number to a given power corresponds to the multiplication of the logarithm by that power. In like manner $M^{\frac{1}{m}} = a^{\frac{x}{m}}$, or the extraction of the root of a given number corresponds to the division of the logarithm by that root. So that if we knew the logarithm which corresponds to any number whatever, and wished to find the product of two numbers, we should merely have to write down the logarithms of the numbers, add them, and then the number whose logarithm is that sum will be the product of the two given numbers; and similarly for the other rules.

Now, tables have been calculated which give us the logarithm corresponding to any number between 1 and 10,000,000. Hence, by using these tables properly, multiplication is performed by means of addition; and in like manner division by means of subtraction, involution by multiplication, and evolution by division.

In the following pages we shall first explain the method by which these tables are calculated, and then proceed to show how they are practically employed.*

15. *The following results follow manifestly from what has been said.*

(1). That if $P = Q$, then $\log._e P = \log._e Q$.

(2). Since $a^1 = a$. $\therefore \log._a a = 1$.

(3). Since $a^0 = 1$. $\therefore \log._a 1 = 0$.

(4). If $M = a^x$, $N = a^y$, then $x = \log._a M$, $y = \log._a N$.
Now, $MN = a^x \times a^y = a^{x+y}$ $\therefore x + y = \log._a MN$

$$\therefore \log._a M + \log._a N = \log._a MN.$$

(5). Similarly, $a^x \div a^y = a^{x-y}$, $\therefore \frac{M}{N} = a^{x-y}$.

$$\therefore \quad x - y = \log._a \frac{M}{N}.$$

$$\therefore \quad \log._a M - \log._a N = \log._a \frac{M}{N}.$$

(6). Again, if $a^x = M$. $\therefore \log._a M = x$.
Now, $M^m = a^{mx}$ $\therefore \log._a M^m = mx$.
$\therefore m \log._a M = \log._a M^m$.

(7). Similarly, $M^{\frac{1}{m}} = a^{\frac{x}{m}}$

$$\therefore \quad \frac{1}{m} \log._a M = \log._a M^{\frac{1}{m}}$$

(8). From (4) it is manifest that
$\log._a M + \log._a N + \log._a P + \ldots . = \log._a MNP \ldots .$

16. *To show that* $\log._a b, + \log._b x = \log._a x$.

Now, suppose $x = a^m$, and $x = b^n$
$\therefore \log._a x = m$, and $\log._b x = n$.

But since $a^m = b^n$ we must have $a = b^{\frac{n}{m}}$

$$\therefore \quad \log._a a = \log._a b^{\frac{n}{m}}$$

$$\therefore \quad 1 = \frac{n}{m} \log._a b.$$

$$\therefore \quad n . \log._a b = m$$

$$\text{or } \log._a b \log._b x = \log._a x.$$

From this it follows, that if we know the logarithm of a given number to a given base, we can find its logarithm to another base, by dividing the first logarithm by the logarithm of the new base; for instance, suppose our tables give the logarithms of numbers to the base 10, and suppose we wished to find the logarithm of a given number (N) to the base 19, we have

$$\log._{10} 19 \log._{19} N = \log._{10} N.$$

Then $\log._{10} 19$ and $\log._{10} N$ are given by the tables, and therefore we know $\log._{19} N$ by division.

17. *The practical advantage of Calculating Logarithms to the Base* 10.

The tables of Logarithms commonly printed, are logarithms to the base of 10. In all future articles, whenever we write $\log. x$, we mean logarithm to the base 10.

We might calculate tables to the base e; and the calculation is obviously rendered much easier when this base is employed by the circumstance that

$$\log._e x = x - \frac{x^2}{2} + \frac{x^3}{3} - \&c.$$

whereas, if we use the base 10. we have

$$\log._e 10. \log. x = x - \frac{x^2}{2} + \frac{x^3}{3} - \&c.$$

---

* An extended table of logarithms will be found at the end of this chapter.

And, in point of fact, the inventor of logarithms, Napier, actually calculated logarithms to this base e, which is hence called the base of the Napierian logarithms.

For the purposes of numerical calculation, however, the base 10 possesses the following decisive advantage over any other.

Suppose $10^x = N$

Then $10^{x+n} = N \times 10^n$.

Now, suppose n to be a whole number, then $N. \times 10^n$ has the same digits as N in the same order, and only differs from it in having its decimal point shifted n places to the right; and again—

$$10^{x-n} = \frac{N}{10^n}.$$

And when n is a whole number, $\frac{N}{10^n}$ only differs from N in having its decimal point shifted n places to the left. It follows, therefore, that *the decimal part* of the logarithm of a number is the same wherever the decimal point may be in the number, and that for every place that the decimal point in the number is shifted to the right, 1. is added to the logarithm; and for every place, it is shifted to the left, 1. is subtracted from the logarithm. Thus the table gives us

log. 7·5684 = ·8790041.
∴ log. 75·684 = 1·8790041.
log. 756·84 = 2·8790041.

So again—

log. ·75684 = —1 + ·8790041.

or, as it is more generally written—

log. ·75684 = $\bar{1}{\cdot}8790041$.

Similarly—

log. ·00075684 = $\bar{4}{\cdot}8790041$.

It is plain, then, that one calculation gives us the logarithm of the above five numbers, and in fact of as many numbers as can be made by shifting the decimal point to different positions in the combination 75684; but if we adopted any other base, we should require a separate calculation for each of them. This advantage, which the base 10 has over any other, was first seen and applied by Briggs, who was professor at Oxford about the year 1670; the logarithms are, therefore, sometimes called the "Briggian Logarithms."

The student will perceive that the base 10 has this advantage, in consequence of our system of notation being decimal. If our system were duodecimal, our logarithms would then have to be calculated to the base 12, to be possessed of a like advantage, and so on for any other system.

N.B.—The decimal part of a logarithm is called the *mantissa:* the whole number is called the *characteristic.*

18. *To show that every number has a Calculable Logarithm.*

It will be observed that—

$$\log._e a = (a-1) - \frac{(a-1)^2}{2} + \frac{(a-1)^3}{3} -, \&c.,$$

may not be (for aught we have yet shown) convergent, unless a < 2. Now, if a be any number, a root of it can always be found, say the n^{th}, which shall be less than 2. Now,

$$\log.^e a^{\frac{1}{n}} = (a^{\frac{1}{n}} - 1) - \frac{(a^{\frac{1}{n}} - 1)}{2} + \frac{(a^{\frac{1}{n}} - 1)^3}{3}, - \&c.$$

which, since $a^{\frac{1}{n}} - 1$ is less than 1, is convergent. Now, $\log.^e a^{\frac{1}{n}} = \frac{1}{n}\log._e a, \therefore \log._e a = n\{(a^{\frac{1}{n}} - 1) - \frac{1}{2}(a^{\frac{1}{n}} - 1)^2,$ $+ \frac{1}{3}(a^{\frac{1}{n}} - 1)^3 - \&c.,\}$ which series being convergent, if n be properly chosen, for every value of a, the value of $\log._e a$ might be found from it, for all values of a. To calculate a table from such a formula would be most laborious; but as the calculation of the common tables presupposes that we know $\log._e 10$, if we treat the subject in its logical order, it would be necessary to calculate $\log.^e 10$ from this series, before going further. We shall find, if we do so, that—

$$\log._e 10 = 2{\cdot}3025851.$$

Hence—

$$\frac{1}{\log._e 10} = {\cdot}434294481.$$

In future pages we shall denote this number by μ. It is called the modulus of the tabular logarithm.

The logarithmic series to the base 10 we have already seen to be—

$$\log._e 10 \log.(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} -, \&c.$$

$$\therefore \log.(1+x) = \mu\left\{x - \frac{x^2}{2} + \frac{x^3}{3} - \&c.\right\}.$$

19. *To derive from the Logarithmic series, others from which the numerical values of Logarithms may be calculated.*

We have seen that

$$\log.(1+x) = \mu\left\{x - \frac{x^2}{2} + \frac{x^3}{3} - \&c.\right\}$$

$$\therefore \log.(1-x) = \mu\left\{-x - \frac{x^2}{2} - \frac{x^3}{3} - \&c.\right\}$$

$$\text{Now } \log.(1+x) - \log.(1-x) = \log.\frac{1+x}{1-x}.$$

$$\therefore \log.\frac{1+x}{1-x} = 2\mu\left\{x + \frac{1}{3}x^3 + \frac{1}{5}x^5 + \ldots\right\}$$

$$\text{Now suppose } \frac{1+x}{1-x} = \frac{q}{p} \therefore x = \frac{q-p}{q+p}.$$

$$\therefore \log.\frac{q}{p} = 2\mu\left\{\frac{q-p}{q+p} + \frac{1}{3}\left(\frac{q-p}{q+p}\right)^3 + \ldots\right\}$$

Suppose $q = p + 1$.

$$\therefore \log.\frac{p+1}{p} = 2\mu\left\{\frac{1}{2p+1} + \frac{1}{3}\cdot\frac{1}{(2p+1)^3} + \ldots\right\}$$

$$\therefore \log. p+1) = \log. p. + 2\mu\left\{\frac{1}{2p+1} + \frac{1}{3}\cdot\frac{1}{(2p+1)^3} + \ldots\right\} \text{ VIII.}$$

From this we can calculate successively the values of log. 2, log. 3, log. 4 .... as far as we please.

Thus, remembering that log. 1 = 0, we have

$$\log. 2 = 2\mu\left\{\frac{1}{3} + \frac{1}{3}\cdot\frac{1}{3^3} + \frac{1}{5}\cdot\frac{1}{3^5} + \ldots\right\}$$

$$\log. 3 = \log. 2 + 2\mu\left\{\frac{1}{5} + \frac{1}{3}\cdot\frac{1}{5^3} + \frac{1}{5}\cdot\frac{1}{5^5} + \ldots\right\}$$

$$\log. 4 = \log. 3 + 2\mu\left\{\frac{1}{7} + \frac{1}{3}\cdot\frac{1}{7^3} + \frac{1}{5}\cdot\frac{1}{7^5} \ldots\right\}$$

In the ordinary tables the logarithms are given calculated to 7 places of decimals. Hence, in making the calculation from the above series we must take in every term >. 00000001; or, since each term is greater than the one that comes after it, we must reduce each term to decimals until we find one < ·00000001, which we can omit, together with all that come after it; all that go before it being reduced to decimals and added together, give the required logarithm. Thus, to find log. 11:—here $p = 10 \therefore 2p + 1 = 21$.

$$\therefore \log. 11 = \log. 10 + 2\mu\left\{\frac{1}{21} + \frac{1}{3}\cdot\frac{1}{21^3} + \frac{1}{5}\cdot\frac{1}{21^5} + \ldots\right\}$$

Now,

$$\frac{1}{21} = ·047619047$$

$$\frac{1}{3}\cdot\frac{1}{21^3} = ·000035993.$$

$$\frac{1}{5}\cdot\frac{1}{21^5} = ·000000049. \qquad \frac{1}{7}\cdot\frac{1}{21^7} < ·0000000001$$

$$\overline{·047655089}$$

$$\text{and } 2\mu = ·868588962$$

$$\therefore 2\mu \times \left\{\frac{1}{21} + \frac{1}{3}\cdot\frac{1}{21^3} + \frac{1}{5}\cdot\frac{1}{21^3} + \cdots\right\} = \begin{matrix}·047655089 \times ·868588962 = \\ ·041392674\end{matrix}$$

But log. 10 = 1.

∴ log. 11 = 1·0413927. To seven places of decimals, which is the logarithm you will find registered in the table. From the formula

$$\log.\frac{q}{p} = 2\mu\left\{\frac{q-p}{q+p} + \frac{1}{3}\cdot\left(\frac{q-p^3}{q+p}\right) + \ldots\right\}.$$

Another very convenient formula can be derived.

$$\text{Thus let } \frac{q}{p} = \frac{x^2}{x^2-1}\cdot \quad \text{Then } \frac{q-p}{q+p} = \frac{1}{2x^2-1}\cdot$$

$$\therefore \log.\frac{x^2}{x^2-1} = 2\mu\left\{\frac{1}{2x^2-1} + \frac{1}{3}\cdot\frac{1}{(2x^2-1)^3} + \ldots\right\}.$$

$$\text{Now } \log.\frac{x^2}{x^2-1} = \log.\frac{x^2}{(x-1)(x+1)} =$$

$$2\log.x - \log.(x-1) - \log.(x+1).$$

$$\therefore \log.(x+1) = 2\log.x - \log.(x-1) - 2\mu\left\{\frac{1}{2x^2-1} + \&c.\right.$$

20. *To explain the use of this last Series.*

The use of this formula, which converges very rapidly, gives us any logarithm in terms of the two that precede it. It will be observed in this formula that $\frac{1}{3}\cdot\frac{1}{(2x^2-1)^3}$ and all the terms following it can be omitted, provided

$$\frac{1}{3}\cdot\frac{1}{(2x^2-1)^3} < .00000001$$

$$\text{and } \therefore \text{ if } \frac{1}{(2x^2-1)^3} < ·000000027.$$

$$\text{and } \therefore \text{ if } \frac{1}{2x^2-1} < ·003.$$

$$\text{Or if } 2x^2 - 1 > 334.$$

$$\therefore \text{ if } x^2 > 169.$$

$$\therefore \text{ if } x > 13.$$

Hence, if we employ this formula to calculate logarithms, we have, for all numbers greater than 13—

$$\log.(x+1) = 2\log.x - \log.(x-1) - \frac{2\mu}{2x^2-1}$$

Again, suppose $x > 10000$. Then

$$\frac{2\mu}{2x^2-1} = \frac{\mu}{x^2}\cdot \times \frac{1}{1-}\frac{1}{2x^2} = \frac{\mu}{x^2}\cdot\left\{1 + \frac{1}{2x^2} + \ldots\right\}.$$

and

$$\frac{\mu}{2x^4} < .00000001.$$

Hence, the formula finally reduces itself to

$$\log.(x+1) = 2\log.x - \log.(x-1) - \frac{\mu}{x^2} \ldots \text{(IX.)}$$

$$\text{Or } \log.(x+1) - \log.x = \log.x - \log.(x-1) - \frac{\mu}{x^2}.$$

$$\text{Now } \frac{\mu}{x^2} - \frac{\mu}{(x+n)^2} = \frac{\mu}{x^2}\cdot\left\{\frac{2n}{x} - \frac{3n^2}{x^2}\ \&c.\right\}.$$

$$\therefore \text{ if } x > 10000, \text{ in which case } \frac{\mu}{x^2} > .0000001.$$

Hence, if we only calculate to 7 places of decimals, n must be at least many hundreds for $\frac{\mu}{x^2}$ to differ sensibly from $\frac{\mu}{(x+n)^2}\cdot$ Now, the formula would give us

$$\log.(x+n+1) - \log.(x+n) = \log.(x+n) -$$

$$\log.(x+n-1) - \frac{\mu}{(x+n)^2}$$

which, unless n is several hundreds, we have seen is practically the same as

$$\log.(x+n) - \log.(x+n-1) = \log.(x+n-1)$$

$$-\log.(x+n-2) - \frac{\mu}{x}$$

$$\text{So that } \log.(x+1) - \log.x = \log.x - \log.(x-1) - \frac{\mu}{x^2}.$$

$$\log.(x+2) - \log.x = \log.(x+1) - \log.x - \frac{\mu}{x^2}.$$

$$\log.(x+3) - \log.(x+2) = \log.(x+2)$$

$$-\log.(x+1) - \frac{\mu}{x^2}.$$

$$\log.(x+n) - \log.(x+n-1) = \log.(x+n-1)$$

$$-\log.(x+n-2) - \frac{\mu}{x^2}$$

∴ adding together

$$\log.(x+n) - \log.x = \log.(x+n-1) - \log.(x-1)$$

$$-n\frac{\mu}{x^2}$$

$$\therefore \log.(x+n) - \log.(x+n-1) = \log.x$$

$$-\log.(x-1) - n.\frac{\mu}{x^2}$$

Now, if n be sufficiently small for $n\frac{\mu}{x^2}$ to be < ·0000001, it is clear that we may omit $n.\frac{\mu}{x^2}$ so long as this is the case, and hence the differences between the successive logarithms will continue the same within that limit.

For instance, we can show by formula (VIII.) that

$$\log.(10000) = 4·00000000.$$

$$\log.(10001) = 4·00004342945.$$

$$\therefore \log.(10001) - \log.10000 = ·00004343.$$

$$\text{and} \qquad \frac{\mu}{(10000)^2} = ·0000000042934.$$

$$\text{Hence } n\frac{\mu}{(100000)^2} < ·0000001.$$

until $n = 20$. So that the logarithms of 10001, 10002, 10003 . . . . 10020. can be found the one from the one before it by merely adding .0000434294.

We shall then have to calculate log. (10020) and log. (10021) from the original formula (VIII.) and find how far we can use the difference between these for deducing log. (10022) by log. (10023), &c. After some 20 or 30 logarithms are thus found by simple addition, a fresh calculation will become necessary: by proceeding in this manner, without any exorbitant labour, a table which gives the logarithm for every number from 10000 up to

99999 can be constructed; which is practically the same as from 1 to 100000.

It is to be observed, that with such a table, by means of a very simple subsidiary calculation, we can obtain the logarithm of any number from 1 to 10000000.

Thus, the tables give us log. 73894, log. 73895, *i.e.*, log. 7389400, log. 7389500, for these only differ from those in the characteristic.

The subsidiary calculation referred to enables us to fill up any one of the logarithms of 7389401, &c., up to 7389499.

21. *To explain the construction and use of the Table of Proportional Parts.*

Suppose N to be a number such as that above referred to, > 1000000; and suppose its log. to be given in the table; then log. $(N + 100)$ is also given in the tables. From these data we want to find log. $(N + \delta)$ where δ lies between 0 and 100.

Now $\log. (N + \delta) = \log. N \overline{\left(1 + \frac{\delta}{N}\right)}$

$$= \log. N + \log. \left(1 + \frac{\delta}{N}\right) = \log. N + \mu \left\{ \frac{\delta}{N} - \frac{1}{2}\left(\frac{\delta}{N}\right)^2 \right.$$

$$\left. \ldots \text{\&c.} \right\}$$

Now $\delta < 100 \quad > 1000000$

$$\therefore \left(\frac{\delta}{N}\right)^2 < \frac{1}{(10000)^2} < \cdot00000001$$

which can be omitted, since we only take in the first seven places of logarithms.

$$\therefore \log. (N + \delta) = \log. N + \frac{\mu}{N} \cdot \delta$$

$$\therefore \log. (N + 100) = \log. N + \frac{\mu}{N} . 100.$$

Now, log. $(N + 100) - \log. N = \Delta$ (suppose) is given by the tables, and we see that—

$$\Delta = \frac{\mu}{N} 100$$

$$\therefore \log. (N + \delta) = \log. N + \Delta \times \frac{\delta}{100}.$$

which is true for every value of δ from 1 to 99.

If a and b are the digits of δ, so that $\delta = 10.a + b$. This formula can be written—

$$\log. (N + \delta; = \log. N + \frac{\Delta a}{10} + \frac{1}{10} \cdot \frac{\Delta b}{10}.$$

We have already seen that the difference between two consecutive logarithms is the same for several logarithms together; accordingly, a small subsidiary table, giving $\frac{\Delta}{10}$. $\frac{\Delta \times 2}{10}$, $\frac{\Delta \times 3}{10}$ .... $\frac{\Delta \times 9}{10}$, is calculated for each different value of Δ, and is printed, as Δ occurs, in the margin of the table. For instance, Δ corresponding to log. 28568, is ·0000152; or, as it is written, 152; it being understood that the last figure, 2, falls under the seventh decimal of the logarithm, In this case the subsidiary table is the accompanying. It is called a Table of Proportional Parts. Since a and b are digits, this table gives at once $\frac{\Delta a}{10}$ and $\frac{\Delta b}{10}$, and therefore $\frac{1}{10} \cdot \frac{\Delta b}{10}$. Hence, by means of this table, we can determine log. $(N + \delta)$ from log. N by addition only.

	152.
1	15
2	30
3	46
4	61
5	76
6	91
7	106
8	122
9	137

Thus, log. 2856800 = 6·4558798.

Now, $\frac{\Delta \times 3}{10} = \cdot0000046$, and $\frac{1}{10} \cdot \frac{\Delta \times 7}{10} = \cdot00000106$ $= \cdot0000011$, as we only take in seven places of decimals. Hence, log. 2856837 = 6·4558798 + ·0000046 + ·0000011 = 6·4558855.

We have now given a full explanation of the principles on which Logarithmic Tables are calculated, so far as that explanation is possible in a purely elementary treatise, and have exemplified those principles in the case of the ordinary tables which (practically) give the logarithms of numbers from 1 up to 10,000,000, to seven places of decimals. The student may ask, what would be done if a case occur in which we have numbers exceeding 10,000,000? The answer to the question is the following:—If the number were, for instance, 97536982, and if the calculation demanded so much accuracy that we could not consider this as equal to 97536980, then a more refined set of tables would be necessary; in point of fact, however, for all ordinary calculations, the degree of accuracy which the common tables allow of is sufficient.

We now proceed to explain the practical method of using the tables:—

THE USE OF A TABLE OF LOGARITHMS.

For the purpose of explanation, the following is printed from p. 78 of Hülsse's edition of Vega's Logarithms.

N. 46000 * L. 662

N	O	1	2	3	4	5	6	7	8	9	P	P
4600	662 7578	7673	7767	7862	7956	8050	8145	8239	8334	8428		
4601	8522	8617	8711	8805	8900	8994	9089	9183	9277	9372		95
4602	9466	9561	9655	9749	9844	9938	*0032	*0127	*0221	*0315	1	10
4603	663 0410	0504	0598	0693	0787	0881	0976	1070	1164	1259	2	19
4604	1353	1447	1542	1636	1730	1825	1919	2013	2108	2282	3	29
											4	38
											5	48
											6	57
											7	67
											8	76
											9	86

(1). *To find the Logarithm, when the number is given in the Tables.*

(*a*). To find the mantissa.

Suppose we want to find the logarithm of 46017. The number N. 46000 at the top of the page will direct us to the page on which we shall find 46017; the number 4601, in the column marked N, will give us the line in which we shall find what we want. Pass your eye along the line, 4601, until it comes to column 7, there we find 9183. You will observe that there is 662 written in column O; this is to be written before every one of the numbers under the other columns, and is only written once to render the tables more compact. Write this in front of 9183, which we before found, and we obtain 6629183. This is the mantissa of the logarithm of 46017; it is, therefore, a decimal, and must be written ·6629183.

So again, to find mantissa of logarithm of 46035, look down col. N for 4603, look along the line 4603 till you come to col. 5, when you find 0881; before this prefix 663, and ·6630881 is the mantissa of logarithm of 46035.

Again, to find the mantissa of a logarithm of 46028, look for 4602 in col. N; along this line, in col. 8, you find *0221; the asterisk in front of this 0221 shows that we must add 1 to the 662, and thus we obtain for the mantissa of this logarithm ·6630221.

(3). To find the characteristic.

We have already explained the principle of doing this: if we apply that principle, we shall obtain*

log. 4.6017 = ·6629182
log. 4601·7 = 3·6629182
log. 4601700. = 6·6629182
log. ·00046017 = $\bar{4}$·6629182
log. ·46017 = $\bar{1}$·6629182

If you examine these cases, you will find that they suggest the following rule:—"*Place your pen between the first and second* FIGURE (NOT *cipher*), *and count one for each figure or cipher, until you come to the decimal point; the number this gives will be the characteristic: if you count to the right, the characteristic is positive; if to the left, the characteristic is negative.* Thus, in finding log. 4·6017, if you place your pen between the first figure (4), and second (6), it falls on the decimal point; in this case, therefore, there is no characteristic. Next, in the case of log. 4601·7. place your pen between (4) and (6), and count $\begin{smallmatrix}4,601\cdot7,\\ |123\end{smallmatrix}$ the characteristic is 3; and as you count to the right, it is *plus* 3. Next, in the case log. 4601700. here the decimal point falls behind the last cipher. Hence, counting as before, we have $\begin{smallmatrix}4\,601700\\ |\,123456,\end{smallmatrix}$ and the characteristic is *plus* 6, Again, in the case, log. ·00046017, the first *figure* is, as before, 4. Hence counting, we have $\begin{smallmatrix}\cdot0004,\ 6017;\\ 4321\end{smallmatrix}$ but here we count to the left, so that the characteristic is negative or $\bar{4}$. Again, in the case, log. ·4601. we have $\begin{smallmatrix}\cdot4\ 6017,\\ 1\,|\end{smallmatrix}$ and the characteristic is $\bar{1}$.

Instead of writing log ·00046017 = $\bar{4}$·6629182, this is frequently written 6·6629182. To explain this, observe that $\bar{4}$·6629182 means — 4 + ·6629182, which clearly equals 6 + ·6629182 — 10, or 6·6629182 — 10. It is usual to omit the — 10. and write 6·6629182: no experienced calculator would forget the — 10, although it is not written down; but as this tract is intended for beginners, we shall never omit the — 10, but as it may suit our purpose write log. ·00046017 = $\bar{4}$·6629182 or 6·6629182 — 10.

To find log. 46. Since 46 = 46000 and the table gives mantissa log. 46000 = ·6627576.

∴ log. 46 = 1·6627576.

Hence, to find the logarithm of any number given in the table, first find the mantissa, and then prefix to it the characteristic, in the manner above explained.

Find the logarithms of the following numbers from the tables at the end of this chapter, viz.:—

72·643	7264·3	8·5972	6315.9
84658	6397200	64532	6·5973.
·057234	·000058	762	·035872
·35872	63500	635	6·35
20000	200	·02	·029

(2). *To find the Logarithm of a Number not given in the Tables.*

The rule for the characteristic is the same as given above. For finding the mantissa we proceed as follows:

The student will observe that each logarithm on p. 521, differs from the one before it by 94 or 95. Call this 95, and construct a table of proportional parts as before explained; this is printed in the column marked PP. We then proceed as follows:—To find log. ·0460267.

N.	L
46026	6630032
P.P 7	67
460267	·6630099

N L

∴ log. ·0460267 = $\bar{2}$·6630099.

In practice this is arranged as follows:—

46026	·6530032
7	67
log. ·0460267	$\bar{2}$·6630099

Again, to find log. 460 3629.

46036		·6630976
2		19
9		8,6
log. 460·3629	=	2·6631004

To find log. 4604·508.

46045	·6631825
08	7.6
log. 460·4508	2·6631833

In like manner the student may find the logarithms of
75·84653 ·0927543. 13·02528.

(3). *To find the Number corresponding to a given Logarithm.*

It very rarely happens that the logarithm is exactly to be found in the tables. If it be, the only difficulty we have to contend with in such a case is that of fixing the decimal point. For instance, find the number corresponding to the logarithm 3·6629089. At the top of the page we have L662; this will direct us to the page on which the logarithm will be found; then, looking in the other part of the table we find 9089, in the column 6 of the line marked 4601 of column N. ∴ the number corresponding to the mantissa ·6629089 is 46016. To fix upon the position of the decimal point, we must modify the rule previously given: place the pen between the first and second figure, and count off as many figures as there are units in the characteristic—to the right if the characteristic be positive, to the left if negative; and if there are not figures enough, add or prefix as many ciphers as necessary; thus, in the present case, $\begin{smallmatrix}4|601\cdot6\\ 123\end{smallmatrix}$

∴ the number corresponding to logarithm 3·6629089 is 4601.6; similarly, that corresponding to $\bar{3}$·6629089 is ·0046016.

(4). *To find the Number corresponding to a given Logarithm, which does not exactly occur in the Tables. We proceed as follows:—*

Find the number corresponding to the logarithm 2·6629319.

The Logarithms 6629277 and 6629372 are in the table; the number, therefore, will be between 46018 and 46019. It will therefore be the former, with something added on. To find this "something" we proceed as follows:—

	6629319
Logarithm next less 46018	6629277
	42
Prop. part corresponding to	4 38
	03 .... 3·8

∴ logarithm of 4601843 is 6629319.
∴ logarithm of 460·1843 is 2·6629319.

(5). *To find the Arithmetical complement of the Logarithm of a Number.*

N.B.—If x be any number whatever, then the ar. comp. of $x = 10 - x$.

Now 10 — 3·7568274 = 6·2431726.
10 — $\bar{2}$·3907526 = 11·6092474.
10 — ·9328243 = 9·0671260.

If you examine these, you will find that the subtraction is performed by subtracting the *last figure* (to the right hand) from 10, and each of the rest from 9; in fact, to take the first case, we should proceed as follows: 4 from 10 leaves 6, and carry 1. Then 1 + 7 = 8; take 8 from 10, leaves 2, and carry 1; but taking 8 from 10 is of course the same thing as taking 7 from 9, and so on. The student may, perhaps, think this very obvious, but he will do well not to despise it.

Hence, to find the ar. comp. of the logarithm of a number, find the logarithm and subtract it from 10, in the manner already explained.

---

* See Art. 17, p. 518.

e. g. Find ar. comp. of log. 46·028.
log. 46·028 = 1·6630221.
ar. . comp. log. 46·028 = 8·3369778.

(6). *To find the product of several numbers by means of a Table of Logarithms.*

We have seen that if N = xyz .... Then
log. N = log. x + log. y + log. z +, &c. ....

Hence, find the logarithm of each number, add them together—this gives the logarithm of the quotient—find the number corresponding to this logarithm, and we have the product itself.

Ex. Find the product of 52·731 × 6·0032 × ·0759
log. 52·731 = 1·7220660
log. 6·0032 = ·7783828
log. ·0759 = 8· 8802418 — 10.

1·3806906
24·026 ·3806815

91
5 91

24·0265 Ans.

N.B.—In any example of this kind, never use a negative characteristic, such as $\bar{2}$·8802418. but 8·8802418 — 10 as above; by doing so, there is nothing but straightforward addition to be performed until the end, when —10 can be easily struck off the characteristic of the sum.

(7). *To divide one number by another by means of a Table of Logarithms.*

We have seen that if $N = \frac{x}{y}$ ∴ log. N = log. x — log. y.
∴ log. N = log. x + 10 — log. y — 10
∴ log. N = log. x + Ar. Comp. log. y — 10.

Hence, "To log. of numerator, add ar. comp. logarithm of denominator, and subtract 10 from the sum—this gives logarithm of quotient.—Find the number corresponding to this logarithm, and the number is the quotient required."

Ex. Divide 37·052 by 6741·6.
log. 37·052 = 1·5688117
Ar. : C. : log. 6741·6 — 10 = 6·1712370 — 10

$\bar{3}$·7400487
54960 ·7400647

20
2 16

4
5 4,0

·005496025 Ans.

(8). *Similarly, if* $N = \frac{abc}{xyz}$. We have—

log. N = log. a + log. b + log. c + Ar. C. log. x — 10 + Ar. C. log. y — 10 + Ar. C. log. z — 10.

By this means log. N is found by a single addition sum. Thus, find the value of $\frac{3·0972 \times 56·035}{·002 \times 8746·5 \times 3·124}$.

log. 3·0972 ·4909693
log. 56·035 1·748594.
Ar. C. log. ·002 — 10 12·6989700 — 10
Ar. C. log. 8746·5 — 10 6·0581657 — 10
Ar. C. log. 3·124 — 10 9·5052890 — 10

·5018534
3 1758 ·5018531

3
02 2,7

3·175802 Ans.

(9). *To find any power of a Number, we have seen that if* $N = a^n$ *log.* N = n *log.* a.

Hence, if we multiply log. of the number by the index, we obtain the logarithm of the power of the given number; and finding the number corresponding, we obtain the power itself.

Thus, find the fifth power of 2·00573
2·0057 ·3022660
3 65
log. 2·00573 = ·3022725
Multiply by index 5

1·5113625
32 461 ·5113619

04 6
5,4

32·46104 Ans.

Again, find the third power of ·02751.
log. ·02751 8·4394906 — 10
3
25 3184718 — 30
or, $\bar{5}$·3184718.

We may in practice write this as as follows:—
log. ·02751 8·4394906 — 10
3

$\bar{5}$·3184718
20810 ·3184599

119
5 104

15
·7 14,6

·00002081957 Ans.

(10). *To find the Root of any Number.*

If $N = a^{\frac{1}{n}}$, then,

$$\text{log. } N = \frac{1}{n}.\ \text{log. } a$$

Hence, "Find the logarithm of the given number; divide it by the number indicating the root—this is the logarithm of the required root—the corresponding number is the root itself."

Thus, extract the 5th root of 72·095.
log. 72·095 5)1·8979051

·3795810
2·3965 ·3795774

36
2 36

2·39652 Ans.

Again: extract the 7th root of ·00972.

Log. ·00972 = $\bar{3}$ ·9876663 = 7·9876663 — 10.

All this has to be divided by 7. This will be effected most easily by adding and subtracting such a multiple of 10 as shall make the negative part 70.

i.e., take log. ·00972 = 67·9876663 — 70.
7)67·9876663 — 70

9 7125238 — 10.
51585 7125234

4
05 4.2

·5158505. Ans.

If we had to extract the 6th root of the above number, we must of course take log. ·00972 = 57·9876663 — 60. And again, to extract the cube root, we must take log. ·00972 = 57·9876663 — 30.

(11). The student must exercise himself in working several examples, like each of those above given. When he has done so, he may then, for practice, work some more complicated examples, such as the following:—

Find the value of $\dfrac{31^{\frac{2}{3}} \times (\cdot05796)^3}{15\sqrt{2}}$

(a)	log. $31^{\frac{2}{3}}$	1·4913617
		2
		3)2·9827234
		·9942411
(b)	log. $(\cdot05796)^3$	8·7631284 — 10
		3
		6·2893852 — 10
(c)	log. 15	1·1760913.
(d)	log. $\sqrt{2}$	2) ·3010300
		·1505150
Hence	log. $31^{\frac{2}{3}}$	·9942411
	log. $(\cdot05796)^3$	6·2893852 — 10
	Ar. C. log. 15 — 10.	8·8239087 — 10.
	Ar. C. log. $\sqrt{2}$ — 10	9·8494850 — 10
		$\bar{5}$.9570200
	90577	·9570179
	4	21
		19
	4	2

·00009057744 Ans.

N.B.—To find the logarithms of a mixed number, reduce it to an improper fraction.

To find the logarithm of a vulgar fraction, use the formula—

If $N = \frac{a}{b}$ then log. N = log. a + Ar. Com. log. b — 10,

precisely as in division, excepting that there is no occasion to find N itself.

Thus, in the following example—

Find log. of $\dfrac{37052}{67416}$

log. 37052 = 4·5688117
Ar. Com. log. 67416—10 = 5·1712370 — 10

9.7400487 — 10

$\therefore$ log. $\dfrac{37052}{67416} = \bar{1}\cdot7400487$

[Before entering into another department of mathematics, we shall make a few observations on those which have already been explained. Although few of our readers will have perused the preceding sections of this volume without possessing some knowledge of mathematics; still the chapters on Arithmetic and Algebra, by Professor Young, are admirably calculated to introduce, in an easy and consecutive method, not only the first elements of the sciences, but also to prepare the way for the more difficult studies involved in Trigonometry, and Algebra applied generally to Geometry and the Conic Sections. With the exception of the chapter on Series and Logarithms, we think that all our readers will have readily mastered what has been advanced. There is no doubt that the last subject presents many points of interest, and yet requires considerable attention so as to permit of its thorough acquaintance. Much of the success of the student, in this respect, will depend on his having well studied what has been taught in reference to the Binomial Theorem, and Arithmetical and Geometrical Progression. Before commencing the study of the later books in Euclid, we advise that he should re-read the chapters devoted to the consideration of the subjects we last named, together with that on Series, &c. The necessity of this he will find out when he arrives at the investigation of the values of sines, tangents, &c., in our future pages. The calculation of trigonometrical tables depends entirely on the application of the principles already explained, in combination with those involved in the elements of Geometry, both plane and spherical. Without such a preparation as we urge on our readers, the study of Trigonometry will be very perplexing. On the other hand, one who has thoroughly acquainted himself with all that has preceded it, will find his future progress comparatively easy. We have arranged each branch of this section on the plan of gradually unfolding the subject. The reader, therefore, cannot, with advantage to himself, omit *any* part. Our plan is progressive, as his course must also be; and following that method, we can promise that his difficulties will gradually melt away before perseverance and close attention. We may extend these remarks also to the study of Euclid. If a person will only dip here and there into that admirable compendium of reasoning, he will *never* understand it. The whole of each "book" depends on reasoning based on the premises enunciated at its beginning. Each proposition is not only derived from its predecessors, but prepares the way for that which follows. Hence, the study of geometry must be taken as a whole; and any one link in the chain being broken, is fatal to the success of those who attempt its study. If any of our readers intend pursuing mathematical science in its higher branches, nothing is more essential than a thorough knowledge of the principles taught in the preceding and subsequent chapters in this section.—ED.]

MATHEMATICAL TABLES.

[Nos. 1000—1609.] TABLE OF LOGARITHMS FROM 1,000 TO 10,000. [Log. 0000000—2065560.]

[Note.—This table is simply a continuation of the preceding one; but when we arrive at No. 434, we commence giving a Table of Differences, by means of which Nos. exceeding 10,000 may be easily calculated.]

MISCELLANEOUS TABLES.

The following tables will be found useful in many calculations, especially those of the squares, cubes, and roots, which will be repeatedly needed in the sections on Mechanical Philosophy and Applied Mechanics. The table giving Napierian Logarithms will be found of interest in connection with the observations at page 517, *et seq.*

NAPIERIAN LOGARITHMS

OF NUMBERS, FROM 1 TO 100.

MATHEMATICS—GEOMETRY.

CHAPTER I.

PLANE GEOMETRY.—THE ELEMENTS OF EUCLID.

INTRODUCTION.

In order to acquire clear conceptions of a *point*, a *line*, and a *surface*, with the definitions of which Euclid sets out, it will be best for the learner to consider them, at first, in connection with a *solid;* that is, with something that has *length*, *breadth*, and *thickness.* All external objects—things that can be seen and felt—are *solids;* and however small the solid may be, it must have some length, some breadth, and some thickness: using these terms in their ordinary acceptation—that is, in the sense in which they are used in common discourse.

The *boundaries* of a solid are called the *surface*, or the *superficies*, of the solid; and, as a boundary, cannot have *thickness;* because, if it had, it would be a *part* of the solid, and not a side, face, or boundary of it: it follows that a surface can have *length* and *breadth* only.

Again—the surface itself has its boundaries, or limits: *these* boundaries are called *lines:* and as a *boundary* of a surface cannot have either breadth or thickness, since it is no *part* of the surface, much less a part of the solid, it follows that a line has *length* only.

Lastly, a line has its limits—a beginning and a termination: we speak of these, in common language, as the *ends* of the line. Euclid calls them *points;* and it is plain that a point, being no *part* of the line, cannot have length; and as breadth and thickness are excluded even from the line itself, it follows that a point has no dimensions or *magnitude.* It merely indicates *position;* the position, namely, of the commencement or termination of a line.

Euclid frequently speaks of taking a point *in* a line, without meaning an *extremity* of the line; but we may conceive a line to be crossed, or cut by other lines, and thus to be divided into shorter portions. Each portion has its extremities; so that we may conceive as many points in the line as we please. We cannot represent *length only* to the eye; it is necessary, therefore, in contemplating the black marks on paper, by which lines are represented, entirely to disregard the *breadth* of them; and to fix the attention upon the *length alone:* the *eye* may see breadth and thickness; the *mind* takes note of length only. It is usual to commence the study of Geometry with definitions, which are as follows.

ELEMENTS OF EUCLID.—BOOK I.

DEFINITIONS.

I.

A *point* has no magnitude: it has *position* only.

II.

A *line* has *length* only.

III.

A *straight line* is that which lies *evenly* between its extreme points.

It is distinguished by uniformity of direction between its extremities.

IV.

A *surface*, or *superficies*, is that which has length and breadth only.

V.

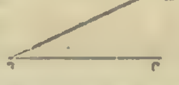
Therefore the boundaries of a surface are *lines.*

VI.

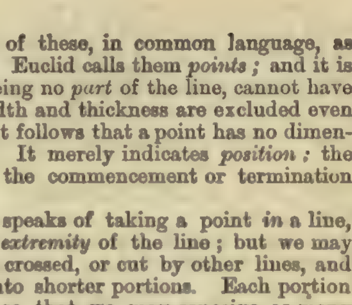
A *plane surface*, or simply a *plane*, is that in which, whatever two points be taken, the straight line, having these points for extremities, lies *wholly* in that surface.

VII.

A *plane rectilineal angle* is the *opening* between two straight lines, which meet together, but which do not unite so as to form one continued straight line.



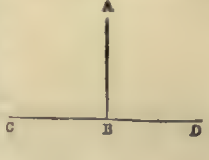
Thus two straight lines A B, C B, meet each other in the point B, forming an *opening*, of which B A and B C are the boundaries, or limits: this opening is called a *plane rectilineal angle*, or simply an *angle.* The two straight lines A B, C B, in the second representation, also meet each other; but they form no *opening or angle;* they unite in forming a continued straight line, A C.



An angle is sometimes referred to by simply naming the letter, placed at the point in which the lines forming the angle meet: in this way reference is made to the angle B, or the angle F, meaning the opening between B A, B C, or that between F D, F E. But if there be two or more openings, or angles, at the same point, this mode of reference will not do: the *sides*, or *boundaries*, of the particular one of those angles meant, must also be pointed out. Thus, if we wish to refer to the angle whose sides are B G, B H, attention must, in some way, be distinctly directed to these sides; because, as there are several angles at B, a reference to this point *alone* would be insufficient. The plan adopted is this: not only the letter (B) at the *vertex* of the angle, as this point is called, is used, but the other two letters (G, H) which mark the *sides* of the angle—the former letter being always placed *between* these two. Thus GBH, or HBG, means the angle whose *vertex* is B, and whose sides are B G, B H. In like manner A B H, or H B A, refers to the angle whose vertex is B, and whose sides are B A, B H: but there is no necessity to [illegible] three letters to denote an angle when there are no other angles at the same point or vertex.

VIII.

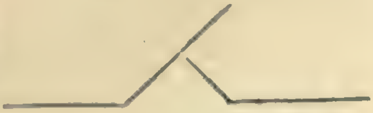
When a straight line (A B) standing on another straight line (C D) makes the adjacent angles (A B C, A B D) equal to one another, each of the angles is called a *right angle;* and the straight lines are said to be *perpendicular* to each other.



Thus the two lines, A B, C D, are perpendicular to each other.

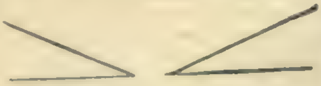
IX.

An *obtuse* angle is that which is greater than a right angle.



X.

An *acute* angle is that which is less than a right angle.

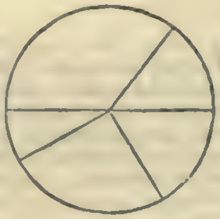


XI.

A *figure* is that which is enclosed by one or more boundaries.

XII.

A *circle* is a plane figure enclosed by one line, which is called the *circumference* of the circle: it is such, that all straight lines, drawn from a certain point within the figure to the circumference, are equal to one another.



XIII.

This point is called the *centre* of the circle.

And any line drawn from the centre to the circumference is called a *radius* of the circle.

XIV.

A *diameter* of a circle is a straight line drawn through the centre, and terminated both ways by the circumference.

A radius is therefore half the diameter, or a *semidiameter*.

XV.

A *semicircle* is the figure contained by a diameter and the part of the circumference cut off by the diameter.

XVI.

Rectilineal figures are those which are enclosed by straight lines only.

XVII.

Trilateral figures, or *triangles*, are enclosed by three straight lines.

XVIII.

Quadrilateral figures, by four straight lines.

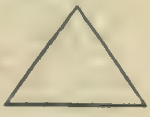
XIX.

Multilateral figures, or *polygons*, by more than four straight lines.

The term polygon, however, is often employed as a general name for rectilineal figures of all kinds, without regard to the number of the sides; so that the rectilineal figures defined above may, without impropriety, be called polygons of three and of four sides respectively.

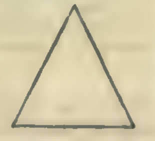
XX.

An *equilateral triangle* is that which has its three sides *equal*.



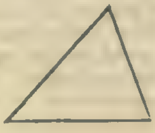
XXI.

An *isosceles triangle* has two of its sides equal.



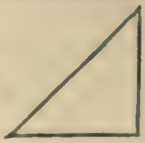
XXII.

A *scalene triangle* has its three sides unequal.



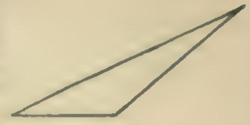
XXIII.

A *right-angled triangle* has one of its angles a right angle.



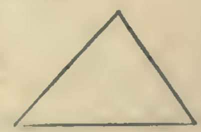
XXIV.

An *obtuse-angled triangle* has one of its angles *obtuse*, or greater than a right angle.



XXV.

An *acute-angled triangle* has each of its angles *acute*, or less than a right angle.



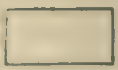
XXVI.

Of four-sided figures, a *square* is that which has all its sides equal, and all its angles right angles.

If the four sides are *equal*, and only *one* of the angles affirmed to be right, the other three angles must be right, of necessity, as will be hereafter proved; this definition is therefore *redundant*.

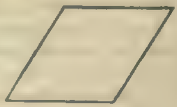
XXVII.

A *rectangle* is that which has all its four angles right angles, whether its sides be equal or not.



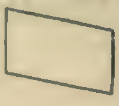
XXVIII.

A *rhombus* is that which has all its sides equal, but its angles are not right angles.



XXIX.

A *rhomboid* is that which has its opposite sides equal to one another, but all its sides are not equal, nor its angles right angles.



XXX.

Parallel straight lines are such as are in the same plane, and which, being produced ever so far both ways, do not meet.

XXXI.

If each pair of opposite sides of a quadrilateral be parallel lines, the figure is called a *parallelogram*.

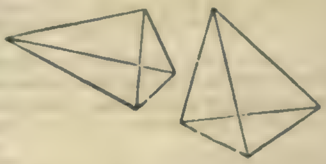
It will be seen hereafter that squares, rectangles, rhombuses, and rhomboids, are all *parallelograms*.

XXXII.

All other four-sided figures, besides those here defined, are called *trapeziums*.

XXXIII.

A line drawn across a figure, joining two opposite corners, or *vertices*, is called a *diagonal*.



POSTULATES.

I.

Let it be granted that a straight line may be drawn from any one point to any other point.

II.

That a terminated straight line may be prolonged to any length in a straight line.

III.

And that circle may be described from any centre, at any distance from that centre.

AXIOMS.

I.

Things which are equal to the same thing are equal to one another.

II.

If equals be added to equals, the wholes will be equal.

III.

If equals be taken from equals, the remainders will be equal.

IV.

If equals be added to unequals, the wholes will be unequal.

V.

If equals be taken from unequals, the remainders will be unequal.

VI.

Things which are double of the same are equal to one another.

VII.

Things which are halves of the same are equal to one another.

VIII.

Magnitudes which coincide, or which may be conceived to coincide, with one another, are *equal*.

IX.

The whole is greater than its part.

X.

Two straight lines cannot enclose a space.

XI.

All right angles are equal to one another.

MARKS AND SIGNS USED FOR ABBREVIATION.

= is the sign of *equality*, and signifies that the quantities between which it is placed are *equal*.

+ is the sign of addition, and signifies that the quantities between which it is placed are to be *added*.

— is the sign of subtraction, and implies that the quantity *after* it, is to be *subtracted* from the quantity *before* it.

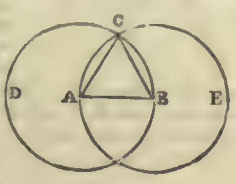
∴ stands for the word *therefore*, or *consequently*.

Besides these marks the following contractions are also frequently used; namely, *ax.* for *axiom*; *post.* for *postulate*; *prob.* for *problem*; *theo.* for *theorem*; *prop.* for *proposition*; *const.* for *construction*; and *hyp.* for *hypothesis*. Q. E. D. stands for "*Quod erat demonstrandum;*" that is, which was to be demonstrated.

PROPOSITION I.—PROBLEM.

To describe an equilateral triangle (A B C) *upon a given finite straight line* (A B).

With centre A, and radius A B, describe the circle * Post. 3. B C D;* and with centre B, and the same radius, B A, describe the circle A C E.



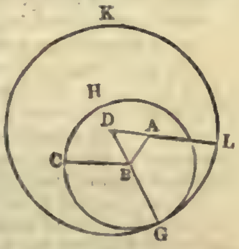
From C, the point in which the circles cut each other, draw * Post. 1. C A, C B,* *the triangle* A B C *shall be equilateral.*

† Def. 12. Because A is the * Ax. 1. centre of the circle B C D, A C = A B,† and because B is the centre of the circle A C E, B C = A B, ∴ A C = B C;* so that A C, B C, A B, are equal to one another; consequently *the triangle* A B C *is equilateral*, and it is described upon A B, *which was to be done.*

PROPOSITION II.—PROBLEM.

From a given point (A) *to draw a straight line* (A L) *equal to a given straight line* (B C).

From A to B draw AB,* and upon AB describe * Post. 1. * Pr. 1. the equilateral triangle B D A.* With centre B, and radius B C, describe the circle † Post. 3. C G H,† and produce DB to meet it in G. Again: with D as centre, and D G as radius, describe the circle G K L, and produce D A to * Post. 2. meet it in L;* A L *shall be equal to* B C.



Because B is the centre of the circle C G H, B C = † Def. 12. B G.†

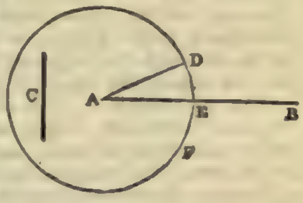
Because D is the centre of the circle G K L, D L = D G.

But D A, D B, parts of D L, D G, are also * Const. equal,* ∴ the remainders, A L, B G, are † Ax. 3. equal;† so that A L, B C are each equal to B G, and are, consequently, equal to each other.* * Ax. 1. Wherefore, *from the given point*, A, *a straight line*, A L, *has been drawn equal to* B C. *Which was to be done.*

PROPOSITION III.—PROBLEM.

From the greater (A B) *of two given straight lines* (A B and C), *to cut off a part equal to the less* (C).

* Pr. 2. From A draw A D = C,* and with centre A, and radius A D, describe the circle D E F,† † Post. 3. cutting off A E from A B: A E shall be = C.

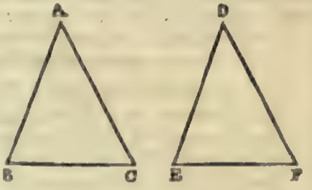


Because A is the centre of the circle DEF, A E = * Def. 12. A D.* But † Const. C = A D,† ∴ A E and C are each = * Ax. 1. A D, ∴ A E = C;* so that, *from the greater line*, A B, *a part* A E, *has been cut off, equal to the less*, C. *Which was to be done.*

PROPOSITION IV.—THEOREM.

If two triangles (A B C, D E F) *have two sides* (A B, A C) *of the one equal to two sides* (D E, D F) *of the other, each to each; that is,* A B = D E, *and* A C = D F, *and have likewise the angles contained by those sides equal, that is, the angle* A = *the angle* D, *then their bases or third sides* (B C, E F) *shall be equal, and also their other angles each to each, namely, those to which the equal sides are opposite, that is, the angle* B = *the angle* E, *and the angle* C = *the angle* F; *the surfaces of the triangles shall also be equal.*

For, conceive the triangle A B C to be laid upon, or applied to, the triangle D E F so that the point A may be on D, and the line A B on D E; then the point B shall fall on E, because A B = * Hyp. D E.* And A B thus coinciding with D E, A C must fall on D F, because the angle A = the angle † Hyp. D;† also the * Hyp. point C must fall on F, because A C = D F.* But B was proved to coincide with E; and since B coincides with E, and C with F, the base B C must coincide with the base E F, otherwise the two straight lines, B C, E F, thus made to coincide at their extremities, would † Ax. 10. inclose a space, which is impossible;† ∴ *the base* B C, *coinciding with the base* E F, *is equal to* * Ax. 8. E F.* Moreover, since the two lines, A B, B C coincide with the two D E, E F, the angle B coincides with the angle E; and since the two lines A C, C B coincide with the two D F, F E, the angle C coincides with the angle F; ∴ *the angle* B = *the angle* E, *and the*



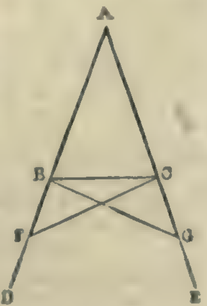
* Ax. 8. *angle* C = *the angle* F.* And as the triangle A B C thus coincides, in every respect, with the triangle D E F, *the surfaces of the triangles must be* † Ax. 8. *equal*; † ∴ *if two triangles, &c.* Q.E.D.

PROPOSITION V.—Theorem.

The angles (A B C, A C B) *at the base* (B C) *of an isosceles triangle* (A B C) *are equal; and if the equal sides* (A B, A C) *be prolonged, the angles* (D B C, E C B) *upon the other side of the base shall be equal.*

In B D take any point, F, and from A E, the greater, * Pr. 3. cut off A G = A F, the less;* and draw F C, G B.

† Const. Because F A = G A,† and A C = AB* ∴ F A, * Hyp. A C are equal to G A, AB, each to each; and the angle A is common to both the triangles A F C, A G B; † Pr. 4. ∴ F C = G B, † *the angle* A C F = *the angle* A B G,† and *the angle* A F C = *the angle* A G B,† these being the angles to which the equal sides are opposite.



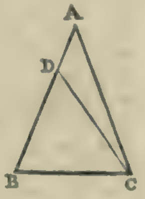
Again: because the whole A F = the whole A G, and that the parts A B, A C are equal, the remainders B F, C G are * Ax 3. equal;* and it was proved that F C = G B, ∴ the two sides B F, F C, are equal to the two C G, G B, each to each: it was also proved that the angle B F C = the angle C G B, ∴ *the angle* F B C † Pr. 4. = *the angle* G C B,† and the angle B C F = the angle C B G. And since it was demonstrated that the whole angle A B G, = the whole angle A C F, the parts of which, the angles C B G, B C F, are also equal, ∴ *the remaining angle* A B C = *the remaining angle* * Ax. 3. A C B.* These are the angles *at the base* of the isosceles triangle A B C, and the angles F B C, G C B, before proved to be equal, are the angles *on the other side of the base.* Therefore *the angles at the base, &c.* Q.E.D.

Corollary.—Every *equilateral* triangle is *equiangular.*

PROPOSITION VI.—Theorem.

If two angles (A B C, A C B) *of a triangle are equal, the sides* (A C, A B) *which subtend*, or are opposite to, *the equal angles shall be equal.*

For, if A B be not equal to A C, one of them, as A B, must be the greater. Let a part B D, equal to A C, the * Pr. 3. less, be cut off,* and draw D C. Then, because in the triangles D B C, A C B, D B = A C, and B C common to both, the two sides D B, B C are = the two sides A C, C B, each to each; and the angles D B C, * Hyp. A C B are equal;* ∴ the triangle D B C = the triangle A C B,† † Pr. 4. a part to the whole, which is absurd. Therefore, A B, A C *are not unequal—that is, they are equal*; ∴ *if two angles, &c.* Q. E. D.

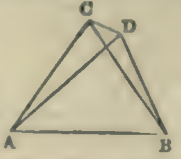


Cor.—Every *equiangular* triangle is *equilateral.*

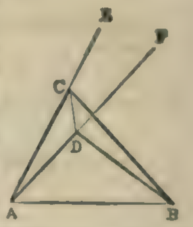
PROPOSITION VII.—Theorem.

Upon the same base (A B), *and on the same side of it, there cannot be two triangles* (A C B, A D B), *having their sides* (A C, A D), *which are terminated in one extremity of the base, equal to one another, and likewise* (B C, B D) *those which are terminated in the other extremity.*

Join C D: then, in the case in which the vertex of each triangle is *without* the other tri- * Hyp. angle, because A C = A D,* † Pr. 5. the angle A C D = A D C.† But the angle A C D is greater than the angle B C D, which is only a part of it; ∴ the angle A D C is greater also than B C D: much more, then, is the angle B D C * Hyp. greater than B C D. Again: because B C = B D,* † Pr. 5. the angle B D C = B C D;† but it has been demonstrated to be greater than B C D, which is impossible, ∴ *in this case it is impossible that* A C = A D, *and likewise* B C = B D.



But if one of the vertices, as D, be *within* the other triangle, prolong A C, A D to E, F. Then, because * Hyp. A C = A D* in the triangle A C D, the angles E C D, F D C, upon the other side of the † Pr. 5. base C D, are equal;† but the angle E C D is greater * Ax. 9. than B C D,* ∴ F D C is likewise greater than B C D: much more, then, is B D C greater than B C D. Again: because B C = † Hyp. B D,† the angle B D C = * Pr. 5. B C D;* but B D C was proved greater than B C D, which is impossible, ∴ *in this case also it is impossible that* A C = A D, *and likewise* B C = B D.

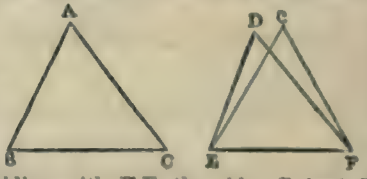


The case in which the vertex of one triangle is *upon* † Ax. 9. a *side* of the other, needs no demonstration.† Therefore, *upon the same base, &c.* Q. E. D.

PROPOSITION VIII.—Theorem.

If two triangles (A B C, D E F) *have two sides* (A B, A C) *of the one equal to two sides* (D E, D F) *of the other, each to each, and have likewise their bases or third sides* (B C, E F) *equal, then the angle* (A) *contained by the two sides of the one shall be equal to the angle* (D) *contained by the two sides equal to them of the other.*

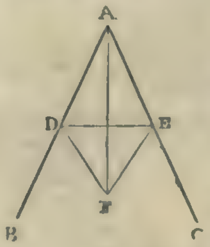
For if the triangle A B C be applied to D E F, so that the point B may be on E, and B C on E F, the point C shall coincide with F, because B C = * Hyp. E F.* And B C thus coinciding with E F, B A and A C must coincide with E D and D F; for if the base B C, coinciding with E F, the sides B A, A C could fall otherwise than on E D, D F, and have different situations, as E G, G F, then upon the same base E F, and on the same side of it, there could be two triangles having the sides E D, E G, terminated in one extremity of the base, equal to one another, and *likewise* the sides F D, F G terminated in the other extremity. But this † Pr. 7. is impossible;† ∴ if the bases coincide, the remaining sides cannot but coincide, and ∴ *the angle* A *must coincide with the angle* D, *and be equal to* * Ax. 8. *it.** Therefore, *if two triangles, &c.* Q.E.D.



PROPOSITION IX.—Problem.

To bisect a given rectilineal angle (B A C); *that is, to divide it into two equal angles.*

Take any point D in A B, and from A C cut off A E = * Pr. 3. A D:* draw D E, and upon it describe an equilateral † Pr. 1. triangle D E F, † so that the vertex F may be on the opposite side of D E to the vertex A. Draw A F, then A F shall bisect the angle B A C.



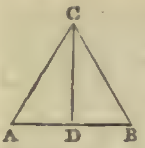
* Const. Because A D = A E,* and that A F is common to the two triangles D A F, E A F: the two sides D A, A F are = the two sides E A, A F, each to each, and the base D F = the base E F; ∴ the angle D A F * Pr. 8. = the angle E A F;* ∴ *the given angle* B A C *is bisected by the straight line* A F. *Which was to be done.*

PROPOSITION X.—Problem.

To bisect a given finite straight line (A B); *that is, to divide it into two equal parts.*

* Pr. 1. Upon AB describe an equilateral triangle ABC,* and bisect the angle A C B by the straight line

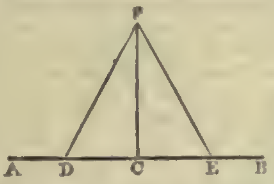
† Pr. 9. C D ;† A B shall be cut into two equal parts in the point D.



Because C A = C B, and C D common to the two triangles A C D, B C D, the two sides C A, C D are = the two C B, C D, each to each ; and the angle A C D = the angle B C D ; ∴ the base A D = * Pr. 4. the base B D;* ∴ *the given line* A B *is divided into two equal parts in the point* D. *Which was to be done.*

PROPOSITION XI.—Problem.

To draw a straight line at right angles to a given straight line (A B), *from a given point* (C) *in it.*



Take any point D in A C, and make C E = C D. Upon D E describe an equilateral triangle D F E,* * Pr. 1. and draw C F ; C F shall be at right angles to A B.

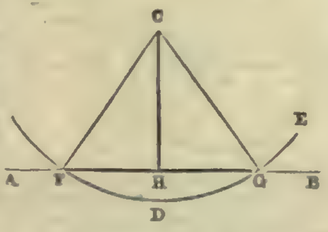
Because D C = E C, and that F C is common to the two triangles DCF, E C F ; the two sides D C, C F are = the two E C, C F, each to each, and the base D F = base E F ; ∴ the angle D C F = angle * Pr. 8. E C F,* and they are adjacent angles. But when the adjacent angles which one straight line makes with another are *equal*, each is called *a right angle* ;† † Def. 8. ∴ *from the given point* C *in the given straight line* A B, *a straight line* C F *has been drawn at right angles to* A B. *Which was to be done.*

PROPOSITION XII.—Problem.

To draw a straight line perpendicular to a given straight line (AB) *of unlimited length, from a given point* (C) *without it.*

Take any point D upon the other side of A B, and with centre C and radius C D describe the circle * Post. 3. E G F* meeting A B in F, G : bisect F G in † Pr. 10. H,† and join C, H.

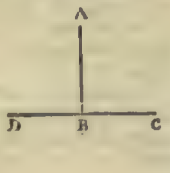
The straight line C H shall be perpendicular to A B. * Const. Draw CF, CG. Then because F H = G H,* and H C common to the two triangles F H C, G H C, the two sides F H, H C are = the two sides G H, HC, each to each, and the base C F = the † Def. 12. base CG;† ∴ the angle C H F = the adjacent angle * Pr. 8. C H G ;* each of them is ∴ a † Def. 8. right angle,† and consequently CH *is perpendicular to* A B ;† ∴ *from the given point* C *a perpendicular* C H *to the given line* A B *has been drawn. Which was to be done.*

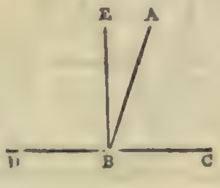


PROPOSITION XIII.—Theorem.

The angles which one straight line (AB) *makes with another* (D C) *upon one side of it, are either two right angles, or are together equal to two right angles.*

For the angle A B C is either equal to A B D, or it is not. * Def. 8. If A B C be = A B D, *each is a right angle.** But if they are not equal, from B draw B E at right † Pr. 11. angles to D C :† then the angles E B C, E B D are right angles, also E B C = E B A + A B C. To each of these equals add E B D, ∴ E B C + E B D = * Ax. 2. E B D + E B A + A B C.* Again : A B D = E B D + E B A. Add A B C to each of these equals, ∴ † Ax. 2. A B D + A B C = E B D + E B A + A B C ;† but it was demonstrated that E B C + E B D are equal to the latter three angles, ∴ A B D + A B C = E B D * Ax. 1. + E B C :* that is, *the two angles* A B D, A B C *are together equal to two right angles.*

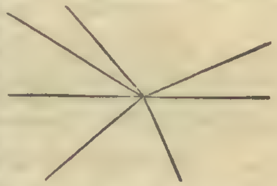




Therefore *the angles which one straight line*, &c. Q.E.D.

Cor. 1.—It is manifest from this, that if two straight lines cross one another, forming *four* angles at the point of intersection, these four angles are together equal to *four right angles.*

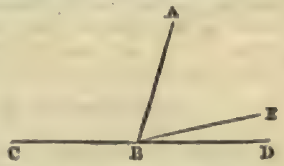
Cor. 2.—And moreover, that if in a straight line any point between its extremities be taken, from which any number of straight lines are drawn, some on one side and some on the other, all the angles thus made at the point will together be equal to four right angles ; those on one side of the proposed line being together equal to two right angles, and those on the other side equal also to two right angles.



PROPOSITION XIV.—Theorem.

If at a point (B) *in a straight line* (A B) *two other straight lines,* (B C, B D), *upon opposite sides of it, make the adjacent angles* (A B C, A B D) *together equal to two right angles, the two straight lines* (B C, B D) *shall be in one and the same straight line.*

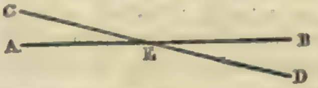
For, if B D be not in the same straight line with C B, let BE be in the same straight line with it. Then because A B makes, with the straight line C B E upon one side of it, the angles ABC, ABE, these are together = two * Pr. 13. right angles.* But A B C, A B D are likewise together = two † Hyp. right angles,† ∴ ABC + ABE = ABC * Ax. 1. + A B D.* Take away the common angle A B C, and there † Ax. 3. remains ABE = ABD, the less to the greater, which is impossible ; ∴ B E is *not* in the same straight line with BC. And in like manner may it be proved that no line, except BD, can be the prolongation of CB; ∴ CB, BD *are in one and the same straight line.* Wherefore, *if at a point,* &c. Q.E.D.



PROPOSITION XV.—Theorem.

If two straight lines (A B, C D) *cut one another, the vertical* (or opposite) *angles shall be equal ;* that is, A E C = D E B, and C E B = A E D.

The angles which A E makes with C D, on one side of * Pr. 13. it, are together equal to two right angles ;* that is, A E C + A E D = two right angles. Again : the angles which D E makes with A B are also together equal to two right an- † Pr. 13. gles ;* that is DEA + DEB = two right angles ; ∴ AEC + AED † Ax. 1. = D E A + D E B.† Take away the common * Ax. 3. angle AED, and there remains AEC = DEB.* And in a similar manner it may be proved that C E B = A E D. Therefore, *if two straight lines,* &c. Q.E.D.



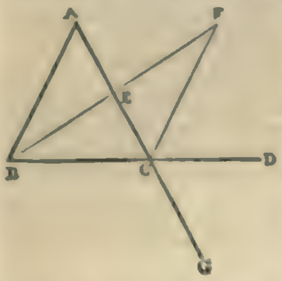
PROPOSITION XVI.—Theorem.

If one side (B C) *of a triangle be prolonged, the exterior angle* (A C D) *shall be greater than either of the interior opposite* (or more remote) *angles.* (B A C, A B C).

* Pr. 10. Bisect A C in E,* draw B E, which prolong, † Pr. 3. and make E F = equal B E :† join F C.

* Const. Because A E = C E,* and E B = E F ;* A E, E B are = C E, E F, each to each and the angle A E B

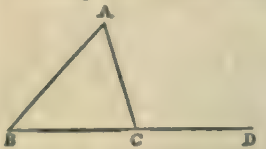
† Pr. 18. = C E F ;† ∴ A B = C F,‡ and the angle A = ‡ Pr. 4. E C F : but A C D is greater than E C F, ∴ A C D *is greater than* A ; ∴ if one side, B C, of a triangle be prolonged, the exterior angle A C D is greater than the interior angle A *opposite to the side prolonged* : but if the side prolonged be A C, the exterior angle will be B C G, and the interior angle opposite, A B C ; ∴ B C G is greater than A B C. But * Pr. 15. A C D = B C G,* ∴ A C D is greater than A B C ; and it was before proved that A C D is greater also than A, ∴ A C D *is greater than either of the interior opposite angles* B A C, A B C. Therefore, *if one side, &c.* Q.E.D.



PROPOSITION XVII.—THEOREM.

Any two angles of a triangle (A B C) *are together less than two right angles.*

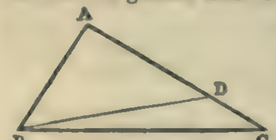
Prolong one of the sides, as B C to D ; then the exterior angle A C D is greater than the interior opposite * Pr. 16. angle B.* To each of these add A C B ; then A C D, A C B are together greater than B, † Ax. 4. A C B ;† but A C D, A C B are together equal to * Pr. 13. two right angles ;* ∴ B, A C B *are together less than two right angles.* And if B A be prolonged, it may be proved, in like manner, that A, B are together less than two right angles ; or if C A be prolonged, that A and A C B are together less than two right angles. Therefore, *any two angles, &c.* Q. E. D.



PROPOSITION XVIII.—THEOREM.

The greater side of every triangle (A B C) *is opposite to the greater angle.*

Let A C be greater than A B ; the angle A B C shall be greater than the angle C. From A C the greater cut off A D = A B the less, and draw B D. Then because A D B is an exterior angle of the triangle B D C, * Pr. 16. it is greater than C :* † Pr. 5. but A D B = A B D,† ∴ the angle A B D is likewise greater than C ; much more, then, is the angle A B C greater than C. Therefore, *the greater side, &c.* Q. E. D.

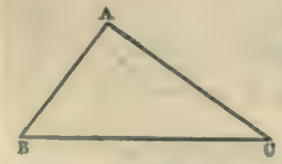


PROPOSITION XIX.—THEOREM.

The greater angle of every triangle (A B C) *is subtended by the greater side,* or has the greater side opposite to it.

Let the angle B be greater than C ; then A C shall be greater than A B.

For, if it be not greater, A C must either be equal to A B, or less than it. If it were *equal,* the angle B * Pr. 5. would = C ;* but it is not, ∴ A C *is not* = A B. If it were *less,* the angle B would be less than † Pr. 18. C ;† but it is not, ∴ A C *is not less than* A B ; and it was shown that it is not *equal* to A B, ∴ A C *is greater than* A B, ∴ *the greater angle, &c.* Q.E.D.

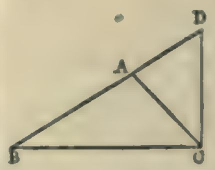


PROPOSITION XX.—THEOREM.

Any two sides (B A, A C) *of a triangle* (A B C) *are together greater than the third side* (B C).

Prolong one of the two sides, as B A, to D, and make * Pr. 3. A D = A C,* the other of the two sides : join D, C.

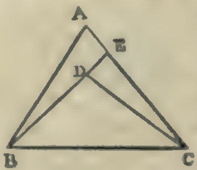
Because A D = A C, the angle † Pr. 5. A C D = D ;† but the angle B C D is greater than A C D, ∴ B C D is greater than D. And because the angle B C D of the triangle D B C is greater than the angle D, and that the greater angle is subtended by the greater * Pr. 19. side,* the side B D is greater than B C : but B D = B A + A D = B A + A C, ∴ B A + A C *is greater than* B C. Therefore, *any two sides, &c.* Q.E.D.



PROPOSITION XXI.—THEOREM.

If from the ends of a side of a triangle there be drawn two straight lines (B D, C D) *to a point within the triangle, these shall be together less than the other two sides* (A B, A C) *of the triangle, but shall contain a greater angle.*

Prolong B D to E. The two sides B A, A E of the triangle A B E are together greater * Pr. 20. than B E.* To each of these unequals add E C, ∴ B A, A C are greater than B E, E C. Again : the two sides C E, E D of the triangle C E D are together greater † Pr. 20. than C D.† To each of these add D B, ∴ C E, E B are greater than C D, D B. But it was shown that B A, A C are greater than B E, E C ; much more then are B A, A C greater than B D, D C. Again : the exterior angle B D C of the triangle C D E is greater * Pr. 16. than C E D ;* and the exterior angle C E B of the triangle A B E is greater than B A C :* *much more then is* B D C *greater than* B A C. Therefore, *if from the ends, &c.* Q.E.D.

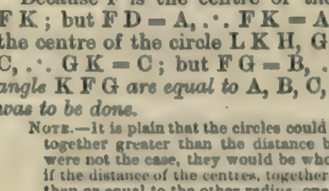


PROPOSITION XXII.—PROBLEM.

To make a triangle of which the sides shall be equal to three given straight lines (A, B, C), *each to each, but any* * Pr. 20. *two of these must be greater than the third.**

Take a straight line D E, terminated at the point D, but unlimited towards E, and make D F = A, F G = B, and G H † Pr. 3. = C.† With centre F and radius F D describe the circle D K L ; and with centre G and radius G H describe the circle H K L, cutting the former in K. Draw K F, K G : the triangle K F G has its three sides equal to the three lines A, B, C.

Because F is the centre of the circle D K L, F D = F K ; but F D = A, ∴ F K = A. Again : because G is the centre of the circle L K H, G H = G K ; but G H = C, ∴ G K = C ; but F G = B, ∴ *the sides of the triangle* K F G *are equal to* A, B, C, *each to each. Which was to be done.*



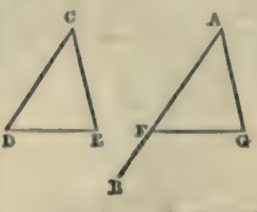
NOTE.—It is plain that the circles could not *cut* unless their radii were together greater than the distance between their centres : if such were not the case, they would be wholly *without* one another. And if the distance of the centres, together with one radius, were smaller than or equal to the other radius, one circle would be wholly *within* the other : the hypothesis precludes both of these circumstances.

PROPOSITION XXIII.—PROBLEM.

At a given point (A) *in a given straight line* (AB) *to make an angle equal to a given angle* (C).

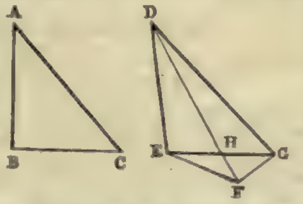
In C D, C E take any points D, E, one in each, and draw D E. Make the triangle A F G, the sides of which shall be equal to those of C D E—namely, A F = C D, A G = C E, * Pr. 22. and F G = D E ;* then the angle A shall be equal to C.

Because A F = C D, A G = C E, and F G = D E, ∴ * Pr. 8. *the angle* A = *the angle* C,* ∴ *at the given point, &c. Which was to be done.*



PROPOSITION XXIV.—THEOREM.

If two triangles (A B C, D E F) *have two sides* (A B, A C) *of the one equal to two sides* (D E, D F) *of the other, each to each, but the angle* (B A C) *contained by the two sides of one of them greater than the angle* (E D F) *contained by the two sides equal to them of the other; the base* (B C) *of that which has the greater angle shall be greater than the base* (E F) *of the other.*

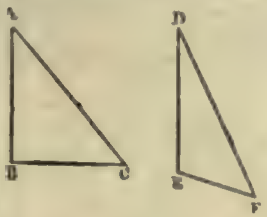


Of the two sides D E, D F, let D E be the side which is *not greater* than the other. Make the angle • Pr. 23. E D G = A,* and make D G = A C or † Pr. 3. D F.† Draw E G, G F, and let H be the point where E G is cut, either by D F or by D F prolonged.

Because D E is not greater than D G, the angle D G E is not greater than • Pr. 19. D E G;* but D H G *is* greater than D E G, ∴ D H G is greater than D G H, and ∴ D G is greater † Pr. 19. than D H;† but D F = D G, ∴ D F is greater than D H, ∴ H G F *is a part of* D G F. Again: the two sides B A, A C are = the two E D, D G, each to • Hyp. & Const. each, and the angle A = E D G,* ∴ B C = E G. And because D F = D G, the angle D F G † Pr. 5. = D G F:† but it was proved that D G F is greater than E G F, ∴ D F G is greater than E G F; much more then is E F G greater than E G F, ∴ in the triangle F E G the angle E F G is greater than E G F, • Pr. 19. ∴ E G is greater than E F;* but, as already proved, E G = B C, ∴ B C *is greater than* E F. Therefore, *if two triangles, &c.* Q.E.D.

PROPOSITION XXV.—THEOREM.

If two triangles (A B C, D E F) *have two sides* (A B, A C) *of the one equal to two sides* (D E, D F) *of the other, each to each, but the base* (B C) *of one greater than the base* (E F) *of the other, the angle* (A) *contained by the sides of that with the greater base shall be greater than the angle* (D) *contained by the sides equal to those of the other.*

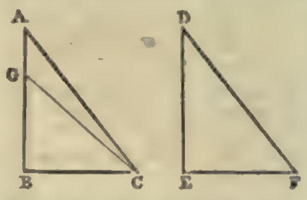


For if A be not greater than D, it must be either equal to it or less. A is not *equal* to D, for then B C would be = E F;* • Pr. 4. but it is not. A is not *less* than D, for then B C would be less than E F:* • Pr. 24. but it is not.† As † Hyp. therefore it is neither equal to nor less than D, A *must be greater than* D, ∴ *if two triangles, &c.* Q.E.D.

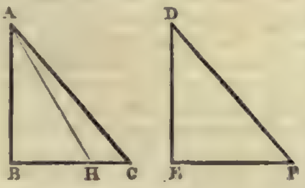
PROPOSITION XXVI.—THEOREM.

If two triangles (A B C, D E F) *have two angles* (B, C) *of the one equal to two* (E, F) *of the other, each to each; and one side equal to one side—viz., either the sides* (B C, E F) *adjacent to the equal angles, or the sides* (A B, D E) *opposite to equal angles in each; then shall the other sides be equal, each to each, and also the third angle of the one to the third angle of the other.*

First let B C = E F, the sides *adjacent* to the angles that are equal each to each. Then if A B, D E be *unequal*, one of them must be the greater. Let A B be the greater, and make B G = D E,* • Pr. 3. and draw G C: then because B G = E D, and B C = E F,† † Hyp. and that the angle B = E, ∴ the angle G C B = • Pr. 4. F:* but the angle A C B = F,† ∴ the angle † Hyp. G C B = A C B, the less to the greater; which is impossible; ∴ A B *is not unequal to* D E, *that is, it is equal to it*, ∴ in the two triangles A B C, D E F, the two sides A B, B C and the included angle B in the one, are respectively equal to the two sides D E, E F and the included angle E in the other, ∴ A C = D F, *and the* • Pr. 4. *angle* A = D.*

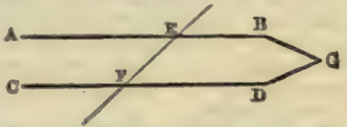


Next let A B = D E, the sides *opposite* to equal angles; in this case, likewise, the other sides shall be equal—namely, A C = D F, and B C = E F and also the angle B A C = D. For, if B C, E F be unequal, let B C be the greater, and make B H = E F.* • Pr. 3. Join A, H: then because B H = E F, and A B = D E, the two A B, B H = D E, E F, each to each; and they contain equal angles; • Pr. 4. ∴ A H = D F,* and the angle B H A = E F D: † Hyp. but E F D = B C A,† ∴ B H A = B C A, the exterior angle equal to the interior and opposite, which • Pr. 16. is impossible;* ∴ B C is not unequal to E F, ∴ B C = E F: and A B = D E, ∴ the two A B, B C = D E, E F, each to each; and they contain equal angles, ∴ A C = D F, and B A C = E D F, ∴ *if two triangles, &c.* Q.E.D.



PROPOSITION XXVII.—THEOREM.

If a straight line (E F) *falling upon two other straight lines* (A B, C D) *makes the alternate angles* (A E F, E F D) *equal, these two straight lines shall be parallel.*

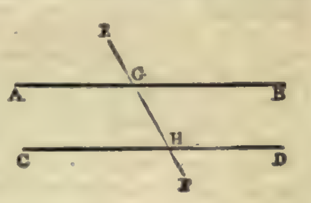


For if they be not parallel they will meet, when prolonged, either towards B, D, or towards A, C. Let them be prolonged and meet in the point G; then G E F will be a *triangle*, and its exterior angle A E F must be • Pr. 16. greater than the interior and opposite angle † Hyp. E F G;* but it is also equal to it,† which is impossible; ∴ A B, C D, when prolonged, do not meet towards B, D. In like manner it may be proved that they do not meet towards A, C. ∴ *they are parallel*, ∴ • Def. 3. *if a straight line, &c.* Q. E. D.

PROPOSITION XXVIII.—THEOREM.

If a straight line (E F) *falling upon two other straight lines* (A B, C D) *make the exterior angle* (E G B) *equal to the interior and opposite angle* (G H D) *upon the same side of the line; or make the interior angles* (B G H, G H D) *upon the same side together equal to two right angles; the two straight lines* (A B, C D) *shall be parallel.*

Because the angle E G B = the angle G H D,* and • Hyp. E G B = A G H,† ∴ A G H = G H D; and † Pr. 15. these are *alternate* angles, ∴ A B *is parallel to* C D.*



• Pr. 27. Again: because the angles B G H, G H D are together = two right angles,* and • Hyp. that A G H, B G H are together also = two right angles,† ∴ † Pr. 13. A G H + B G H = B G H + G H D. Take away B G H, then A G H = G H D; and these are • Pr. 27. *alternate* angles, ∴ A B *is parallel to* C D,* ∴ *if a straight line, &c.* Q. E. D.

NOTE.—Propositions XXVII. and XXVIII. clearly prove the *existence* of parallel lines, or of lines such that, however far they be prolonged, they can never meet. And by aid of the first of these propositions, if a straight line be given, one parallel to it may always be drawn (see Prop. XXXI.) But, to proceed further in the doctrine of parallel lines, requires assent to a principle which must now be formally stated, and unhesitatingly admitted as true: it is the principle affirmed in Euclid's twelfth axiom. In most editions of Euclid, this is placed, with the other axioms, at the commencement of the Book. It has been here kept out of view till it can no longer be dispensed with; and this has been done because, in the first place, we should not be called upon to give assent to what concerns anything, of the possible existence of which there may be reasonable doubt. Till he has reached Prop. XXVII. (which proposition is all-sufficient for the construction of Prop. XXXI.), the learner may fairly question whether it be *possible* for what are called parallel lines to exist: he now knows that parallel or *never-meeting* lines may be actually drawn.

In the next place, from the property demonstrated in Proposition XVII., namely, that any two angles of a *triangle* are together less than two right angles, he knows—what he could not know at an earlier stage of his progress—an important particular respecting a pair of *meeting-lines*, crossed by a third line; namely, that in a pair of *meeting-lines*, the two interior angles on one side of the crossing line, are together *less than two right angles;* and, as a consequence (Prop. XXVIII.), that when these interior angles are together *equal* to two right angles, the lines crossed must be *non-meeting*, or *parallel lines*. It is the *converse* of the first-mentioned property that he is now to be called upon to receive as true; viz., that if a straight line, crossing *a pair of lines*, make the two interior angles, on the same side of it, together *less than two right angles*, the pair crossed shall be *meeting-lines*. This is the twelfth axiom, and is thus expressed in Euclid:—

AXIOM XII.—If a straight line meet two straight lines, so as to make the two interior angles, on the same side of it, taken together, *less than two right angles*, these straight lines, being prolonged, shall at length *meet* upon that side on which are the angles that are less than two right angles.

The propositions already referred to enable us to see distinctly what it is that this axiom assumes, and moreover inform us that the assumption is, at least, perfectly *consistent with demonstrated truth*. That it is necessarily true, must be admitted, upon reflecting for a moment upon that peculiarity of a *straight* line, really implied in its designation, though not expressly adverted to in its definition—*its undeviating sameness of direction.*

It is obvious, from this uniformity of direction, that if two straight lines, however far prolonged, *never* meet, then, at no part of their course, can either make any approach towards the other; for if two straight lines *approach* one another, their continuance, in the same undeviating directions, necessitates their *meeting*, if indefinitely prolonged. We cannot doubt this, and yet have an accurate conception of an unlimited straight line; since *uniformity of direction* must enter that conception. It follows, therefore, that parallel lines must be, throughout, *equidistant lines.* But two *distinct* straight lines, through the same point, cannot be throughout equally distant from a third; so that two straight lines, through the same point, cannot *both* be parallel to the same straight line. It has been seen (Prop. XXVIII.) that *one* (C D) is parallel to another (A B), if the interior angles (B G H, D H G) be *equal* to two right angles; a *second* (H K), which would cause the interior angles (B G H, K H G) to be *less* than two right angles, being a distinct line from C D, must therefore *meet* A B if prolonged. And this is the assertion of the twelfth axiom.

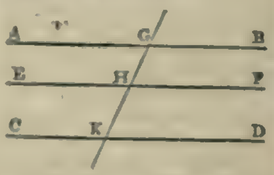
PROPOSITION XXIX.—THEOREM.

If a straight line (E F) *fall upon two parallel straight lines* (A B, C D) *it makes the alternate angles* (A G H, G H D) *equal; and the exterior angle* (E G B) = *the interior and opposite* (G H D) *upon the same side; and likewise the two interior angles* (B G H, G H D) *upon the same side together* = *two right angles.*—[See the preceding diagram.]

For if A G H be not = G H D, one of them, as A G H, must be the greater. Add the angle B G H to each of them, ∴ A G H + B G H are greater than B G H + G H D. But A G H + B G H = two right angles,* ∴
* Pr. 13. B G H + G H D are less than two right
† Ax. 12. angles, ∴ A B, C D, if prolonged, will meet,† which is impossible, since (by hypothesis) they are parallel; ∴ A G H *is not unequal to* G H D, *that is, it is*
* Pr. 15. *equal to it.* Again: A G H = E G B,* ∴ E G B = G H D. Add to each of these B G H, ∴ E G B + B G H = G H D + B G H; but E G B + B G H = two
† Pr. 13. right angles,† ∴ B G H + G H D = *two right angles,* ∴ *if a straight line, &c.* Q. E. D.

PROPOSITION XXX.—THEOREM.

Straight lines (AB, C D) *which are parallel to the same straight line* (E F) *are parallel to each other.*

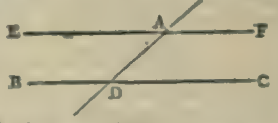


Let the straight line G H K cut A B, E F, C D: then, because A B is parallel to E F, the angle A G K
* Pr. 29. = G H F,* and because E F, C D are also parallel, the angle G H F
† Pr. 29. = G K D,† ∴
* Pr. 27. A G K = G K D, ∴ A B *is parallel to* C D.* ∴ *straight lines, &c.* Q. E D.

PROPOSITION XXXI.—PROBLEM.

To draw a straight line through a given point (A) *parallel to a given straight line* (B C).

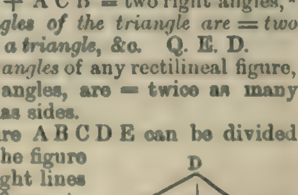
In B C take any point D: join A D; and at the point
* Pr. 23. A in A D make the angle D A E = A D C;* and prolong E A to F; then E F *shall be parallel to* B C.



Because A D, falling upon E F, B C, makes the alternate angles E A D, A D C equal, E F *is paral-*
* Pr. 27. *lel to* B C,* ∴ *through the given point A a line E F parallel to* B C *is drawn. Which was to be done.*

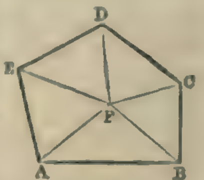
PROPOSITION XXXII.—THEOREM.

If a side (B C) *of a triangle* (A B C) *be prolonged, the exterior angle* (A C D) *is* = *the two interior and opposite angles* (A, B); *and the three interior angles of every triangle are together* = *two right angles.*



* Pr. 31. Through C draw C E parallel to A B;* then the alternate angles B A C, A C E are equal,†
† Pr. 29. and because B D falls upon the said parallels, the exterior angle E C D is = the interior and opposite angle
* Pr. 29. A B C.* It was proved that A C E = B A C, ∴ *the whole exterior angle* A C D = A + B, *both the interior and opposite angles.* To each of these equals add A C B, ∴ A C D + A C B = A + B + A C B: but A C D + A C B = two right angles,*
* Pr. 13. ∴ *the three angles of the triangle are* = *two right angles,* ∴ *if a side of a triangle, &c.* Q. E. D.

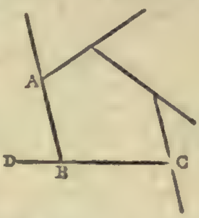
COR. 1.—All the *interior angles* of any rectilineal figure, together with four right angles, are = twice as many right angles as the figure has sides.



For, any rectilineal figure A B C D E can be divided into as many triangles as the figure has sides, by drawing straight lines from a point F within the figure to each of its vertices. And, by the preceding prop., all the angles of these triangles are = twice as many right angles as there are triangles; that is, as there are sides of the figure. But these same angles are equal to the angles of the figure together with the angles at F, the common vertex of the triangles; that is, to-
* Pr. 13. gether with four right angles;* ∴ *all the*
Cor. 2. *angles of the figure, together with four right*

angles, are = twice as many right angles as the figure has sides.

COR. 2.—All the *exterior angles* of any rectilineal figure are together = four right angles.

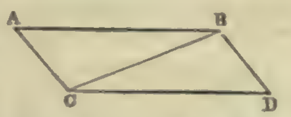


Because every interior angle A B C, with its adjacent exterior angle A B D, is = two
* Pr. 13. right angles,* .·. all the interior + all the exterior are = twice as many right angles as there are sides to the figure; that is, by the above corollary, to all the interior angles + four right angles, .·. *all the exterior angles are = four right angles.*

This remarkable property can scarcely fail to arrest the student's special attention; as, previously to its demonstration, he would be little likely to expect that if the sides of a rectilineal figure be prolonged, one after another, the exterior angles thus formed would have the *same amount* whether the figure had *three* sides, or *three thousand.*

PROPOSITION XXXIII.—THEOREM.

The straight lines (A C, B D) *which join the extremities of two equal and parallel straight lines* (A B, C D) *towards the same parts, are also themselves equal and parallel.*

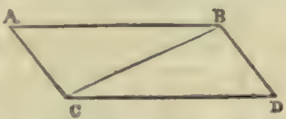


Draw B C, which joins the extremities of the parallels towards *opposite* parts; then the alternate angles A B C,
* Pr. 29. B C D are equal.* And because A B = C D, and B C common to the two triangles A B C, D C B, the two sides A B, B C and the included angle are respectively = the two D C, C B and the included angle; .·. A C =
† Pr. 4. B D,† and the angle A C B = D B C; and these
* Pr. 27. are *alternate* angles, .·. A C *is parallel to* B D;* *and it was shown that* A C = B D; .·.*the straight lines, &c.* Q. E. D.

PROPOSITION XXXIV.—THEOREM.

The opposite sides and angles of a parallelogram A C D B *are equal, and the diagonal* (B C) *bisects it; that is, divides it into two equal parts.*

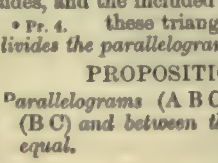
DEF.—A parallelogram is a four-sided figure, of which the opposite sides are parallel; and the *diagonal* is the straight line joining two of its opposite vertices.



Because A B is parallel to C D, and B C meets them, the angle A B C =
* Pr. 29. D C B;* and because A C is parallel to B D, and B C meets them,
† Pr. 29. the angle A C B = D B C,† .·. the two triangles A B C, D C B have two angles A B C, A C B, in the one = D C B, D B C, in the other, each to each, and the side B C, adjacent to the equal angles, common to the two triangles; .·. A B = C D, *and* A C = B D; *and the*
* Pr. 26. *angle* A = D.* Again: because the angle A B C = D C B, and the angle D B C = A C B, .·. *the whole angle* A B D = *the whole angle* A C D; and it was proved that A = D, .·. *the opposite sides and angles of a parallelogram are equal.* Also the diagonal bisects it: for it has been shown that the triangle A C B has two sides, and the included angle A = respectively to two sides, and the included angle D in the triangle D B C, .·.
* Pr. 4. these triangles are equal,* .·. *the diagonal* B C *divides the parallelogram into two equal parts.*

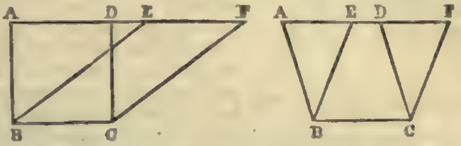
PROPOSITION XXXV.—THEOREM.

Parallelograms (A B C D, E B C F) *upon the same base* (B C) *and between the same parallels* (A F, B C) *are equal.*



Suppose, first, that the sides A D, E F, opposite to the base B C, terminate in the *same point* D; then, since each parallelogram is double of the triangle B D C,*
* Pr. 34. *the parallelograms are equal.*

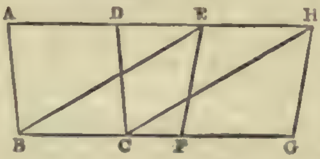
Next, let the sides A D, E F terminate in different points, D, E; then A D = B C,
† Pr. 34. and E F = B C,† .·. A D = E F, and D E is



common, .·. the whole, or remainder, A E = the whole, or
* Pr. 34. remainder, D F: also A B = D C,* .·. A E, A B
† Pr. 29. = D F, D C, each to each; also the angle A = F D C,† .·. the triangle E A B = triangle F D C. Take the triangle E A B from the trapezium A B C F, and from the *same* trapezium take the equal triangle F D C; the remainders must be equal; that is, *the parallelogram* E B C F = *the parallelogram* A B C D; .·. *parallelograms upon the same base, &c.* Q. E. D.

PROPOSITION XXXVI.—THEOREM.

Parallelograms (A B C D, E F G H) *upon equal bases* (B C, F G) *and between the same parallels* (A H, B G) *are equal.*



Draw B E, C H. Then because B C = F G, and F G = E H; .·. B C = E H; and these are parallels, and joined towards the same parts by B E, C H, .·. E B, H C are equal and
* Pr. 33. parallel,* .·. E B C H is a paral-
† Pr. 34. lelogram,†
* Def. and it is = A B C D,* also E B C H = E F G H,*
* Pr. 35. .·. *the parallelogram* A B C D = E F G H, .·. *parallelograms upon equal bases, &c.* Q. E. D.

PROPOSITION XXXVII.—THEOREM.

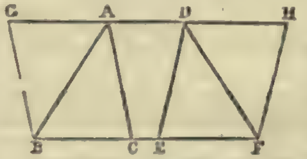
Triangles (A B C, D B C) *on the same base* (B C) *and between the same parallels* (E F, B C) *are equal.*

This proposition is only a particular case of that which follows; and as the particular is not made use of in the more general demonstration, it may be omitted, as quite superfluous. Prop. XXXVIII. proves that triangles between the same parallels are equal, provided only that their bases are *equal*, without any restriction as to whether the bases *coincide* or not. Whatever is proved as to *equal* things is, of course, proved when the things are not only *equal*, but *identical*. Prop. XXXV. is, like the present, only a particular case of that next in order, but the proof of the latter requires that the particular case be previously established; so that, although Prop. XXXVI. really includes Prop. XXXV., yet Prop. XXXV. must not on that account be suppressed.

The enunciation of the present useless proposition is retained here, solely in order that Euclid's subsequent propositions may not be disturbed.

PROPOSITION XXXVIII.—THEOREM.

Triangles (A B C, D E F) *upon equal bases* (B C, E F) *and between the same parallels* (B F, G H) *are equal.*



Through B draw B G
* Pr. 31. parallel to C A,* and through F draw F H parallel to E D,* the lines thus drawn terminating in G H. Then G B C A, D E F H are parallelograms,†
† Pr. 34. and, being on equal bases, and between the
Def. same parallels, they are *equal*,* .·. their halves
* Pr. 36. are equal; that is, *the triangle* A B C = *the triangle* D E F, .·. *triangles upon equal bases, &c.* Q. E. D.

PROPOSITION XXXIX.—THEOREM.

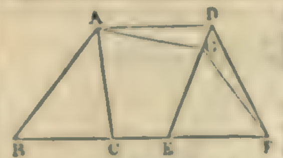
Equal triangles (A B C, D B C) *upon the same base* (B C) *and on the same side of it, are between the same parallels.*

This proposition, like Prop. XXXVII., is superfluous; it is included in the next.

PROPOSITION XL.—THEOREM.

Equal triangles (A B C, D E F) *on the same side of the same straight line, and having equal bases, are between the same parallels.*

Draw A D. Then if A D be not parallel to B F, let

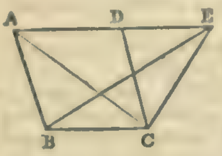


some other line A G be parallel to B F, and draw G E F. The triangle A B C = • Hyp. the triangle G E F,† as they are on equal bases and between the same parallels. But the triangle A B C • Pr. 38. = the triangle D E F,* ∴ triangle D E F = triangle G E F, though one is only a part of the other, which is impossible, ∴ any other line A G is *not* parallel to B F, ∴ A D *is the parallel to* B F *drawn from* A, ∴ *equal triangles*, &c. Q. E. D.

NOTE.—Whether the *supposed* parallel, A G, be considered to meet E D, or E D prolonged—that is, whether A G be imagined on the one side of A D, or on the other—the reasoning remains the same.

PROPOSITION XLI.—THEOREM.

If a parallelogram (A B C D) *and a triangle* (E B C) *be upon the same base and between the same parallels, the parallelogram shall be double the triangle.*



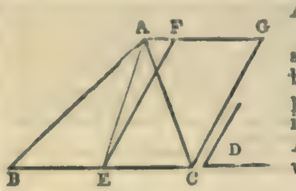
Draw A C, then triangle A B C = triangle E B C, because they are on the same base and are between the same parallels.* But • Pr. 37. A B C D is double the † Pr. 34. triangle A B C,† ∴ A B C D *is also double the triangle* E B C, ∴ *if a parallelogram, &c.* Q. E. D.

NOTE.—The learner will perceive that this thorem is unnecessarily restricted to the case in which the bases *coincide*; he may generalise it himself, proving that if a parallelogram and a triangle be upon *equal* bases, &c.

PROPOSITION XLII.—PROBLEM.

To describe a parallelogram that shall be equal to a given triangle (A B C), *and have one of its angles equal to a given angle* (D).

• Pr. 10. Bisect B C in E,* and make the angle CEF † Pr. 23. = D.† Also through A draw A F G parallel • Pr. 31. to B C, and through C, C G parallel to E F:* then F E C G is the parallelogram required. For draw A E: the triangle A B E = † Pr. 38. triangle A E C,† since they are on equal bases and between the same parallels, ∴ triangle A B C is double the triangle A E C. But F E C G is likewise double the triangle • Pr. 41. A E C,* ∴ *parallelogram* F E C G = *triangle* A B C, *and the angle* C E F † Const. = D,† ∴ a parallelogram has been described as required.

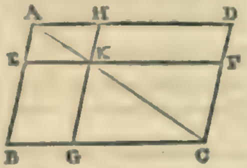


PROPOSITION XLIII.—THEOREM.

The complements (B K, K D) *of the parallelograms* (E H, G F) *which are about the diagonal* (A C) *of a parallelogram are equal.*

The parallelogram E H, G D, through which the diagonal A C passes. are said to be *about the diagonal*, and the remaining parallelograms B K, K D, which make up the whole figure, are called the *complements* of the former.

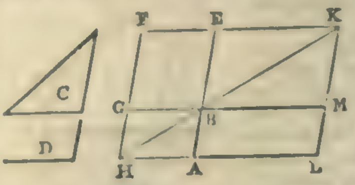
Because B D is a parallelogram, and A C its diagonal, • Pr. 34. ∴ triangle A B C = triangle A D C.* Again, because E H is a parallelogram, ∴ triangle A E K = † Pr. 34. triangle A H K;† and, for a like reason, triangle K G C = triangle K F C, ∴ A E K + K G C = A H K + K F C. But the whole A B C = the whole A D C, ∴ the remainders—that is, the *complements* B K, K D—*are equal*, ∴ *the complements, &c.* Q. E. D.



PROPOSITION XLIV.—PROBLEM.

To a given finite straight line (A B) *to apply a parallelogram which shall be equal to a given triangle* (C), *and have one of its angles equal to a given angle* (D).

Make the parallelogram B F = triangle C, and having • Pr. 42. the angle E B G = D,* so that B E may be in the same straight line with A B; and prolong F G to H. † Pr. 31. Through A draw A H, parallel to B G or E F,† meeting the prolongation of F G in H, and draw H B. Then because H F falls on the parallels A H, E F, the angles A H F, H F E are together = two right • Pr. 29. angles,* ∴ B H F + H F E are *less* than two right angles, ∴ H B, F E, if prolonged, must † Ax. 12. meet.† Let them meet in K; and draw K L • Pr. 31. parallel to E A, or F H;* and prolong H A, G B, to L, M. Then L F is a parallelogram, of which the diagonal is H K; and L B, B F are the *complements* of the parallelograms A G, M E, about the diagonal, † Pr. 43. • Const. ∴ L B = B F;† but B F = C,* ∴ L B = C. † Pr. 15. And because the angle G B E = A B M,† and • Const. G B E = D,* ∴ A B M = D, ∴ *to the straight line* A B *the parallelogram* L B *is applied* = C, *and having an angle* A B M = D. Which was to be done

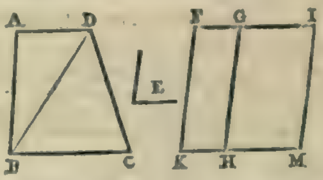


PROPOSITION XLV.—PROBLEM.

To describe a parallelogram equal to a given rectilineal figure, and having an angle equal to a given angle (E).

First, let the figure be a *four-sided* one, A B C D. Draw D B, and describe the parallelogram F H = the • Pr. 42. triangle A D B, and having the angle K = E;* and to G H apply the parallelogram G M = the triangle † Pr. 44. D B C, having the angle G H M = E.† *The figure* F M *shall be the parallelogram required.*

• Const. Because the angles K, G H M are each = E,* ∴ K = G H M. Add to each of these the angle K H G, ∴ K + K H G = G H M + K H G; but K + K H G = two right angles,† † Pr. 29. ∴ G H M + K H G = two right angles, and consequently K H, H M are in the • Pr. 14. same straight line.* And because H G meets the parallels K M, F G, the angle M H G = H G F;† † Pr. 29. add to each of these the angle H G L, ∴ M H G + H G L = H G F + H G L; but the former are • Pr. 29 = two right angles;* ∴ H G F + H G L = two right angles, ∴ F G, G L are in the same straight † Pr. 14. line.† And because K F, M L are each • Pr. 30. parallel to H G, ∴ K F is parallel to M L,* and K M, F L are by construction parallel; ∴ F M is a † Pr. 34. parallelogram.† And because the triangle Def. A B D = F H, and the triangle D B C = • Const. G M,* ∴ *the whole* A C = *the parallelogram* F M. Again, let the figure be *five-sided*. then, having drawn D C, there will be, besides the four-sided figure A C, a triangle upon D C. A parallelogram, equal to this triangle, may be applied to L M, just as G M = D B C was applied to G H; and thus, however numerous be the sides, *a parallelogram may be described equal to the given rectilineal figure, and having the angle* K = *the given angle* E.

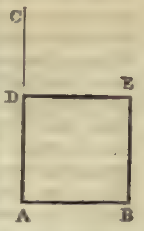


COR.—From this it is manifest how, to a given straight line, to apply a parallelogram which shall have an angle equal to a given rectilineal angle, and shall be equal to a given rectilineal figure.

PROPOSITION XLVI.—PROBLEM.

To describe a square upon a given finite straight line (A B).

• Pr. 11. Draw A C at right angles to A B.* and make † Pr. 3. A D = A B.† Through D draw D E parallel to • Pr. 31. A B, and through B draw B E parallel to A D,*



∴ A E is a parallelogram, ∴ A B † Pr. 34 = D E, and A D = B E;† but A B = A D, ∴ the four sides A B, A D, D E, E B are all equal, ∴ A E is *equilateral.* Likewise, all its angles are right angles; for since A D meets the parallels A B, D E, the angles A + A D E * Pr. 29. = two right angles;* but A † Const. is a right angle,† ∴ A D E is a right angle; but the opposite angles * Pr. 34. of a parallelogram are equal,* ∴ B, E are each right angles, ∴ the figure A E is *rectangular*, and it was proved to be *equilateral;* it is ∴ *a square, and it is described upon the given straight line* A B. Which was to be done.

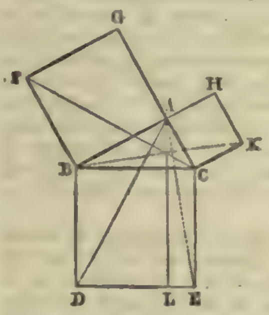
Cor.—Hence, every parallelogram that has *one* right angle, has all its angles right angles.

Note.—It may be easily proved that the figure A E is rectangular, provided it have *one* right angle A, and that it be equilateral; for if the diagonal D B be drawn, the figure will be divided into two equal triangles (Pr. VIII.), ∴ A = E, ∴ the triangles are right-angled isosceles triangles, and (Pr. V. and XXXII.) each base angle is half a right angle, ∴ the angles A, B, E, D are all right angles. Hence, *a square is a four-sided figure, which has all its sides equal, and one of its angles a right angle;* that the other three are also right angles is demonstrable, as above, and ought not to be assumed in a definition.

PROPOSITION XLVII.—Theorem.

In any right-angled triangle (B A C), *the square* (B E) *described upon the side* (B C) *subtending the right angle, is equal to the squares* (B G, C H) *described upon the sides containing the right angles.*

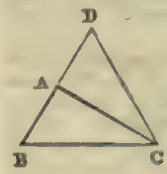
* Pr. 46. The squares being described,* through A draw † Pr. 31. A L parallel to B D or C E;† draw also A D, * Hyp. F C. Then, because B A C is a right angle,* and that B A G is also a right angle, C A, A G are in the † Pr. 14. same straight line.† For a like reason, A B, A H are in the same straight line. Now the angle D B C = F B A, each being a right angle; add to each the angle A B C, ∴ D B A = F B C; also the two sides A B, B D = the two F B, B C, each to each, ∴ *the triangle* A B D = *the triangle* F B C.* * Pr. 4. Now the parallelogram B L is double the triangle A B D, because they are on the same base B D, and between the same paral- † Pr. 41. lels B D, A L;† and the square B G is double the triangle F B C, because these also are on the same base, and are between the same parallels F B, G C; but the doubles of equals are themselves equal, ∴ B L = B G.



In like manner, by drawing A E, B K, it may be demonstrated that C L = C H, ∴ the whole square B E = the two squares B G, C H; that is, *the square described upon* B C *is equal to the squares described upon* A B, A C, ∴ *in any right-angled triangle, &c.* Q. E. D.

PROPOSITION XLVIII.—Theorem.

If the square described upon (B C) *one of the sides of a triangle* (A B C) *be equal to the squares described upon the other two sides, the angle* (A) *contained by these two sides is a right angle.*



From A draw A D at right angles * Pr. 11. to A C,* and make A D † Pr. 3. = A B,† and draw D C. Then, because A D = A B, the square of A D = the square of A B: to each of these add the square of A C, ∴ the squares of A D, A C = the squares of A B, A C. But the square of D C = the squares of A D, A C, because * Pr. 47. D A C is a right angle,* and the square of B C is by hyp. = the squares of A B, A C, ∴ the square of D C = the square of B C, ∴ D C = B C. Hence, in the two triangles A B C, A D C, there are two sides B A, A C in the one, equal to the two D A, A C in the other, each to each, and the base B C equal to the base * Pr. 8. D C, ∴ the angle B A C = D A C.* But D A C is a right angle, ∴ B A C is a right angle, ∴ *if a square, &c.* Q. E. D.

REMARKS AND COMMENTS ON THE FIRST BOOK OF EUCLID.

The following observations on the general character of geometrical reasoning, and on the First Book of Euclid in particular, are intended for the guidance and instruction of those whose acquaintance with the subject is limited to what has now been delivered. We think it very probable that, among such persons, there may be some who, however attentively they may have read the portion now completed, have failed to perceive, so clearly as is desirable, the main object and intention of a course of geometrical study. It is true that the demonstrations themselves are so free from obscurity, and so thoroughly convincing, that no doubt can remain on the mind of an attentive reader as to the truth of the several conclusions arrived at; so that anything added to these demonstrations, by way of elucidation of the steps, or as confirmatory of the results, would be felt by the merest beginner to be an incumbrance rather than an aid.

There is no doubt, however, that Geometry is sometimes taken up with erroneous expectations as to what it teaches; and is read with a pliant docility of mind—a passive acquiescence in the dicta of the teacher—which Euclid himself would be the first to condemn. It is chiefly for the purpose of guarding *you* against such mistakes that we append the following remarks to the first book of the elements. We should have *prefixed* them, could we have been quite certain that you would have been familiar with the geometrical terms which would have been employed. We offer them here, in the expectation that you will give the foregoing part a second reading, guided by the additional light here to be given, in reference to the objects and advantages of Geometry, and also as regards the true spirit in which its principles should be studied.

A youth, destined ultimately for some mechanical or scientific occupation, is told—and properly told—that, to excel in his calling, he must study Euclid; this study is usually associated in his mind with a case of mathematical instruments, scales, compasses, parallel-rulers, &c. Now, without expressly *forbidding* these things, it is of importance that he should be distinctly informed that, for aught that appears to the contrary, Euclid never handled, or even saw, compasses, parallel-rulers, &c., in his life. It is certain that he gives no countenance to the use of any such mechanical contrivances in his work. Had Euclid been asked, there is no doubt that he would have declared his inability to describe a circle, and even to draw a straight line. What *we* call *practical geometry* Euclid was entirely regardless of; indeed the application of geometry to the practical business of life was viewed by the ancient geometricians rather as a degradation of the purely intellectual science they cultivated, than as enhancing its value; and we accordingly find that but few of Euclid's *problems*, or practical constructions, are such as a skilful workman would follow.

Important and extensive as are the practical applications of geometry, it should nevertheless be borne in mind that the *Elements* would have existed, just as they now do, if these applications had never been thought of. The availability of geometry in practice is merely a contingent and accidental circumstance, uncontemplated by the geometricians, just as their theory of the conic sections was elaborated without any prospective regard to the future demands of physical astronomy, or to the discoveries of Newton.

And it is right to contemplate geometry under this purely intellectual aspect, and to study it as a strictly abstract science. Practical operations are all more or less imperfect. There are imperfections of vision, of the hand, of the instruments employed. Pure Euclidean geometry tolerates no such imperfections, however minute or unimportant they may be in a practical point of view. The circle of Euclid is a *perfect* circle—such a circle, in fact, as no human being ever formed. In like manner, the straight line of Euclid is rigorously what it is affirmed to be—*perfectly* straight, and *perfectly* breadthless. You see, therefore, that we were fully warranted in saying, that Euclid could not describe a circle, nor draw a straight line; he has not, indeed, attempted to do either; the marks and diagrams which he exhibits to the eye, in connection with his reasonings, are nothing more than the outward symbols, of what *actually exists in the mind alone.* And the truths of geometry become applicable to visible and tangible squares, circles, &c., only on the supposition or *assumption* that they are perfect copies of our intellectual conceptions of these things. A very able writer on Logic and mental Philosophy (Mr. Stuart Mill), denies to the lines and figures of geometry, the perfection here contended for. Assuming that all our conceptions of form originate in our contemplation of outward objects, which is no doubt true, he maintains that our ideas of squares, circles, &c., are only copies of the confessedly imperfect forms presented to our eyes. We would submit, however, that the mind can *conceive* what it may surpass the powers of the hand to *execute;* and that we can *imagine* a perfection which art cannot attain. A mere approximation to the perfect form—which is all that can be presented to the eye—will suggest the practically-unattainable perfection to the mind; and it may be safely asserted that the very infirmity of our visual organs contributes to this perfection; since defects, too minute to be visible in the outward object, cannot possibly accompany the mental impression of that object.

We have thought it right, in these introductory remarks, thus to state broadly, and unambiguously, what the subject-matter of geometry really is. The objects with which it deals, and to which its reasonings are applied, are our perfect mental conceptions of figure, and not the imperfect pictured forms which, to help these conceptions, are traced upon paper. These are merely the outward representations, or visible symbols of the purely intellectual forms which they very conveniently serve to suggest; though, from the physical and instrumental imperfections which we know to be attached to them, they are not accurately the things themselves; these latter, by an act of abstraction, being freed from all material encumbrances; so that, in fact, the forms and figures of geometry are exclusively in the *mind*, and not in *matter*.

This is no bar to the practical applications of the science. Whether a tangible square be perfect or imperfect is of no moment, practically speaking, so long as its imperfections are undiscoverable by the senses; inasmuch as the rigorous conclusions of geometry may be applied to it without practical or appreciable error.

We now proceed to consider the basis upon which the entire structure of geometry rests—a basis so simple that a child might lay the foundation-stones; yet supporting a fabric which, though so extensive, is, at the same time, so secure, that the most powerful intellect cannot disturb its stability. We need scarcely say that we allude to the axioms and postulates of the science; and, in connection with the consideration of these, shall take occasion to offer some suggestions as to the proper frame of mind in which Euclid should be studied.

Supposing, then, that you have your Euclid in your hands, we commence by first directing your attention to the fact, that the work is divided into distinct sections, or *Books;* and that each book commences with an explanation of the technical terms employed in it; with a concise but satisfactory description of the lines and figures to be reasoned about, and a statement of the elementary propositions to be *admitted as possible*, in the practical constructions, and of the elementary propositions to be *admitted as true* in the reasonings.

You will at once see, that in entering upon any doctrine which is to be established, not by the influence of authority, but by the force of reasoning and sound argument, it is of much importance that preliminaries such as these should be clearly and satisfactorily settled. If a person desire to communicate his own convictions to another, and, in undertaking to do so, make *reasoning* the only channel through which to convey them, there must be—first, a mutual concurrence as to the meaning of the terms employed; and secondly, a like concurrence as to the fundamental principles to be assumed by the one party, and admitted by the other. A good deal of what goes by the name of reasoning and argument, in the common affairs of life, is nothing but a sort of wrangling disputation, solely from the neglect to establish a clear understanding on these points at the outset. Euclid is careful to preclude this fertile source of ambiguity, confusion, and error. He commences the several portions of his subject with *Definitions* of the things to be discussed, and of the peculiar terms to be employed in the discussion; he then tells you what he expects you to admit as practically, or at least, as *conceivably* possible; and lastly, what he requires you to concede, without demonstration, as necessarily true.

You should not hurry over the definitions; they have been framed with great care. The character of a good definition is this: that it is just sufficiently descriptive of the thing defined to distinguish it from all other things, but not more than sufficient for this purpose. If anything more than what merely suffices to identify the object defined be declared in a definition, that definition is said to be *redundant:* it involves the *assumption* of some property or peculiarity of the object, which it is the province of *reasoning* to deduce from the properly-restricted definition of it. All the properties of geometrical figures are in this way deduced from, or as it were drawn out of, the definitions of those figures; for in the definitions they are all virtually implied, and lie concealed. If you were to define an equilateral triangle as that which has three equal sides and three equal angles, you would make a statement which is quite correct, as a *statement*, but very faulty as a *definition:* the equality of the three sides *necessitates* the equality of the three angles (Prop. V., Cor.), so that the equality of the angles is virtually implied in the equality of the sides—a truth which must be discovered to us by reasoning, not assumed in a so-called definition. You will observe that Euclid invariably constructs his figures solely in reference to the descriptions of those figures embodied in the definitions, quite regardless, at the time, of all other properties of them; and you will perceive that he has furnished particulars just sufficient for this purpose, without one superfluous item.

We need scarcely state, that in speaking of Euclid here, the emendations of Simson and other modern editors are uniformly kept in view. It is much to be regretted that, in the editions of Euclid most generally studied, acknowledged blemishes are allowed to remain in the text, while the proper emendations are given in the form of notes at the end. Our veneration for a writer on science should never be considered as ground sufficient for us to endorse his errors and defects, nor even to except to them only indirectly, and in the form of supplementary annotation; they ought, in justice to him, as well as to those for whom he wrote, to be expunged from the text of his instructions. In a work of taste or imagination, the case would be different; an editor would have no right to replace the author's views and peculiarities by his own; but a book of science, so extensively used in education as Euclid is, should be rendered as perfect as possible; and an editor of such a book could incur little blame for expunging every admitted blemish from the text of his author. We have generally acted under this impression.

Having thus previously established the *existence* of his geometrical forms, Euclid then proceeds, in his *Theorems*, to deduce, by reasoning, all those properties necessarily, though not obviously, implied in the definitions; but, as already noticed, before these existences can be proved, that is to say, before the constructions employed by Euclid in his *Problems* can be actually effected, assent must be given to the practicability, or, to be more explicit, to the conceivability of certain fundamental *operations:* these are enumerated in the *Postulates:* and that before the reasonings in his *Theorems* can be entered upon, assent must, in like manner, be given to certain fundamental and necessary *truths;* these are enumerated in the *Axioms.* You perceive, therefore, that the definitions furnish the raw material worked *upon*, and that the postulates and axioms furnish the implements worked *with*—the postulates supplying the elements of the constructions, the axioms the elements of the reasonings.

And here we must caution you against a very prevalent mistake. Do not for a moment imagine that Euclid required his postulates to be *granted*, because the fundamental operations, under that head, are so easy of performance; nor that his axioms are to be assented to because the truths so-called are so easy of proof. His reasons for these preliminary stipulations were of a directly opposite kind; he bargains with you to grant the possibility of his fundamental problems (the postulates), solely because he is unable, practically, to perform them; and he calls upon you to admit, without proof, his fundamental theorems (the axioms), solely because he is unable to demonstrate them. A postulate and an axiom should each have a twofold character: a postulate should be a conceivable, but, at the same time, a really impracticable *operation;* an axiom should be a self-evident, but, at the same time, an indemonstrable *truth.* Euclid asks us to "*grant* that a straight line may be drawn from any one point to any other," from sheer necessity; the apparent simplicity of the operation is in reality a cause of its difficulty. What operation, still more simple, could be made subsidiary to the drawing of a straight line? And how could he direct the performance of the latter, without some operation still more elementary? Besides, an isolated straight line, according to Euclid's strict definition, has no visible or external existence. Euclid's *line* is merely the abstraction *length;* and length, unaccompanied by other dimensions, cannot, of course, be actually exhibited. The finest line that you could draw upon paper would be a solid bar of ink; and the finest line an artist could engrave upon steel would be a sunken channel, with both breadth and depth. You may possibly think that, as the physical or material lines here adverted to are so very slender, it is not worth while to make any objection to them on the score of their width or thickness; but the "near enough," or the "that'll do" system, has no place whatever in *Euclid's* system, which is one of rigid, uncompromising accuracy. A line that you could draw and exhibit would no more be regarded as a line that Euclid had defined, than a beam of timber would be. Remember that with *him* "a miss is as good as a mile."

As with the postulates, so with the axioms; they are inserted from necessity, and solely because Euclid was unable to demonstrate them. That self-evidence alone was not considered by him as sufficient to justify the claim of a proposition to a place among the axioms, is plain, from his uniform practice of demonstrating whatever can be demonstrated, and assuming only what cannot; taking care, however, *in general*, that the truth assumed shall be, not only an ultimate truth, but also a thing perceived to be true as soon as enunciated. We say, *in general*, because there is one remarkable exception—the 12th axiom of the first book is indemonstrable, but not self-evident; it has one of the characteristics of an axiom, but not the other. In the preceding book, we have thought it prudent to keep this so-called axiom out of sight, till the 29th proposition was reached; because up to that point its aid is not required: and arguments, abundantly sufficient to produce full conviction of its truth, could be adduced *then*, though they could not have been employed at the opening of the subject.

Now you must not be surprised or disappointed that geometry—pre-eminently the science of demonstrated truth—should thus require to rest upon principles which must be gratuitously admitted. No reasoning process whatever can even be conceived to exist, unsupported by a like foundation. A proposition may be affirmed on the one side, and denied on the other; but the matter cannot be reasoned out—it cannot be *argued*, unless some common first principle or principles be at the commencement agreed to by both parties. If everything be denied, there may be assertion and contradiction, dispute and altercation, but certainly no *argument.* The noticeable thing in Euclid's first principles, or axioms, is, that, with the exception mentioned above, they are such as nobody in his senses would think of controverting, inasmuch as the truth of them is self-evident; that is, so immediately obvious, that nothing of the kind, anterior to them in obviousness and simplicity, can possibly be adduced; for if anything could, then *that* thing—being the more simple and elementary—would itself become the axiom, or first principle, by aid of which the former might be demonstrated. You see, therefore, that it is essential to the very nature of an axiom that it should be too simple and elementary to admit of demonstration by help of anything more simple and elementary. The axioms are, on this account, self-evident, indemonstrable truths. Proposition II., of Book III.—namely, that "If any two points be taken in the circumference of a circle, the straight line which joins them shall fall *within* the circle"—is a proposition as self-evident, to any one who has a clear conception of a circle, as that which affirms that "two straight lines cannot inclose a space;" but as it is demonstrable, it is very properly placed in the body of the work.

But it is time to give you a few words of advice as to the disposition of mind with which you should sit down to the study of geometry, and to notice some of the intellectual advantages which you have a right to expect from the time and attention devoted to the subject.

You have already seen what the preliminary conditions are, which Euclid makes with you: he considers these to have been conceded, without the slightest qualification or reserve. As far as he is committed, he will take care that they are faithfully adhered to, and he stipulates that they shall be equally binding upon you. They are fully and fairly placed before you in the Definitions, the Postulates, and the Axioms. In these matters he seems to assume a sort of magisterial authority, from which he allows no appeal. If you refuse to subscribe to the conditions which he himself lays down, he, on his part, refuses to be your guide: he can conduct you through the rich domain you wish to explore upon no other terms: he is inflexible as to his preliminary arrangements for the journey; and he as good as tells you, as he told King Ptolemy of old, that "there is no royal road to geometry."

If, therefore, you have any notion still lingering in your mind, about a line, or a triangle, or a circle, &c., not strictly in accordance with what he authoritatively declares to be *the* notion, you must dismiss either it or *him.* If you have any scruples or misgivings about his postulates or axioms, you must, in like manner, overcome them: you must examine them, and re-examine them, till you are fully convinced that the postulates are really conceivable operations, and that the axioms are really unquestionable truths; for, depend upon it, he will tie you down most rigidly to the *conditions*, and allow of no escape, evasion, or qualification. It matters nothing to him by what process of mind you satisfy yourself of the truth of his axioms, nor by what mechanical contrivances you seek to give an outward representation of lines, triangles, and circles; you may use pen, ruler, compasses, or whatever you please, for your own individual convenience or assistance; but remember, that he himself takes no cognizance of these things. If, without any instrumental aid at all, and by mere freedom of hand, you were to sketch the outline of an inclosed figure, and make *that* the representation, to yourself, of a circle, Euclid would find no fault with you, provided only you still, in imagination, endowed it with the characteristics of the true circle that he had defined. You will find a carpenter, or a mason, much harder to please, in a matter of this kind, than you would find Euclid. If you have carefully read what has preceded, you will see that we are quite justified in making this statement; for you will have learned that Euclid is not concerned with the *representations*, but with the *things* themselves, the purely intellectual conceptions.

Taking it, then, as a settled matter, that you receive

Euclid's definitions—that you *do* "grant" his postulates, and that you *do* fully acquiesce in the truth of his axioms, all preparatory ground is cleared; and you may proceed at once to the business proposed. And here you are to observe, that both you and your author occupy different positions. Euclid at once, from this point, drops his authority as a master; you withdraw your submission as a docile and obedient pupil. What he *says*, you are to regard no longer—only what he *proves*. You are to exercise a vigilant watchfulness over every statement he makes, receiving just so much of it as you cannot help receiving, and no more. *Faith*, in anything he advances, is not to be thought of. Be as sceptical as you please—nay, as sceptical as you can. Euclid would not thank you for any gratuitous concession whatever; all he demands is, that you will honestly respect the preliminary articles of agreement; and, in spite of all your opposition, and of all your scepticism, he will *compel* you —however much against your wish—to do unqualified homage—not to *him*—but to the truth he propounds.

And this is the attitude of mind you are to assume in entering upon the propositions of geometry. There must be no yielding to the dicta of a teacher—no intellectual obeisance to the authority of a great name. Every truth you acquire, you must *so* acquire as to feel and know it to be a truth, from your own perfect individual *conviction* that it is so. Your conviction must be so thoroughly inwrought and complete, that if a Newton, or even a greater than Newton, should attempt to controvert a truth thus secured, the effect of such an attempt upon your mind would be about the same as an endeavour to convince you that you are an inhabitant of the moon.

Now we think that, from these unqualified statements, you may fairly make two inferences, well worthy of consideration. The first is, that even in this, our frail and erring state, there is offered to our notice a system of unadulterated and incontrovertible TRUTH, built up by purely human effort, and consolidated and rendered imperishable by purely human reason. The second inference is, that the reasoning process, by which such an intellectual structure has been reared, must surely be of the most faultless kind—no logical error can have been committed—no conceivable objection unanticipated, and no case of exception unprovided for.

These considerations alone seem to us amply sufficient to incline all who have the time and opportunity, to a diligent study of geometry, apart from all regard to practical applications. Only reflect for a moment upon the *habits of mind* which such study must necessarily foster, where they in any way exist, or *create* where they are wanting. The frequent contemplation of *Truth* has a salutary and an ennobling influence. Next to Inspired Truth, the truths of pure science furnish the most exalted materials upon which the human mind can exercise its powers. He who is earnestly and *successfully* engaged in this exercise, comes, at length, to love truth for its own intrinsic excellence; to be fascinated with its unadorned beauty; and to entertain increased repugnance towards the deformities of falsehood. Habits of mind, whether good or bad, are the fruits of seeds usually sown in youth; they become formed and fixed from the natural effects of those trains of thought in which we most frequently indulge in early life; and hence the study of geometry, and of the sciences which carry out its pure principles, have an important influence, even in a *moral* point of view. To secure the operation of this influence is surely deserving an effort. The properties of geometrical figures may be matters of perfect indifference to us—we may take but little direct interest in what relates to triangles, parallelograms, and circles; but we cannot be indifferent to a truthful habit of mind; and though all the theorems of Euclid be forgotten, yet if *this* remain as an abiding result, how great will be the acquisition we shall have made!

But the *intellectual* advantages connected with the study of the "exact sciences," are even more certain and palpable than the *moral* advantages here alluded to. You cannot read a proposition of Euclid as it ought to be read—and indeed as it must be read, in order to be fully understood—without a concentration of attention more intense than most other subjects, out of mathematics, demand; and since, as just noticed, there must be no disposition to admit anything whatever, without the most complete conviction of its truth, a habit of scrutinising evidence, and of distinguishing between plausibilities and proofs, is insensibly but securely acquired. There is, perhaps, no faculty of the mind which in early life stands in more need of cultivation than the reasoning faculty; for that every one reasons, or at least engages in what goes by the name of reasoning, is so generally admitted as a distinguishing peculiarity, that man has been even defined to be "a reasoning animal." Locke says, "Would you have a man reason *well*—let him learn geometry;" that is to say, if to reason well be the only end in view—all the truths of Euclid being regarded as utterly valueless—still let geometry be studied. Yet geometry supplies no rules; it prescribes no directions for conducting a logical process; but, what is better, it places before us a collection of the most exquisite models. It teaches by example, not by precept; and no one, with proper attention, can fail to profit by its lessons.

You see, therefore, that Euclid is something more than a mere problem-book for the use of architects and surveyors: it is the most finished treatise on the "Art of Reasoning" that the world possesses; and it is chiefly as such that we are anxious to recommend to our young friends a careful study of its contents. It may fail to render you much direct professional service; but the mental discipline it furnishes will strengthen your judgment, improve your logic, give additional acuteness to your penetration, and, in fact, so enlarge and invigorate all the faculties of your mind, that you will be enabled to bring a higher degree of intellectual power to bear upon any pursuit in which you may earnestly engage. It is not the properties of geometrical figures that can do this: it is the reasonings by which they are established. The several stages at which you arrive, in your progress through Euclid, may present but few points of attraction; but you *must* be benefited by the invigorating influence of the journey.

And here it may perhaps be as well, in order to prevent misunderstanding, that we should offer a remark or two in reference to a direction given you above—namely, that you should approach the demonstrations of Euclid in a *sceptical* spirit. It has been foolishly, and most unjustly affirmed by some, that the study of pure science has a tendency to produce *general scepticism*. Now all truths are harmonious; they have common features and common attractions, recommending themselves to our homage by the same dignified aspect and bearing. How can scientific truth ever be out of keeping with inspired truth? A religious sceptic is generally something more than a mere *neutral* as respects divine things: he is usually a *denier*; that is, he embraces a *negative proposition*, and acts upon it without proof! How does geometry sanction this? In Euclid there are negative propositions as well as affirmative ones. We recommend you, anterior to proof, to be equally sceptical as to *both*. In things out of geometry, geometrical demonstration is, of course, not to be had; it would be folly to look for it; yet, if in such things an affirmative be declared on the one hand, and a negative on the other, do you not think that the logic of geometry, as well as the logic of common sense, would incline us to *that*, in support of which *some* evidence was offered, rather than to that which had no such support at all?

But there are sceptics of a different stamp from the class noticed above; men of literary and philosophical habits, who do not content themselves with a "cold negation." They address themselves to the task of undermining the existing evidences of the truth of Christianity.

Such a man was David Hume, a distinguished writer of the last century. He wrote an essay to prove that *a miracle* never could have been performed, or, at least, that we have no reliable evidence of its performance. He laid down certain preliminary principles, and dressed his performance in the garb of *fair reasoning.* But Hume knew nothing of mathematics; and, in invading its province, he trod upon slippery ground, and *fell.* Those who *did* know something of the "exact sciences" betook themselves to the investigation; they started upon precisely the same principles as Hume did, without the assumption of a single additional particular, and they arrived, by a train of reasoning which it is impossible to disturb, at a conclusion *directly opposite to his.* Had Hume known but a little of mathematics, and had he revised his so-called *argument,* in the same sceptical spirit which we recommend to you, a regard for his own literary reputation merely, would have precluded him from ever publishing to the world his *Essay on Miracles.**

You have already seen that the propositions of geometry are of two kinds—problems and theorems. A proposition is called a *problem,* when the thing proposed is an operation to be performed—a construction to be effected: its object is a practical result, to be brought about by a suitable disposal and combination of the elementary materials furnished by the *postulates.* A proposition is called a *theorem,* when the thing proposed is a truth to be demonstrated; and for this demonstration the elementary materials are furnished by the *axioms.* It usually happens, however, that the proof of a theorem requires the previous introduction of certain lines and constructions; and hence it is that Euclid commences his first book with problems instead of theorems. The only theorem in this book, that is quite independent of a problem, is Proposition IV. Euclid probably considered it more systematic to introduce the problems, which he foresaw would be indispensable as soon as the fourth proposition was disposed of, at the *beginning* of the book, than to interpose them between propositions so closely related as the fourth and fifth.

Of the three problems thus found to be necessary to meet the demands of the subsequent theorems, the second is the only one which seems to require any comment. Beginners in general find it difficult, and are apt to consider that there is an unnecessary parade of geometrical apparatus exhibited to effect so simple a matter as the drawing of one straight line equal to another. There is no doubt that a mere mechanic would pronounce the proceeding a very round-about one; he would accomplish the business at once, by drawing a straight line from A at random; and then, having taken the length B C in his compasses, he would apply one foot at A, fixing it there as a centre, and with the other foot would cut off the required length A L; thus dispensing with all Euclid's machinery—the circles and the equilateral triangle. Now this is all very well for the purposes of the practical workman, who neither seeks nor expects rigid accuracy in his constructions; but you must remember that Euclid ignores compasses, and that the instrumental transference of one line to another is not warranted by any postulate. No one can take *accurately* any stipulated length in a pair of compasses; the limitation of his vision precludes his pronouncing, with perfect certainty, that he has got *exactly* the proposed length, neither more nor less. If the minute error, whether in excess or in defect, be only so small as to escape his senses, he cannot take cognizance of it; and he not only practically, but from necessity disregards it. But without any additional postulate, Euclid shows you how the thing proposed may be done without the possibility of any error at all. In the ordinary editions of Euclid, we think justice is scarcely done to the process indicated. You are directed, first, to draw a line A E *longer* than B C, and are then shown how to cut off a part A L *equal* to B C. The ingenuity of Euclid's mode of proceeding would be more apparent, if no superfluity of length were at first introduced. It certainly seems a thing of much greater difficulty to draw a line from a point A, till a certain prescribed length be attained, and then, but not till then, to stop. We would therefore recommend you to leave the prolonging of D A to the very last; so that, having performed every other part of the construction, prolong D A, as a final step, till the prolongation reaches to the circumference of the outer circle. A line A L will thus have been drawn equal to B C, and there will be no excess of length to throw away. This is the mode of proceeding adopted in the present work.

As to the other two problems, the first and third, but little need be said; the directions given by Euclid for the construction of them are too clear and explicit to render further explanation necessary. It may be well, however, to invite your attention to two particulars in connection with Proposition I., which instructs us how to describe an equilateral triangle upon a given finite straight line. Some commentators object to the word *finite* as superfluous, considering the condition, "a *given* straight line," to imply that the *length* is fixed and determinate. But a line may be given in *position* only, without any limitation as to *length,* as in Proposition XI.; or it may be given in *length* merely, without any restriction as to *position:* thus the line to be constructed in Proposition II. is to have a given length, but is unrestricted as to position or direction. By "a given *finite* straight line," Euclid means a line of given length, and with given extremities; and if any objection at all be made, in reference to this word *finite,* we think it should be urged against the omission of it in Proposition II., rather than against the introduction of it in Proposition I. In the *first* proposition, we dare say Euclid thought it prudent to prevent all cavil, to state explicitly that the extremities, A, B, are given; and that he did not consider it necessary to repeat this in Proposition II. Whenever a line is given in position merely, and restriction as to its length forbidden, Euclid characterises it as "a given straight line of unlimited length," as in Proposition XII.; but when it is a matter of perfect indifference whereabouts the extremities are (position alone being all that we are concerned with), the terms "a given straight line" are those always employed, as in Proposition XXXI. A mere glance at this proposition will show you that the given straight line of Proposition I. cannot be so entirely free from restriction, as to length, as the given straight line of Proposition XXXI.; and hence the propriety of the restrictive term *finite* in the former. We should not have said so much about a mere word, had it not been for the hypercriticism of others. You must therefore regard these remarks, not as a comment upon *Euclid,* but as a comment upon his commentators.

The other matter we should wish you to notice, in connection with this first proposition, is, that what is called "the point C, in which the circles cut," is, in fact, either of *two* points, one on each side of A B, so that a second equilateral triangle may be described, on the opposite side of the given line; and it is this latter position which the equilateral triangle, introduced into the construction of Proposition IX., is to take. We shall only further notice, that it would have been somewhat more explicit if Euclid had referred to the point C as where the *circumferences* cut, rather than as where the *circles* cut; though it is quite true that the circles themselves interpenetrate there; but the distinction, very properly made by Euclid in his definitions, between circle and circumference, is in danger of being overlooked by a beginner, in consequence of Euclid's mode of expression, in reference to intersecting circumferences.

Proposition IV. is the first of Euclid's *theorems;* and, being the first, and involving no construction, its proof depends solely on the axioms. The demonstration hinges upon what has been called the method of *superposition;* that is, the imagining one figure to be placed upon another, with a view to their perfect adaptation and coincidence, and thence to the inference of their complete *equality* (Axiom 8). If you wish to try the experiment whether or not you have any taste or aptitude for geometrical reasoning, you may, if you please, *commence* with this theorem, and study the three preceding problems afterwards. It is a very beautiful specimen of Euclid's mode of argumentation; and is quite within range of the powers of the merest beginner. But before you address yourself to it, it may be as well to reflect, that the relative *positions* of two things can have nothing to do with their relative *magnitudes*; that the two triangles, affirmed under certain conditions to be *equal*, and placed side by side before you on the paper, must remain equal, however their relative positions be altered; whether one be turned upside down, or be made to overlap the other, can make no difference as to the equality or inequality of the two in *magnitude*. You will thus see that, for the purpose of instituting an inquiry as to the equality of the triangles, it is quite allowable to imagine one to be placed upon, or to be applied to the other, with the view of ascertaining whether, by a suitable adjustment, a complete adaptation may be brought about. In this manner Euclid directs you to apply the triangle A B C to the triangle D E F in a certain way—namely, so that the point A may be on D, and the straight line A B upon D E. He then affirms that B must coincide with E; and as he never affirms anything without immediately answering the inquiry *why?* he adds, *because* A B is *equal* to D E. The adjustment is thus brought about as far as the sides A B, D E are concerned. He then asserts that, this partial adjustment remaining undisturbed, A C must fall upon D F, *because* the angle or opening A is equal to the angle or opening D. If A C fell *beyond* D F, the angle A would be *greater* than the angle D; and if A C fell *short of* D F, the angle A would be *less* than the angle D; Euclid's conclusion, therefore, is irresistible. As A C then necessarily falls upon D F, the point C must as necessarily fall upon or coincide with the point F, *because* A C is *equal* to D F. And thus having proved, first, that B coincides with E, and then that C coincides with F, he infers, in virtue of the 10th axiom, that the base B C must coincide with the base E F. Hence the adaptation is complete; there is perfect coincidence, and therefore perfect equality in every respect.

---

* See Babbage's *Bridgewater Treatise*—Appendix. Also Young's *Three Lectures on Mathematics.*

Proposition V. is always found to be more or less perplexing to a learner; and it is certainly one of the most, if not *the* most knotty of the propositions in the first book. We would recommend a beginner, after completing the construction as directed, to erase the base B C of the original triangle, in order that nothing may divert his attention from the two triangles A F C, A G B. The line thus expunged may be restored after these triangles have been proved to be in all respects equal: they are nothing more than the two triangles already considered in Proposition IV. in a different position, one triangle partially overlapping the other. Young students are sometimes deterred from prosecuting the study of Euclid by the length and difficulty of this proposition. They should be apprised that the propositions are not arranged in the order of their difficulty; that none more troublesome than this fifth will ever after be met with, and that the last theorem in the book is quite as easy as the first. A great point will be gained, if you master this fifth proposition; for you may then conclude with confidence that you will find yourself fully adequate to all that follows: but you must not come to this conclusion till, closing the book, you find yourself able to demonstrate the theorem step by step without a reference to it. This mode of testing your progress must be resorted to all along. It is not enough that you read and understand Euclid's demonstrations—you must acquire the ability of furnishing these demonstrations yourself; you may vary the language, but you must preserve the rigour of the argument, affirming nothing without a reason.

We do not clearly see why the fifth proposition should be called *Pons asinorum*, or *the asses' bridge*. They say it is because "asses" stick at it; but we believe it was the *twentieth* proposition that was so designated by some of the ancients; for Proclus informs us, in his *Commentary on Euclid*, that the Epicureans derided the twentieth proposition as being manifest "even to asses;" for if a bundle of hay were placed at one extremity of the base of a triangle, and an ass at the other, the animal would not be such an ass as to take the crooked path to the hay instead of the straight one; as he would know the direct course to be the shorter: *this* was therefore called the *asses' bridge*.

The sixth proposition you will find very easy after the fifth: it is what is called the *converse* of the first part of the former proposition. A theorem is said to be the converse of another, when the hypothesis and the consequence, in that other, change places. The hypothesis in Proposition V. is, that two *sides* of the triangle are equal; the inference or consequence is, that the two *angles* opposite to them are equal. The hypothesis in Proposition VI. is, that two *angles* of a triangle are equal; and the consequence is, that the two *sides* opposite to them are equal: the one proposition is therefore the converse of the other. In general, Euclid demonstrates the converse of a previous theorem *indirectly*, or by what is called the *reductio ad absurdum* method; that is, he commences with a denial of the truth stated; and, reasoning from the contradictory statement, as if it were true, shows that an absurdity, or impossibility, is the unavoidable consequence; thus proving that the thing contradicted cannot be otherwise than true. Throughout the whole of this book, the last proposition is the only converse theorem that is not demonstrated in this indirect manner. It is not every theorem that is true both directly and conversely. You should take note of those that Euclid proves to be *convertible*, and endeavour to discover for yourself which of his propositions hold conversely, though only proved directly. For example, Proposition XXXIV. proves that if the opposite sides of a quadrilateral are *parallel*, they are likewise *equal*. It is also true conversely, that if the opposite sides are *equal*, they are likewise *parallel*, as you may prove for yourself, after the direct proposition has been established.

Proposition VII. is merely subsidiary to the proposition next following; it is what in some geometrical writings would be called a *Lemma*. You see that the demonstration of it rests almost entirely on Proposition V. In some modern books on geometry this proposition is dispensed with, and the eighth established independently of it; but, as an intellectual exercise, Proposition VII. is as useful as any in the book. Besides, a proposition, though manifestly introduced as merely subsidiary to something else, may yet possess intrinsic excellence of its own sufficient to justify its retention in the system. For instance, the proposition before us teaches us this fact, which is certainly not without interest; namely, that a physical triangle, supposed to have its sides freely movable about joints at its vertices, cannot possibly be thrust out of shape by any force whatever. You may break the bars forming the framework, but you cannot make the frame itself assume another shape.

Proposition VIII. is the *second* proposition, in the geometry of triangles, which proves that two triangles are equal in every respect—that is, that each is but an exact copy of the other—provided *three* things in one are respectively equal to three corresponding things in the other. The three things may be two sides and the included angle, as we learn by Proposition IV., or the three sides, as the present proposition teaches. And we may as well observe here, that there is only one other proposition in the Elements where the like equality of two triangles is inferred from an equality of three things in one to three corresponding things in the other: it is Proposition XXVI. On these three propositions the practical part of *plane trigonometry* is founded. A triangle, in the language of trigonometry, is said to have six *parts*—the three sides and the three angles; and when certain sets of *three* of these are given—either of the sets, namely, mentioned in Propositions IV., VIII., and XXVI.—the remaining three, which we see by these propositions must be fixed and invariable, become determinable, and are matters of computation.

And here it may not be amiss to say a word or two about the form of expression continually employed by Euclid, when comparing figures together, for the purpose of establishing their equality. He always speaks of two sides or angles of the one being equal to two sides or angles of the other, *each to each*. Learners are apt to omit this qualifying condition, "each to each," as if the frequent repetition of these words were only so much useless tautology; but precision requires that they should always be retained. If you were to say that two sides of one triangle are equal to two sides of another, your meaning might be taken to be, that the *aggregate* or *sum* of the two sides of one triangle is equal to the aggregate or sum of the two sides of the other; but the addition of the words "each to each" would preclude the possibility of such a mistake, and would show that the sides, taken separately and individually in the one triangle, were affirmed to be equal to corresponding sides in the other.

The four propositions next following are *problems*. You may be pretty sure that Euclid has postponed them till they became indispensable. We do not think Euclid *liked* problems; at all events, there is less careful finish about them than in his theorems. Proposition IX., for instance, needs mending a little; it professes to teach how to bisect an angle, of whatever magnitude it may be. Now, suppose that the triangle A D E, in the book, is an *equilateral* triangle, and that we want to bisect the angle D A E. Euclid tells us to construct an equilateral triangle on D E; and without the diagram before our eyes, where the construction is exhibited in its completed state, we should naturally describe the equilateral triangle he directs, *above* D E, and not *below:* in which case we should get nothing; for our new equilateral triangle would simply cover the one already there, and the point, F, falling on A, would have no separate existence; so that there would be no guide to the drawing of A F, the bisecting line; it should have been distinctly stated, therefore, that the equilateral triangle, to be described on D E, should have its vertex, F, on the opposite of D E to the point A. This restriction is introduced in the present edition.

In going over Euclid's proposition without the book, as we have recommended above, always refrain from *copying the diagrams.* We know that such is the usual practice; but it should be condemned. The progress of the diagram should just keep pace with that of the text, and no line should be introduced till it is actually demanded by the text. It would be nearly as faulty as to write out the whole text, and then to supply the diagram (as the boy did who said he would tell the story first, and draw the picture afterwards), as to commence with the completed diagram, and then supply the text. In a printed book, the diagram must, of course, be presented *completed:* but in your own private practice you should make it grow to maturity along with the text. In the whole course of your geometrical studies, let us urge upon you never to allow your judgment or conviction to be in the slightest degree biassed by your visual impressions from the *diagram.* Let two lines look ever so like two equal lines, do not forestal the reasoning, and conclude them equal from their appearance; remember always that you are engaged in a purely *intellectual* process, and that you are not to be allured by the *matter* from the *mind.* Graphical accuracy, in the figured form, is of no moment; logical accuracy, in the abstract reasoning, is all that you have to attend to; and therefore we think it worse than waste of time to be over-scrupulous with scale and compasses, in reference to the lines introduced into Euclid's demonstrations; we have already given you some hints on this matter.

There is nothing that calls for special notice till we reach Proposition XVI. This is easy enough, as far as Euclid carries the demonstration; but when, at the close, he says, as in other editions of the Elements he is made to do, "in the same manner it may be demonstrated," a beginner is likely to feel a difficulty. There is really a good deal to do before the proof can be completed; and, when completed, "in the *same* manner," there is a needless amount of complication. We would advise you to finish the reasoning rather differently. By carefully looking at the argument, you will see that this truth is established, and nothing more; namely, that if one side of a triangle (*any* side, of course) be produced, the exterior angle is *greater than that interior angle which is opposite to the side thus produced;* the angle A C D is thus greater than A. Let now A C be produced to G; then, since the exterior angle is greater than that interior one which is opposite to the side produced, the angle B C G is greater than A B C; but B C G is equal to A C D (by the fifteenth), therefore A C D is greater than A B C; but A C D was shown to be greater also than B A C; *therefore* A C D is greater than *either* of the interior and opposite angles, B A C, A B C. It is this form of completing the demonstration that has been adopted in the present work.

Proposition XVII. would seem, at first sight, to have been introduced without any object. The truth of it is clearly implied in Proposition XXXII., and it is not required in any of the intervening propositions. But that Euclid had an object is not to be questioned; and it seems to have been this:—It was desirable that, at some convenient place, before the introduction of the theorems respecting parallel lines, something should be established by demonstration that would diminish the repugnance, very properly felt at the outset, to the *twelfth axiom.* We have recommended you (p. 540) to keep this axiom in the background till you arrive at Proposition XXIX., where a reference to it becomes indispensably necessary. The axiom is no other than the *converse* of this seventeenth proposition; *this* shows that if two meeting or non-parallel lines, B A, C A, be cut by a third line, B D, the two interior angles, C B A, B C A, on the same side of it, are together *less than two right angles;* and the twelfth axiom asserts, *conversely,* that if a straight line cutting two others make the two interior angles on the same side of it *less than two right angles,* those must be non-parallel or meeting lines.

The seventeenth proposition, therefore, enables us to see more clearly the exact amount of assent demanded of us by the twelfth axiom, and prevents our overrating that amount. If two lines cut by a third *meet,* the two interior angles are less than two right angles: this is *proved.* If two lines cut by a third make the two interior angles less than two right angles, *they meet:* this is *assumed.*

Passing over, for the present, the intermediate propositions, let us suppose Proposition XXIX. to be reached. The two propositions immediately preceding sufficiently show that the lines called parallel lines *exist;* the twenty-ninth demonstrates a property of them, admitting the truth of the axiom just mentioned. Geometers without number have tried, some to evade this axiom altogether, and others to prove it by establishing the converse of Proposition XVII.; but all have failed. What can be the cause of this failure? Is it not in the imperfect definition of a *straight line?* Our conception of a straight line, independently of all formal definition, necessarily involves two ideas; namely, that of *length,* and that of *uniformity of direction. Length* is implied in the word *line;* and *invariability of direction* in the term *straight.* A line which changes its direction is a *crooked* line or a *curved* line; a line that never changes its direction is a *straight* line. Now it necessarily follows, from this uniformity of direction, that if two straight lines, however far prolonged, can *never* meet, then at no part of their course can either make any *approach* towards the other; for if two lines, proceeding in any two directions, *approach* and continue undeviatingly to pursue those directions, they cannot fail eventually to *meet.* It follows, therefore, that parallels must *throughout* be equidistant; but *two* distinct straight lines, through the same point, cannot *throughout* be equidistant from a third; so that *two* straight lines through a point cannot *both* be parallel to the same straight line. Proposition XXVIII. shows that *one* (C D) will be parallel to another (A B), provided a line, cutting both, make the interior angles together *equal* to two right angles; a *second* line through H, which causes the interior angles to be *less* than two right angles, being distinct from C D, must therefore meet A B, if prolonged; and this is the assertion of the twelfth axiom.

What is here said, remember, is not a *demonstration* of this *axiom.* An *axiom,* you know, is an indemonstrable truth. All we wish to show is, that it *is* an axiom; that is, a truth necessarily implied in the correct conception of the thing to which it refers. If you steadily contemplate your conception of a straight line, giving due consideration to its distinguishing peculiarity —*uniformity of direction*—you must see that *two*, from the same point, cannot *both* be equidistant from a third; *one* may be parallel to this third, or everywhere equidistant from it, since, as we have seen, parallels are *possible*; but *one* must of necessity meet it.

Of the propositions passed over, the 22nd and 24th are the only ones requiring any special notice here. Both these, as given in the text of Dr. Simson, are open to objection. In the first of them, it is taken for granted that the two circles employed in the construction must *cut* one another; and in the second, it is assumed that the point F falls *below* the line E G. You will find these defects acknowledged in the notes at the end of Simson's *Euclid;* but they were first pointed out by Mr. Thomas Simpson, in his *Elements of Geometry*. The emendations of the latter were, however, but ill received by the "restorer of Euclid," who treated the "remarker," as he called him, with a good deal of contempt; the more to be reprobated, as the poor self-taught weaver (for such Simpson in early life was) was very superior, as a man of science, to his academical opponent, great as were the merits of the latter in the field of ancient geometry. The biography of Thomas Simpson is full of instruction and encouragement to the young and unaided student, who cannot fail to view with interest the steps by which a person in Simpson's position, without books, money, or friends, plying his humble calling among the lowest ranks of society, was conducted, by the force of perseverance, to the proud eminence which he eventually attained. In the annals of science he ranks among the most distinguished mathematicians of the last century; and yet, at the age of nineteen, he was ignorant of the first rudiments of common arithmetic.[*]

The defect above alluded to, in Dr. Simson's version of the 24th Proposition, is removed in the present edition; and the objection made to the reasoning in the 22nd may be disposed of as follows:—After having described the circles, as at page 538, reason thus: *One of these circles cannot be wholly without the other*, for then F G, the distance of their centres, would be either equal to, or *greater* than the sum of the radii; but, by hypothesis, it is *less*. *Neither can one of the circles—*as, for instance, that whose centre is G—*be wholly within the other;* for then the radius, F D, of the latter would be equal to, or *greater* than F H; but, by hypothesis, it is *less*; hence, since one circle can be neither *wholly* without the other, nor *wholly* within—they must be *partly without* and *partly within* one another, ∴ they must *cut* in some point K. This completion of the proof may be introduced in a second reading of the first book.

Proposition XXXII. is among the most interesting theorems of this first book; but an objection to the demonstration of it may be made, the occasion for which had better be removed. You are directed to draw, through the point C, a line C E parallel to A B, by Proposition XXXI.; and it is then inferred that the alternate angles B A C, A C E are equal, by an appeal to Proposition XXIX.; but to draw the parallel C E, surely everybody would proceed by making the angle A C E equal to B A C; that is to say, we should first make the alternate angles equal to get the parallels, and should then make use of the parallels to prove the alternate angles equal. You will at once see that we should avoid this circuitous method of proceeding, by making the angle A C E equal to B A C by Proposition XXIII.; and then inferring the parallelism of A B, C E from Proposition XXVII., so that Proposition XXXI. need not be called into operation at all.

The corollaries to this proposition are remarkably beautiful; and the second, especially, cannot fail to excite, in a person who reads it for the first time, a feeling of surprise. It would indeed be a feeling of *incredulity*, if this were possible in geometry. That the sum of the exterior angles, formed by prolonging the sides of a rectilineal figure, should always be *exactly* the same, whether the figure have three sides or as many thousand, is a truth so far beyond the reach of practical observation and experiment, and apparently so improbable, that, in the absence of geometry, its existence could scarcely have been suspected, much less established; and yet an argument of half-a-dozen lines produces in every mind the fullest conviction of the fact.

But the corollary that precedes this, though less striking, has, perhaps, the greater practical interest; among other things, we learn from it that—the sum of the angles of a four-sided figure is *twice* as great as the sum of the angles of a three-sided figure; the sum of the angles of a five-sided figure, *three* times as great; of a six-sided figure, *four* times as great, and so on; but the most noticeable practicable inference is, that only *three* regular figures,[†] namely, the equilateral triangle, the square, and the regular six-sided figure or *hexagon*, can, by repetition, completely cover a surface; in other words, that, without leaving any blanks or interstices, we may cover a surface with a mosaic work of equilateral triangles, or of squares, or of regular hexagons, but not with regular figures of any other kind. It would be impossible, for instance, to form a piece of tessellated pavement with slabs of any other regular figure but one of these three; because the uniting together of any other forms, by adjusting side to side, would not fill up the space about the corners—there would be either left an angular gap, or else the stones must overlap one another. You will readily see the truth of this from the following considerations:—

Let us first consider the equilateral triangle: as the three angles make two right angles, each must be $\frac{1}{3}$ of two right angles—that is, $\frac{1}{6}$ of *four* right angles; consequently, if *six* equilateral triangles were placed side by side, a corner or vertex of each being at the same common point, all the angular space about that point would be completely occupied; and no one triangle would overlap another, for the angles about a point amount to just four right angles (Prop. XIII., Cor. 2). Let us next consider the square; and, as each angle of a square is a right angle, it is plain that *four* squares, each with a vertex at the same point, when placed in contact, will exactly fill the space about the point.

The figure next in order is the regular *pentagon*, or five-sided figure. The corollary teaches us that the sum of its five equal angles amounts to six right angles; consequently each angle is *one* right angle and *a fifth*. Now you cannot multiply $1\frac{1}{5}$ by any whole number that will make the product 4—no such number exists; in other words, you cannot arrange the angles of pentagons round a point, as the common vertex of all, so as to fill up the *four* right angles about that point; the pentagon, therefore, must be rejected. The next figure is the hexagon. By the corollary we learn that its six equal angles amount to eight right angles: consequently each angle is equal to $\frac{1}{6}$ of eight right angles; or, which is the same thing, to $\frac{1}{3}$ of four right angles. It follows, therefore, that three regular hexagons, placed side by side, round a point, as a common vertex, will exactly fill the space about that point.

We need not extend the examination any further; for, as the sides of regular figures increase in number, the angles increase in magnitude; and, as it has just been seen that *three* angles of a six-sided regular figure, make four right angles, more than *two* of a seven, or eight, or nine-sided figure, could never be required; but if *two* equal angles of any figure could make *four* right angles, each angle would equal *two* right angles, which is absurd. It thus follows, that if space about a point is to be filled up by the juxtaposition of regular figures, these figures must be either equilateral triangles, squares, or regular hexagons.

Of these three classes of figures, it is demonstrable, by more advanced principles, that the hexagon will enclose a given amount of space, with less extent of outline or border than either of the others; so that if a given surface were to be divided into regular compartments, of equal area, by a network of costly materials, economy, guided by science, would suggest the hexagon as the figure to be chosen. And this is the figure selected by the bee in the construction of the honeycomb. You have seen that of all the figures of geometry, there are but *three* which can so cover a surface as to leave no waste of room—no interstices. The bee chooses one of *them*. Of these three, the hexagon is that which most economises material:—the bee chooses *it*. It is necessary, too, as well for compactness and strength, as for the safe lodgment of the grub, that the hexagonal cell should terminate in a solid angle. Her choice of angles, that *would do*, is to be made from an infinite variety; but among all these, mathematicians have discovered, by a profound analysis, that there is *one*, and but one, mode of formation by which the object would be attained with the least expenditure of materials; and this one the bee adopts. She closes her hexagonal tube with an angular termination, formed by three plane faces. Each plane cuts off or excludes a portion of the tubular space; but the space within the solid angle just makes up for what is thus rejected; and the faces of the solid angle are so shaped, and so inclined, as to fulfil all the mathematical conditions of a *minimum* of surface; so that while the angular space just compensates for the tubular space cut off, it effects the compensation not only with *less* amount of material, but with the *least* amount possible. The compensating space might be secured in an infinite number of ways. Of this endless variety there is *one* way more economical than any other, and that one is chosen by the bee.

---

[*] See account of Simpson, in *The Pursuit of Knowledge under Difficulties;* also Hutton's *Mathematical Dictionary*.

[†] Right-lined figures are said to be *regular*, when they are both *equilateral* and *equiangular*.

You must regard this reference to the architecture of the bee as a digression, into which we have been allured by the preceding examination of Euclid's corollary. But the subject is full of instruction; and when your mathematical knowledge is sufficiently extensive to enable you fully to estimate the science of the honeycomb, you may, like the ancient geometrician Pappus, feel even additional reverence for the Creator's power, and additional gratitude that you have been endowed with faculties to comprehend and admire the exquisite geometry of the bee.

Proposition XXXVII. may be omitted. It is included in the more general theorem which follows, and which is demonstrated independently of the particular case. What is proved of triangles upon *equal* bases is, of course, proved of triangles on the *same* base.

Propositions XXXV. and XXXVI., about parallelograms, seem to be related to one another, just as these two propositions about triangles are related. But there is a difference; for, although the thirty-fifth is only a particular case of that which follows, yet it is not superfluous, since the particular case is required in the proof of the general theorem. The thirty-ninth proposition, however, like the thirty-seventh, *is* superfluous; as the general theorem which follows does not require its aid. The forty-first, too, might have been replaced by a proposition of wider generality. You can give it the extension here suggested by putting "equal bases" for "the same base" in the enunciation, and modifying the construction and demonstration accordingly.

Before passing on to the few remaining propositions, it may be worth while to notice that the term *trapezium* is used in the thirty-fifth proposition for the first time. This is, in fact, the *only* place in which it occurs in the *Elements*, though it is a term frequently employed in the applications of geometry to practical matters, such as mensuration, surveying, &c.

Proposition XLII. requires a word or two. The line A E is improperly introduced, in other editions, into the *construction*; you will see, by attending to the details, that the required parallelogram is completed without any aid from this line; it is in the *demonstration* alone that A E becomes necessary, and therefore its introduction should be deferred till the construction is completed.

Of the forty-seventh proposition but little need be said here. It is stated to have been discovered by Pythagoras, who is recorded to have sacrificed a hundred head of oxen to the gods on the occasion; but this is probably a fable. The multiplication table has also been generally attributed to the same philosopher; but the modern French geometrician, M. Chasles, in his historical researches, has shown this to be a mistake.

The proposition in question is one of the most important, in its practical applications, of all the theorems of geometry. Many forms of demonstration have been given; but that of Euclid is not to be surpassed in elegance and clearness.

The last proposition is remarkable only for the peculiarity of its demonstration; it is the converse of the preceding, and is demonstrated in the *direct* manner, contrary to Euclid's general practice of demonstrating converse propositions *indirectly*. As an exercise, you may supply an indirect demonstration yourself: other exercises on the first book are here subjoined.

EXERCISES ON BOOK I.

1. Prove that the two diagonals of a parallelogram bisect each other.

2. If in the sides of a square, at equal distances from the four vertices, four points be taken, one in each side, the figure formed by the four straight lines, joining the four points, will also be a square.

3. From two given points to draw two straight lines, to meet in a given straight line, and to make equal angles with it.

4. Prove that the two lines drawn, as in the last exercise, are, together, *less* than any other two lines from the points meeting in the given line.

5. To divide a right angle into three equal parts.

6. The diagonals of a rhombus intersect each other at right angles.

7. If the three sides of a triangle be bisected, the perpendiculars drawn to the sides from the three points of bisection will all meet in the same point.

8. The straight line which bisects two sides of a triangle will be parallel to the third side.

9. If the middle points in the sides of any quadrilateral figure are joined by four straight lines, the figure so formed will be a parallelogram.

10. The sum of the angles of a four-sided figure is twice as great as the sum of the angles of a three-sided figure; the sum of the angles of a five-sided figure, three times as great; of a six-sided figure, four times as great; and so on.

11. Through a given point, between two non-parallel straight lines, to draw a third straight line, terminating in the former, which shall be bisected at the given point.

12. From whatever point within an equilateral triangle perpendiculars be drawn to the sides, their sum shall always be the same.

13. If from any point within a parallelogram, lines be drawn to the four vertices, each pair of opposite triangles thus formed will be, together, equal to half the parallelogram.

14. If two triangles have two sides of the one equal to two sides of the other, each to each, and if the angle contained by the two sides of the one, *together with* that contained by the two sides of the other, make two right angles, the two triangles will be equal in surface, or area.

15. In the figure to Proposition XLVII., if F D, G H, E K, be joined, the triangles F B D, G A H, K C E, will all be equal to one another, and to A B C.

16. Prove the *converse* of Proposition XXXIV.; namely—if the opposite sides of a quadrilateral be equal, or if the opposite angles be equal, the figure will be a parallelogram.

17. If the points of bisection of the three sides of a triangle be joined, the triangle will be divided into four component triangles, all equal to one another.

CHAPTER II.

ELEMENTS OF EUCLID.—BOOK II.

DEFINITIONS.

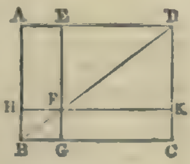
I.

Every right-angled parallelogram, or *rectangle*, is said to be *contained* by any two of the sides which contain one of its angles: that is, by any two *adjacent* sides.

Thus the rectangle A C is said to be *contained* by the adjacent sides A B, B C, or by A D, D C, and is often called, for brevity, "the rectangle A B·B C;" or "the rectangle A D·D C." And when the adjacent sides are made equal to two detached lines, each to each, it is common to refer to the rectangle as contained by the lines to which the adjacent sides have been made equal. Thus the rectangle B H, in Proposition I. following, is referred to as the rectangle A·B C, because B G = A.

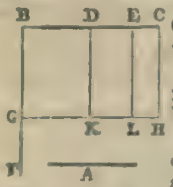
II.

In every parallelogram, either of the parallelograms about a diagonal, together with the two complements, is called a *gnomon*. Thus the parallelogram H G, together with the complements A F, F C, is a gnomon; it is expressed by the *three* letters A G K, or E H C, at the opposite vertices of the parallelograms, which make the gnomon.



PROPOSITION I.—THEOREM.

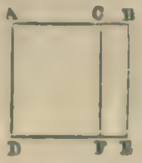
If there be two straight lines (A and B C), *one of which* (B C) *is divided into any number of parts, the rectangle contained by the two straight lines is equal to the rectangles contained by the undivided line and the several parts* (B D, D E, &c.) *of the divided line.*



* 11 I. From B draw B F at right angles to B C,* † 3 I. and make B G = A.† Though G draw G H parallel to B C, and through D, E, C, draw D K, E L, C H * 31 I. parallel to B G.* Then the rectangle B H = B K + D L + E H; but B H is contained by A and B C, † Const. for B G = A,† and B K is contained by A and B D, for B G = A; also, D L is contained by A and D E, * 34 I. for D K = B G* = A; and, in like manner, E H is contained by A and E C, ∴ *the rectangle* A·B C = A·B D + A·D E + A·E C, however many divisions there may be in B C; ∴ *if there be two straight lines, &c.* Q. E. D.

PROPOSITION II.—THEOREM.

If a straight line (A B) *be divided into any two parts* (A C, C B) *the rectangles contained by the whole and each of the parts, are together equal to the square of the whole line:* that is, A B·A C + A B·B C = A B^2.

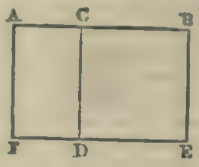


* 46 I. Upon A B describe the square A E,* and through C draw C F parallel to A D or † 31 I. B E.† Then A E = A F + * Const. C E; but A E is A B^2,* and A F = A D·A C = A B·A C, because A D = A B; also C E = A B·B C, for B E = A B, ∴ A B·A C + A B·B C = A B^2; ∴ *if a straight line, &c.*—Q. E. D.

NOTE.—This proposition might have been made a corollary to the preceding, since it is only that particular case of the former in which the two proposed lines (A, BC) are *equal*. It is also obvious that the restriction of the number of parts to *two* is unnecessary.

PROPOSITION III.—THEOREM.

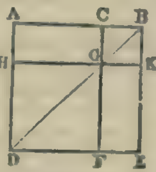
If a straight line (A B) *be divided into any two parts* (A C, C B), *the rectangle contained by the whole and one of the parts is equal to the rectangle contained by the two parts, together with the square of the aforesaid part:* that is, A B B C = A C C B + B C^2.



Upon B C describe the square * 46 I. C E;* prolong E D to F, and through A draw A F parallel † 31 I. to C D or B E.† Then A E = A D + C E; but A E is the rectangle A B·B C, for B C = B E; and A D is the rectangle A C·C B, for C D = C B; also C E is B C^2, ∴ A B B C = A C·C B + B C^2; ∴ *if a straight line, &c.* Q. E. D.

PROPOSITION IV.—THEOREM.

If a straight line (A B) *be divided into any two parts* (A C, C B) *the square of the whole line is equal to the squares of the two parts, together with twice the rectangle contained by the parts:* that is, A B^2 = A C^2 + C B^2 + twice A C·C B

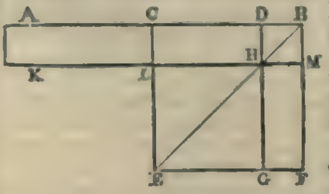


* 46 I. Upon A B describe the square A E:* draw B D; through C draw C G F parallel to A D or B E, and † 31 I. through G draw H K parallel to A B or D E;† then C F, A D being parallels, the angle B G C = * 29 I. A D B:* but A D B = A B D, because A B = † 5 I. A D,† A E being a square, ∴ C G B = C B G, * 6 I. ∴ C B = C G;* but C B = G K, and C G = B K, ∴ C K is *equilateral*. It is likewise *rectangular*, for C G, B K being parallels, the angles K B C, G C B are = two right an- † 29 I. gles:† but K B C is a right angle, ∴ G C B is a right angle, ∴ C G K, G K B, opposite to these, * 34 I. are right angles,* ∴ C K is *rectangular*; and since it is also *equilateral*, it is *a square*—the square of C B. For a similar reason H F is the square of H G, or of A C, ∴ H F, C K are A C^2, C B^2. And because the complement A G = † 43 I. the complement G E,† and A G is the rectangle A C·C B, for C G = C B, ∴ G E = A C C B, ∴ A G + G E = twice A C·C B; and H F + C K = A C^2 + C B^2, ∴ H F + C K + A G + G E = A C^2 + C B^2 + twice A C·C B; that is, A B^2 = A C^2 + C B^2 + *twice* A C·C B, ∴ *if a straight line, &c.* Q E D.

COR.—From this it is manifest, that parallelograms about the diagonal of a square are likewise squares.

PROPOSITION V.—THEOREM.

If a straight line (A B) *be divided into two equal parts* (in C), *and also into two unequal parts* (in D), *the rectangle contained by the unequal parts, together with the square of* (C D) *the line between the points of section, is equal to the square of half the line:* that is, A D·D B + C D^2 = C B^2.



* 46 I. Upon C B describe the square C F:* draw B E; through D draw D H G parallel to C E † 31 I. or B F,† and through A draw A K parallel to C L or B M. The complement C H = * 43 I. H F:* to each of these add D M, ∴ C M = D F: but C M = † 36 I. A L,† since A C = C B, ∴ A L = D F; to each of these add C H, ∴ A H = D F + C H: but A H is the * 4 II. Cor. rectangle A D·D B, for D H = D B;* and D F + C H is the gnomon C M G, ∴ C M G = A D·D B:

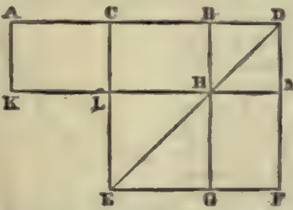
† 4 II. Cor. to each of these add LG or CD^2,† $\therefore CMG + LG = AD\cdot DB + CD^2$: but $CMG + LG = CF = CB^2$, $\therefore AD\cdot DB + CD^2 = CB^2$; $\therefore$ *if a straight line, &c.* Q. E. D.

Cor.—From this it is manifest, that the difference of the squares of two unequal lines, AC, CD, is equal to the rectangle contained by their sum and difference; that is, $AC^2 - CD^2 = AD\cdot DB$, where $AD = AC + CD$, and $DB = CB - CD = AC - CD$.

PROPOSITION VI.—Theorem.

If a straight line (AB) *be bisected* (in C), *and prolonged to any point* (D), *the rectangle contained by the whole line* (AD) *thus prolonged, and the prolonged part* (BD), *together with the square of* (CB) *half the line bisected, is equal to the square of* (CD), *the line made up of the half and the prolonged part:* that is, $AD\cdot DB + CB^2 = CD^2$.

• 46 I. Upon CD describe the square CF:* draw DE, and through B draw BHG parallel to CE or DF, and through H draw KLM parallel to † 31 I. AD, or EF;† also through A draw AK parallel to CL or DM. Then because $AC = CB$, • 36 I. $AL = CH$;* but $CH = HF$,† $\therefore AL$ † 43 I. $= HF$: to each of these add CM, $\therefore AM =$ gnomon CMG; but AM is the rectangle $AD\cdot DB$, • 4 II. Cor. for $DM = DB$,* $\therefore CMG = AD\cdot DB$: † 4 II. Cor. add LG or CB^2† to each of these, $\therefore CMG + LG = ADDB + CB^2$; but $CMG + LG = CF = CD,^2$ $\therefore AD\cdot DB + CB^2 = CD^2$; $\therefore$ *if a straight line, &c.* Q. E. D.



PROPOSITION VII.—Theorem.

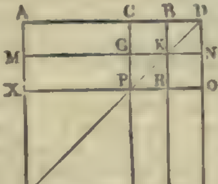
If a straight line (A B) *be divided into any two parts* (in C), *the squares of the whole line, and of one of the parts, are equal to twice the rectangle contained by the whole and that part, together with the square of the other part:* that is, $AB^2 + BC^2 =$ twice $AB\cdot BC + AC^2$. [See Diagram, Prop. IV.]

• 46 I. Upon AB describe the square AE,* and construct the figure as in the preceding propositions. Then † 43 I. because $AG = GE$,† if CK be added to each, $AK = CE$, $\therefore AK + CE =$ twice AK. But $AK + CE =$ gnomon $AKF + CK$, $\therefore AKF + CK =$ twice AK; but twice $AK =$ twice $AB\cdot BC$, for • 4 II. Cor. $BK = BC$,* $\therefore AKF + CK =$ twice $AB\ BC$. To each of these add HF or AC^2, $\therefore AKF + CK + HF =$ twice $AB\cdot BC + AC^2$: but $AKF + CK + HF = AB^2 + BC^2$, $\therefore AB^2 + BC^2 =$ twice $AB\cdot BC + AC^2$; $\therefore$ *if a straight line, &c.* Q. E. D.

PROPOSITION VIII.—Theorem.

If a straight line (A B) *be divided into any two parts* (in C), *four times the rectangle contained by the whole and one of the parts* (BC), *together with the square of the other part* (A C), *is equal to the square of the line* ($AD = AB + BC$), *made up of the whole and that part:* that is, four times $AB\cdot BC + AC^2 = AD^2$.

• 3 I. Prolong AB to D, so that $BD = CB$;* † 46 I. and upon AD describe the square AF;† and construct two figures such as in the preceding. Then because $CB = BD$, and $CB = GK$, and $BD = KN$,* • 34 I. $\therefore GK = KN$. For a like reason, $PR = RO$; and because $CB = BD$, and $GK = KN$, $\therefore CK = BN$, † 36 I. and $GR = RN$.† But $CK = BN$, being com- • 43 I. plements,* $\therefore BN = GR$, $\therefore$ the four rectangles, BN, CK, GR, RN, are *equal*, and are therefore quadruple of CK. Again, because $CB = BD$, and $BD =$ † 4 II. Cor. BK† $= CG$, • 34 I. and $CB = GK$* $=$ † 4 II. Cor. GP,† $\therefore CG = GP$, and because $CG = GP$, and $PR = RO$, $\therefore AG =$ • 36 I. MP,* and $PL = RF$. But $MP = PL$, being † 43 I. complements,† $\therefore AG = RF$ $\therefore$ the four, AG, MP, PL, RF, are equal, and are together quadruple AG. And it was proved that the four, CK, BN, GR, RN, are quadruple CK, $\therefore$ the eight rectangles, which compose the gnomon AOH, are quadruple of AK; and because $AK = AB\cdot BC$, for $BK = BC$, $\therefore$ four times $AB\cdot BC =$ four times AK: but it was proved that $AOH =$ four times AK, $\therefore$ four times $AB\cdot BC = AOH$. To each of • 4 II. Cor. these add XH or AC^2,* $\therefore$ four times $AB\cdot BC + AC^2 = AOH + XH$; but $AOH + XH = AD^2$, $\therefore$ *four times* $AB\cdot BC + AC^2 = AD^2$; $\therefore$ *if a straight line, &c.* Q. E. D.

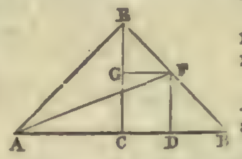


Note.—For another and shorter demonstration of this proposition, see the remarks at the end of Book II.

PROPOSITION IX.—Theorem.

If a straight line (A B) *be divided into two equal, and also into two unequal parts* (in C and D), *the squares of the two unequal parts are together double of the square of half the line* (A C), *and of the square of the line* (C D), *between the points of section:* that is, $AD^2 + DB^2 =$ twice $AC^2 +$ twice CD^2.

• 11 I. From C draw CE at right angles to AB;* † 3 I. and make it $= AC$ or CB.† Draw EA, EB; and through D draw DF parallel to CE, and through F • 31 I. draw FG parallel to BA:* draw also AF. Then because $AC = CE$, the angle $EAC = AEC$;† † 5 I. and because ACE is a right angle, the two others, AEC, EAC, must together make one right • 32 I. angle;* and as they are equal, each must be half a right angle. For a like reason, each of the angles, CEB, EBC, is half a right angle, $\therefore AEB$ is a right angle. And because GEF is half a right angle, and EGF a right angle, for it is $=$ † 29 I. ECB,† $\therefore$ the remaining angle EFG is half a right angle, $\therefore GEF = EFG$, • 6 I. and $\therefore EG = GF$.* Again, because B is half a right angle, and FDB a right angle, † 29 I. for it is $= ECB$,† $\therefore$ the remaining angle, BFD, is half a right angle, $\therefore$ • 6 I. $B = BFD$, and $\therefore DF = DB$.* And because $AC = CE$, $\therefore AC^2 = CE^2$, $\therefore AC^2 + CE^2 =$ twice AC^2; but $AE^2 = AC^2 + CE^2$, because ACE is a right † 47 I. angle,† $\therefore AE^2 =$ twice AC^2. Again, because $EG = GF$, $\therefore EG^2 = GF^2$, $\therefore EG^2 + GF^2 =$ twice • 47 I. GF^2: but $EF^2 = EG^2 + GF^2$,* $\therefore EF^2 =$ † 34 I. twice GF^2; and $GF = CD$,† $\therefore EF^2 =$ twice CD^2: but $AE^2 =$ twice AC^2, $\therefore AE^2 + EF^2 =$ twice • 47 I. $AC^2 +$ twice CD^2: but $AF^2 = AE^2 + EF^2$,* because AEF is a right angle, $\therefore AF^2 =$ twice $AC^2 +$ twice CD^2: but $AD^2 + DF^2 = AF^2$, because ADF is † 47 I. a right angle,† $\therefore AD^2 + DF^2 =$ twice $AC^2 +$ twice CD^2; and $DF = DB$, $\therefore AD^2 + DB^2 =$ *twice* $AC^2 +$ *twice* CD^2; $\therefore$ *if a straight line, &c.* Q. E. D.

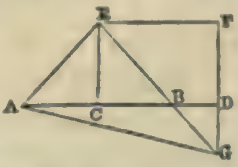


PROPOSITION X.—Theorem.

If a straight line (A B) *be bisected* (in C), *and prolonged to any point* (D), *the square of the whole line thus prolonged, and the square of the part of it prolonged* (D B), *are together double the square of* (A C) *half the line bisected, and of the square of* (C D) *the line made up of the half and the prolonged part:* that is, $AD^2 + DB^2 =$ twice $AC^2 +$ twice CD^2.

• 11 I. From C draw CE at right angles to AB,* † 3 I. and make it $= AC$ or CB;† and draw AE, EB. Through E draw EF parallel to AB, and through • 31 I. D draw DF parallel to CE.* Then because EC, FD are parallels, the angles $CEF + EFD =$ two † 29 I. right angles,† $\therefore BEF + EFD$ are *less* than two right angles, $\therefore EB$, FD, if prolonged, will meet • Ax. 12. towards B, D.* Let them meet in G; and draw AG. Then because $AC = CE$, the angle CEA † 5 I. $= EAC$,† and ACE is a right angle, $\therefore CEA$, • 32 I. EAC are each half a right angle.* For a like reason, CEB, EBC are each half a right angle, $\therefore$ AEB is a right angle. And because EBC is half a right angle, DBG also is half a right angle, for † 15 I. they are vertically opposite :† but BDG is a right angle, being $= DCE$, $\therefore$ the remaining angle DGB is half a right angle, and is $\therefore = DBG$, $\therefore BD =$ * 6 I. DG.*

Again, because EGF is half a right angle, and that F is a right angle, being $=$ the opposite angle ECD,† $\therefore$ † 34 I. the remaining angle FEG is half a right * 6 I. angle, $\therefore FEG = EGF$, $\therefore GF = FE$.*



And because $EC = CA$, $\therefore EC^2 = CA^2$, $\therefore EC^2 + CA^2 =$ twice CA^2: but $EA^2 = EC^2 +$ † 47 I. CA^2,† $\therefore EA^2 =$ twice AC^2. Again, because $GF = FE$, $\therefore GF^2 = FE^2$, $\therefore GF^2 + FE^2 =$ twice FE^2; but * 47 I. $EG^2 = GF^2 + FE^2$,* † 34 I. $\therefore EG^2 =$ twice FE^2, and $FE = CD$,† $\therefore EG^2 =$ twice CD^2. But it was demonstrated that $EA^2 =$ twice CA^2, $\therefore AE^2 + EG^2 =$ twice $AC^2 +$ twice CD^2; * 47 I. but $AG^2 = AE^2 + EG^2$,* $\therefore AG^2 =$ twice † 47 I. $AC^2 +$ twice CD^2; but $AD^2 + DG^2 = AG^2$,† $\therefore AD^2 + DG^2 =$ twice $AC^2 +$ twice CD^2; but $DG = DB$, $\therefore AD^2 + DB^2 =$ *twice* $AC^2 +$ *twice* CD^2; $\therefore$ *if a straight line, &c.*

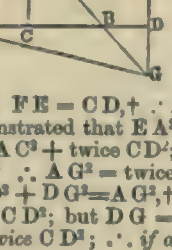
NOTE.—For other demonstrations of the last two propositions, see the remarks at the end of this book.

PROPOSITION XI.—PROBLEM.

To divide a given straight line (AB) *into two parts, so that the rectangle contained by the whole, and one of the parts, shall be equal to the square of the other part.*

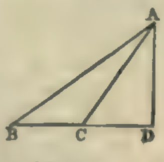
* 11 & 3 I. From A draw AC perpendicular and equal † 10 I. to AB;* bisect AC in E,† and draw BE. * 3 I. † 3 I. Prolong CA to F, making $EF = EB$,* and from AB cut off $AH = AF$:† AB *shall be divided in* H, *so that* $AB \cdot BH = AH^2$.

* 46 I. Complete the square BC, as also the square FH;* and prolong GH to K. Then because AC is bisected in E and prolonged to F, the rectangle $CF \cdot FA +$ † 6 II. $AE^2 = EF^2$;† but $EF =$ * Const. EB,* $\therefore CF \cdot FA + AE^2 = EB^2$; but $BA^2 + AE^2 = EB^2$, because EAB is a right angle, $\therefore CF \cdot FA + AE^2 = BA^2 + AE^2$: take away AE^2, which is common to both, $\therefore CF \cdot FA = BA^2$. But $FK = CF \cdot FA$, for $AF = FG$; and $AD = BA^2$, $\therefore FK = AD$. Take away AK, common to both, $\therefore FH = HD$: but $HD = AB \cdot BH$, for $AB = BD$, and FH is AH^2, $\therefore AB \cdot BH = AH^2$; $\therefore AB$ *is divided in* H, *so that* $AB \cdot BH = AH^2$. Which was to be done.



PROPOSITION XII.—THEOREM.

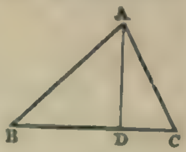
In an obtuse-angled triangle (ABC), *if a perpendicular* (AD) *be drawn from either of the acute angles to the opposite side prolonged, the square of the side* (AB) *subtending the obtuse angle is greater than the squares of the sides* (BC, CA) *containing the obtuse angle, by twice the rectangle contained by the side upon which, when prolonged, the perpendicular falls, and the line, without the triangle, between the perpendicular and the obtuse angle;* that is, $AB^2 = BC^2 + CA^2 +$ twice $BC \cdot CD$.



Because BD is divided into two parts in C, $BD^2 =$ * 4 II. $BC^2 + CD^2 +$ twice $BC \cdot CD$.* To each of these add DA^2, $\therefore BD^2 + DA^2 = BC^2 + CD^2 + DA^2 +$ twice $BC \cdot CD$; but $AB^2 = BD^2 + DA^2$, and $CA^2 =$ † 47 I. $CD^2 + DA^2$,† $\therefore AB^2 = BC^2 + CA^2 +$ *twice* $BC \cdot CD$; that is, *the square of* AB *is greater than the squares of* BC, CA *by twice* BC·CD; $\therefore$ *in an obtuse-angled triangle, &c.* Q. E. D.

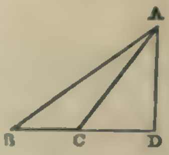
PROPOSITION XIII.—THEOREM.

In every triangle (ABC), *the square of a side* (AC) *subtending an acute angle, is less than the squares of the sides* (CB, BA) *containing that angle, by twice the rectangle* (CB·BD) *contained by either of these sides, and the straight line intercepted between the perpendicular* (AD) *and the acute angle* (B): that is, $AC^2 = CB^2 + BA^2 -$ twice $CB \cdot BD$.



First, let AD fall *within* the triangle; then, because CB is divided into two parts in D, $CB^2 + BD^2 =$ twice * 7 II. $CB \cdot BD + DC^2$.* To each of these add AD^2, $\therefore CB^2 + BD^2 + AD^2 =$ twice $CB \cdot BD + DC^2 + AD^2$: but $BA^2 = BD^2 + AD^2$, and $AC^2 = DC^2$ † 47 I. $+ AD^2$,† $\therefore CB^2 + BA^2 = AC^2 +$ twice $CB \cdot BD$. From each of these take twice $CB \cdot BD$, $\therefore AC^2 = CB^2 + BA^2 -$ twice $CB \cdot BD$.

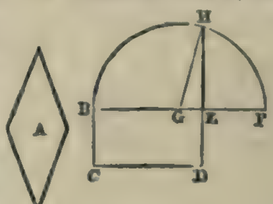
Secondly, let AD fall without the triangle; then, because D is a right * 16 I. angle, ACB is greater than † 12 II. a right angle,* $\therefore AB^2 = AC^2 + CB^2 +$ twice $BC \cdot CD$.† To each of these add BC^2, $\therefore AB^2 + BC^2 = AC^2 +$ twice $BC^2 +$ twice $BC \cdot CD$. But because BD is divided into two parts in C, $DB \cdot BC = BC \cdot CD + BC^2$,* * 3 II. and the doubles of these being equal, $\therefore AB^2 + BC^2 = AC^2 +$ twice $DB \cdot BC$. From each of these take twice $DB \cdot BC$, $\therefore AC^2 = AB^2 + BC^2 -$ *twice* $DB \cdot BC$; $\therefore$ *in every triangle, &c.* Q. E. D.



PROPOSITION XIV.—PROBLEM.

To describe a square that shall be equal to a given rectilineal figure (A).

* 45 I. Describe the rectangle $BD = A$.* Then, if the sides of it, BE, ED, are *equal*, it is a *square*, and what was required is now done; but if they are not equal, prolong one of them, BE to F, and make $EF = ED$. † 10 I. Bisect BF in G,† and with centre G and radius GB, or GF, describe the semicircle BHF, and prolong DE to H. The square described upon EH shall be equal to the given figure A. Draw GH. Then because BF is divided into two equal parts in G, and into two unequal parts in E, $BE \cdot EF + EG^2$ * 5 II. $= GF^2$;* but $GF = GH$, $\therefore BE \cdot EF + EG^2 = GH^2$; but HE^2 † 47 I. $+ EG^2 = GH^2$† $\therefore BE \cdot EF + EG_2 = HE^2 + EG^2$. Take away EG^2, which is common to both, $\therefore BEEF = EH^2$; but $BE \cdot EF = BD$, because $EF = ED$, $\therefore BD = EH^2$; but $BD = A$, $\therefore EH^2 = A$; $\therefore$ *a square described upon* EH *is* $=$ *to the given rectilineal figure.* Which was to be done.



REMARKS ON BOOK II.

All the propositions in this book, except the last three, concern the divisions of straight lines into parts, and the equality of rectangles having certain of these parts for their sides. The first proposition is little more than an axiom, as its object is to show that any rectangle BH is equal to the sum of the partial rectangles BK, DL, &c., into which it is divided: but, as already observed (p. 545), Euclid does not regard as an axiom any proposition that admits of demonstration.

Proposition II. might, without impropriety, have been appended as a corollary to Proposition I., as already stated in the text; since, if the line A, in Proposition I., be considered to be *equal* to the line BC, this proposition will virtually include the next following.

Proposition V. authorises us to affirm, as an inference, that the rectangle contained by the two *halves* of a straight line, is *greater* than the rectangle contained by any two *unequal* parts of it, since it shows that to this latter rectangle something must be *added*, to make up the square of half the line.

In attempting the propositions in this book, without reference to the text, you will find it useful to keep in remembrance, that in all the constructions, up to Proposition VIII. inclusive, the *greatest* square mentioned in the enunciation is always to be described *first;* and that in each proposition after the fourth, the lines employed in that fourth are always to be introduced. After this partial construction, the completion of the diagram, in each case, will readily present itself.

It may, too, be deserving of notice, that the demonstrations in Propositions V. and VI. may, with advantage, be conducted rather differently from the method of Euclid. Thus, in Proposition V., having proved, as in the text, that the *projecting* rectangle A L is equal to the *marginal* rectangle D F, we may proceed as follows:—Take each of these rectangles from the entire figure; then the remainder C F will be equal to the remainder $AH + LG$; that is, to the rectangle $AD \cdot DB$ (for $DB = DH$), and the square of C D, since $LH = CD$: and this completes the demonstration.

In like manner, in Proposition VI., having proved, as in the text, that the projecting rectangle A L is equal to the marginal rectangle H F, take each rectangle from the entire figure; then the remainder C F is equal to the remainder $AM + LG$; that is, $CD^2 = AD \cdot DB + CB^2$, which completes the proof.

Proposition VIII. is usually found, by a beginner, to be a little perplexing; and Propositions IX. and X., though very elegantly demonstrated by Euclid, are felt to be somewhat lengthy. We shall, therefore, here show how these three propositions may be otherwise demonstrated.

Prop. VIII.—Having made

$BD = CB$, the reasoning may be as follows:

By Prop. IV.,

$$AD^2 = AB^2 + BD^2 + 2AB \cdot BD;$$

that is, $AD^2 = AB^2 + CB^2 + 2AB \cdot CB$.

Also, Prop. VII.,

$$AB^2 + CB^2 = 2AB \cdot CB + AC^2;$$

$$\therefore AD^2 = 2ABCB + AC^2 + 2AB \cdot CB;$$

that is, $AD^2 = 4AB \cdot CB + AC^2$.

Which was to be demonstrated.

Prop. IX.—By Prop. IV.,

$$AD^2 = AC^2 + CD^2 + 2AC \cdot CD;$$

$$\therefore AD^2 + DB^2 = AC^2 + CD^2 + 2AC \cdot CD + DB^2;$$

that is, $AD^2 + DB^2 = BC^2 + CD^2 + 2BC \cdot CD + DB^2$.

But, Prop. VII.,

$$BC^2 + CD^2 = 2BC \cdot CD + DB^2;$$

$$AD^2 + DB^2 = BC^2 + CD^2 + BC^2 + CD^2;$$

that is, $AD^2 + DB^2 = 2BC^2 + 2CD^2 = 2AC^2 + 2CD^2$.

Which was to be demonstrated.

Proposition X.—The demonstration of this may be made to depend on the preceding proposition, as follows:—

Prolong C A to H,
making $AH = BD$;
then $HC = CD$, and
$HB = DA$.

And since H D is divided equally in C, and unequally in B, ∴ by Proposition IX.,

$$HB^2 + BD^2 = 2HC^2 + 2CB^2;$$

that is, $AD^2 + BD^2 = 2CD^2 + 2AC^2$.

Which was to be demonstrated.

Although the foregoing demonstrations occupy less space than those of Euclid, we would by no means recommend them to your preference. Those of Euclid are among the finest of his specimens of clear and consecutive reasoning, and you will observe that they are altogether independent of second-book propositions. They are thus simpler, though longer than those given above. There is, too, a beauty in the reiterated appeals to the forty-seventh of the first book, that more than compensates for the length of the argument. The demonstrations above, however, may be useful as exercises on the application of second-book propositions.

There are but two *problems* in this second book; and each of these, as given in the editions of Simson and others, exemplifies the remark made in the commentary on the preceding book, in reference to Euclid's apparent indifference as to the neatness and finish of his *constructions*.

In the editions alluded to, the whole of the diagram in Proposition XI., with the exception of the prolongation of G H to K, is made to appear as essential to the construction of the problem; that is, to the determination of the point H. You have seen, however, that to the discovery of this point, the actual construction of the two squares A D, A G is not necessary; they are wanted only as a part of the machinery in the *demonstration* that the point H, previously found, divides the proposed line as required.

In Proposition XIV., too, the drawing of G H is made to enter into the construction of the problem, instead of being postponed for use in the demonstration, as is done in this edition.

You will not fail to notice the connection between Propositions XII. and XIII., and Proposition XLVII. of the first book. The three together furnish certain corresponding relations between one side of a triangle and the other two, whether the angle opposite that one be right, obtuse, or acute.

It may not, perhaps, be out of place here to notice, that the word *equal*, employed so frequently in this and in the preceding book, in reference to rectangles, triangles, &c., is used by Euclid in two somewhat different senses. In the earlier propositions of the first book—the fourth, eighth, and twenty-sixth, for instance—the test of equality is perfect *coincidence*, as the result of superposition; but in Propositions XXXV., XXXVI., &c., as also in most of the propositions of this second book, the condition of coincidence is excluded, and the figures are declared to be equal if they are proved to inclose the same extent of surface. Legendre, a distinguished French geometer, has proposed to discriminate between these two kinds of equality: figures which, though equal in surface, do not admit of coincidence, he prefers to call—not *equal* figures, but *equivalent* figures. We think the distinction an appropriate one; and while upon these minor matters of mere phraseology, we would venture further to suggest, that instead of speaking of lines as *greater* and *less*, the more explicit and restrictive terms *longer* and *shorter* would be preferable; and that *part* of a line, or *portion* of a line, are, either of them, designations that might appropriately supply the place of *segment* of a line.

EXERCISES ON BOOKS I. AND II.

1. In any triangle, the squares of the two sides are together equal to the square of half the base, and of the straight line from the vertex to the middle of the base.

2. The squares of the four sides of a parallelogram, are together equal to the squares of the two diagonals.

3. If from any point lines be drawn to the four vertices of a rectangle, the squares of those drawn to opposite vertices will, together, be equal to the squares of the other two.

4. In every parallelogram, the squares of the four sides are, together, equal to the squares of the two diagonals.

5. If from any point whatever, lines be drawn to the four vertices of a parallelogram, twice the sum of their squares will be equal to the squares of the diagonals, together with eight times the square of the line drawn from the given point to the intersection of the diagonals.

6. From the last exercise prove that the following curious property exists; namely:—If from the point of intersection of the diagonals of a parallelogram, a circle be described with any radius, the squares of the lines drawn from any point in the circumference to the four corners of the parallelogram, will always amount to the same sum.

7. In any quadrilateral, the sum of the squares of the four sides is equal to the sum of the squares of the diagonals, together with four times the square of the line joining the middle points of the diagonals.

8. Prove the *converse* of Example 2; namely:—If the squares of the sides of a quadrilateral are together equal to the squares of the diagonals, the figure must be a parallelogram.

9. Let a straight line be divided according to Proposition XI., Book II., and from the greater segment cut off a part equal to the less: prove that this greater segment will thus be divided also according to the same proposition.

In Book III., the properties of circles are investigated.

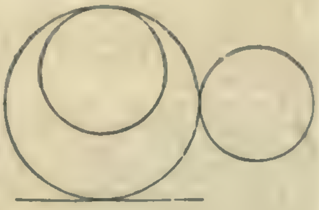
CHAPTER III.

ELEMENTS OF EUCLID.—BOOK III.

DEFINITIONS.

I.

A straight line is said to *touch* a circle when it *meets* the circle, and being prolonged, does not *cut* it.



II.

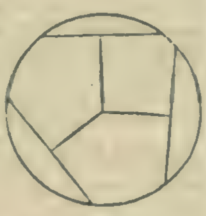
Circles are said to *touch* one another, which *meet*, but do not cut one another.

III.

Straight lines are said to be equally distant from the centre of a circle, when the perpendiculars drawn to them from the centre are equal.

IV.

And the straight line on which the greater perpendicular falls is said to be farther from the centre.



V.

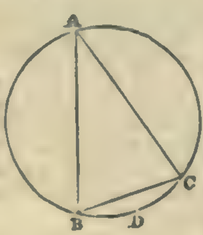
An *arc* of a circle is any part of the circumference.

VI.

A *segment* of a circle is the figure contained by an arc of a circle and the straight line joining its extremities, which straight line is called the *chord of the arc*, or the *base of the segment.*

VII.

An *angle in a segment* is the angle contained by two straight lines drawn from any point in the arc of the segment, to the extremities of the chord of the arc, or base of the segment. Thus A is an angle in the segment B C D.

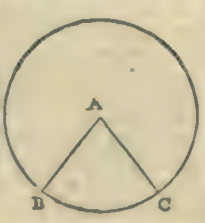


VIII.

And an angle is said to insist or *stand* upon the arc intercepted between the straight lines that contain the angle. Thus A stands upon the arc B D C.

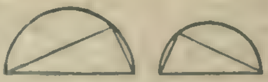
IX.

A *sector* of a circle is the figure contained by two straight lines drawn from the centre, and the arc between them. A B C is a *sector*, so is the remaining part of the circle.



X.

Similar segments of circles are those in which the angles are equal, or which contain equal angles.

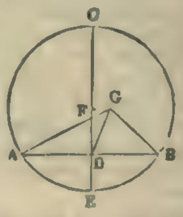


PROPOSITION I.—PROBLEM.

To find the centre of a given circle (A B C).

Draw any straight line A B, terminating in the •10 I. circumference, and bisect it in D:* draw D C at †11 I. right angles to A B,† prolong it to E, and bisect •10 I. C E in F:* the point F shall be the centre of the circle.

For if it be not, let G, a point *out of the line* C E, be the centre: and draw G A, G D, G B. Then because †Const. D A = D B,† and D G common to the two triangles A D G, B D G, the two sides A D, D G are = the two B D, D G, each to each, and the base G A = the base G B, •Def. 12 I. because G is the centre,* ∴ the angle G D A = G D B:† †8 I. but when a straight line standing upon another makes the adjacent angles *equal*, each angle is •Def. 8 I. a right angle:* ∴ G D B is a right angle: but †Const. F D B is likewise a right angle,† ∴ G D B = F D B, the less to the greater, which is impossible, ∴ the centre cann to be at any point *out of the line* C E: it must ∴ be at a point *in* C E, and ∴ at the *middle* of C E, ∴ F *is the centre,* which was to be found.

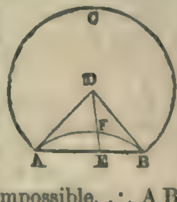


Cor.—From this it is manifest that if *a chord* of a circle (as A B) be bisected by a perpendicular, that perpendicular will pass through the centre.

PROPOSITION II.—THEOREM.

If two points (A B) *be taken in the circumference of a circle* (A B C), *the straight line or chord* (A B) *which joins them shall fall within the circle.*

For if not, let it fall without, as A E B. Find D, •1 III. the centre of the circle,* and draw D A, D B. In the arc A B take any point F, draw D F, and produce †Def. 12 I. it to E: then because D A = D B,† the angle •5 I. D A B = D B A:* and because A E, a side of the triangle D A E, is prolonged to B, the exterior angle †16 I. D E B is greater than D A E:† but D A E = D B E, as just proved: ∴ D E B is greater than D B E; but to the greater angle the greater side is •19 I. opposite,* ∴ D B is greater †Def. 12 I. than D E: but D B = D F,† ∴ D F is greater than D E, which is impossible, ∴ A B does *not* fall without the circle. And since D B, the radius of the circle, is greater than D E, and that E is *any point* on the chord, between A and B, ∴ no point between A and B can be *on* the circumference, ∴ *the chord* A B *is wholly within the circle,* ∴ *if any two points,* &c. Q. E. D.

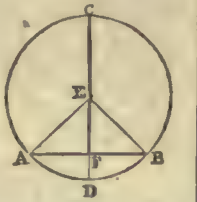


PROPOSITION III.—THEOREM.

If a straight line (C D) *through the centre of a circle* (A B C) *bisect a chord* (A B), *which does not pass through the centre, it shall cut it at right angles; and if it cut the chord at right angles, it shall bisect it.*

•1 III. Take E, the centre of the circle,* and draw

† Hyp. E A, E B. Then because A F = F B,† and F E common to the two triangles A F E, B F E, and also * 8 I. E A = E B, ∴ the angle A F E = B F E,* † Def. 8 I. ∴ *each is a right angle*,† ∴ C D, *drawn through the centre, bisecting the chord* A B, *that does not pass through the centre, cuts it at right angles.*

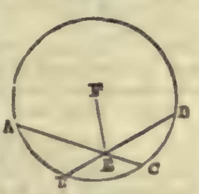


Now let C D cut A B at right angles: C D shall bisect A B. For, the same construction being made, because E A = E B, the angle E A F * 5 I. = E B F;* and the right angle A F E = B F E, ∴ in the two triangles, E A F, E B F, there are two angles in the one = two in the other, each to each; and E F, opposite to equal angles, one in each, is com- † 26 I. mon to both, ∴ A F = F B;† that is, *the chord* A B *is bisected by the diameter* C D, *which is perpendicular to it*; ∴ *if a straight line, &c.* Q. E. D.

PROPOSITION IV.—THEOREM.

If in a circle (A B C D) *two chords* (A C, B D) *cut one another, and do not pass through the centre, they do not bisect each other.*

For let them cut in E; and suppose A E = E C, *and* B E = E D. If *one* of the chords pass through the centre, it is plain it cannot be bisected by the other which does not pass through the centre, because the middle of the former is the centre.

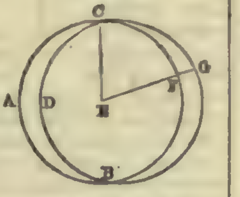


But if neither pass through the centre, take F, the centre;* * 1 III. and draw F E. Then, because F E, through the centre, bisects A C *not* through the centre, † 3 III. it cuts it at right angles,† ∴ F E A is a right angle. Again, * Hyp. because F E bisects B D,* a chord not through the centre, it cuts it also at right † 3 III. angles,† ∴ F E B is a right angle; but it was proved that F E A is a right angle, ∴ F E A = F E B, the less to the greater, which is impossible, ∴ A C, B D *do not bisect one another*; ∴ *if in a circle, &c.* Q. E. D.

PROPOSITION V.—THEOREM.

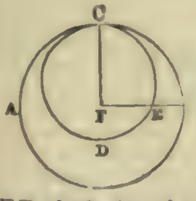
If two circles (A B C, C D G) *cut one another* (as in the point C), *they shall not have the same centre.*

For, if it be supposed possible, let E be the common centre. Draw E C, and draw E F G, meeting the circumferences in F and G. Then, because E is the centre of the circle A B C, * Def. 13 I. E C = E F.* Again, because E is the centre of the circle C D G, E C = E G. But it was shown that E C = E F, ∴ E F = E G, the less to the greater, which is impossible, ∴ *the two circles have not a common centre*; ∴ *if two circles, &c.* Q. E. D.



PROPOSITION VI.—THEOREM.

If two circles (A B C, C D E) *touch one another, they shall not have the same centre.*

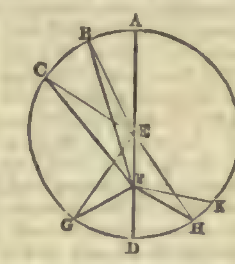


Let them touch at C, then if they have a common centre, let it be F. Draw F C, and F E B, meeting the circumferences in E and B. Then, because F is the centre of A B C, * Def. 13 I. F C = F B;* also, because F is the centre of C D E, F C = F E:* but it was shown that F C = F B, ∴ F E = F B, the less to the greater, which is impossible, ∴ *the two circles have not a common centre*; ∴ *if two circles, &c.* Q. E. D.

PROPOSITION VII.—THEOREM.

If any point (F), *not the centre, be taken in the diameter* (A D) *of a circle* (A B C D), *then of all lines* (F A, F B, F C, &c.) *which can be drawn from it to the circumference, the greatest is that* (F A) *which passes through the centre* (E), *and* (F D), *the other part of the diameter, is the least. And of the others, that which is nearer to the line through the centre is always greater than one more remote. And from the same point* (F) *there can be drawn two, and only two, straight lines that are equal, one upon each side of the diameter.*

Draw E B; then because any two sides of a triangle are together greater than the third side, F E, E B are * 20 I. greater than F B;* but E A = E B, ∴ F E + E A; that is, F A is greater than F B, and F B is any other line, ∴ *the line through the centre is the greatest.* Again, draw E C: then, because E B = E C, and F E common to the triangles B E F, C E F, ∴ the two sides F E, E B are = the two F E, E C, each to each; but the angle B E F is greater than C E F, ∴ F B is greater than † 24 I. F C,† ∴ *the line nearer to that through the centre is greater than one more remote.*



Again, draw E G: then because E F + F G are greater * 20 I. than E G,* and that E G = E D, ∴ E F + F G are greater than E D. Take away the common part E F, ∴ F G is greater than F D, and F G is any other line, ∴ F D *is the least of all the lines from* F *to the circumference.*

Also *two*, but only two, equal straight lines can be drawn from F to the circumference, one upon each side of the diameter A D. For F G being any straight line † 23 I. from F, at E make the angle F E H = F E G,† and draw F H. Then, because E G = E H, and E F common to the triangles G E F, H E F, the two sides E G, E F are = the two E H, E F, each to each, and the * Const. angle G E F = H E F,* ∴ F G = F H.† But, † 4 I. besides F H, no other line equal to F G can be drawn from F to the circumference. For, if there can, let it be F K: then, because F K = F G and F G = F H, ∴ F K = F H; but one of these must be nearer to the line through the centre than the other, so that a line nearer to that through the centre is *equal* to one more remote, which has been proved to be impossible, ∴ *besides* F H *no other line* = F G *can be drawn*; ∴ *if any point, &c.* Q. E. D.

PROPOSITION VIII.—THEOREM.

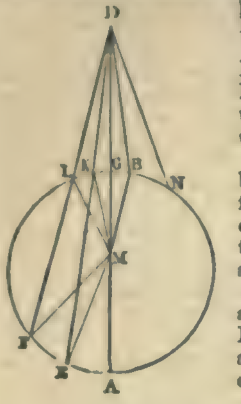
If any point (D) *be taken without a circle* (A B F), *and straight lines* (D A, D E, D F, &c.) *be drawn from it to the circumference, of which one* (D A) *passes through the centre* (M), *of those which fall upon the concave part of the circumference, the greatest is that* (D A) *which passes through the centre; and of the rest, that which is nearer to the one through the centre is always greater than one more remote. But of those which fall upon the convex part of the circumference, the least is that* (D G) *which, when prolonged, passes through the centre; and of the rest, that which is nearer to the least is always less than one more remote. Also two, and only two, equal straight lines can be drawn from the same point* (D) *to the circumference, one upon each side of the line through the centre.*

* 1 III. Take M the centre of the circle,* and draw M E. Then because A M = E M, add M D to each, ∴ A D = E M + M D; but E M + M D are greater than † 20 I. E D,† ∴ A D is greater than E D, and E D is any other line, ∴ A D, *the line through the centre, is the longest.*

Again, draw M F. Then, because E M = F M, the two E M, M D are = the two F M, M D, each to each; but the angle E M D is greater than F M D, ∴ E D is * 24 I. greater than F D;* that is, *a line* D E, *nearer to that through the centre, is greater than* D F, *one more remote.*

Now draw M K. Then because M K + K D are greater

† 20 I. than M D,† and that M K = M G, ∴ the remainder K D is greater than the remainder G D; that is, G D is less than K D, any other line from D to the convex part of the circumference, ∴ D G *is the least line.* Draw M L: then because M L D is a triangle, and that M K, D K are drawn from the extremities of a side to a point K, within the triangle, ∴ M K + D K are less than M L * 21 I. + D L:* but M K = M L, ∴ the remainder D K is less than the remainder D L; that is, *a line nearer to the least is less than one more remote.*



Also, there can be drawn *two*, but only two, equal straight lines from D to the circumference, one on each side of D A, the line through the centre. For draw any straight line D K, and at M make † 23 I. the angle D M B = D M K;† and draw D B. Then because M K = M B, the two M K, M D are = the two M B, M D, each to each; and the angle K M D = * Const. B M D,* ∴ D K = † 4 I. D B,† *so that two equal lines can be drawn*, and the demonstration is the same whether D K be drawn to the convex or to the concave part of the circumference. But, besides D B, no straight line drawn from D to the circumference, can be = D K. For, if there can, let it be D N. Then because D K = D N, and D K = D B, ∴ D N = D B; but one of these must be nearer to that through the centre than the other, ∴ a line nearer to that through the centre is = one more remote, which has been proved to be impossible; ∴ *if any point, &c.* Q. E. D.

PROPOSITION IX.—THEOREM.

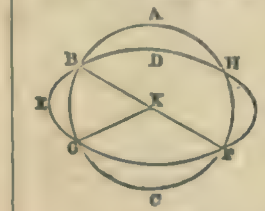
If any point be taken, from which there may be drawn more than two equal straight lines to the circumference of a circle, that point is the centre of the circle.

For if the point were *not* the centre, only *two* equal straight lines could be drawn from it to the circumfer- * 7 & 8 III. ence;* ∴ *if any point, &c.*

PROPOSITION X.—THEOREM.

One circumference of a circle cannot cut another in more points than two.

For suppose the circumference F A B C to cut the circumference D E G F in more than two points, viz., in B, G, F. Take the centre K, of the circle F A B C,* * 1 III. and draw K B, K G, K F. Then because K is the centre of the circle F A B, these lines are all *equal;* so that from a point K, to the other circumference D E G F, *more than two* equal straight lines are drawn, viz., the *three* K B, K G, K F, ∴ K is the centre † 9 III. of the circle D E G F,† ∴ the same point is the centre of two circles that cut one * 5 III. another, which is impossible;* ∴ *one circumference, &c.* Q. E. D.

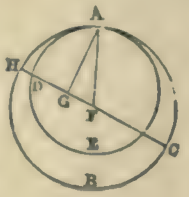


PROPOSITION XI.—THEOREM.

If one circle (A D E) *touch another* (A B C) *internally in a point* (A), *the straight line which joins their centres being prolonged, shall pass through the point of contact* (A).

Let F be the centre of A B C, and G, the centre of A D E; F G, when prolonged, shall pass through A.

For if not, let F G, prolonged, cut the circumferences in D and H. Draw A F, A G: then, because two sides of a triangle are together greater than the third side, * 20 I. F G + G A are greater than F A:* but F A = F H, ∴ F G + G A are greater than F H. Take away the common part F G, ∴ G A is greater than G H: but G A = G D,† ∴ † Def. 12 I. G D is greater than G H, which is impossible, even could D, H coincide, ∴ F G *being prolonged, cannot but pass through the point* A; ∴ *if one circle, &c.* Q. E. D.

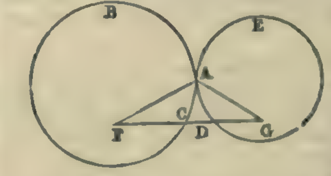


PROPOSITION XII.—THEOREM.

If two circles (A B C, A D E) *touch each other externally in a point* (A), *the straight line which joins their centres shall pass through the point of contact* (A).

Let F be the centre of A B C, and G that of A D E: F G shall pass through A.

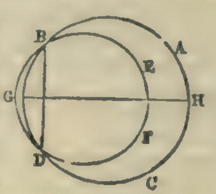
For if not, let F G cut the circumferences in C, D, and draw F A, G A. Then because F is the centre of A B C, F A = F C: and because G is the centre of A D E, G A = G D, ∴ F A + G A = F C + G D ∴ the whole F G *is not less than* F A + G A, even though C, D be supposed to coincide; but a side F G, of the triangle A F G, is less than the other two * 20 I. sides,* which is impossible, ∴ F G *cannot pass otherwise than through the point of contact* A; ∴ *if two circles, &c.* Q. E. D.

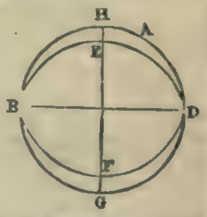


PROPOSITION XIII.—THEOREM.

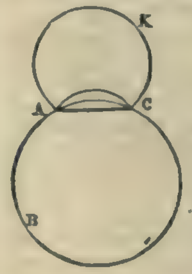
One circle cannot touch another in more than one point, whether it touch it on the inside or on the outside.

For, if it be supposed possible, let the circle E B F touch the circle A B C in *two* points; and first on the *inside*, in the points B, D. Join B, D, and draw G H, * 10 & 11 I. bisecting B D at right angles.* Then because the points B, D are in the circumference of each of the circles, B D falls within each of them, † 2 III. ∴ their centres are in G H, * 1 III. Cor. which bisects B D at right angles,* ∴ G H passes through the point of contact B, and through the † 11 III. point of contact D:† but the points B, D are *without* the straight line G H, which is absurd; ∴ *one circle cannot touch another on the inside in more than one point.*





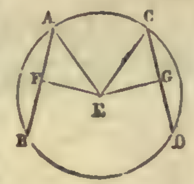
Nor can two circles touch on the *outside* in more than one point. For suppose the circles A C K, A B C to touch in *two* points, A, C. Join A, C: then because A, C are in the circumference A C K, A C, which joins them, falls within the circle A C K.* * 2 III. But the circle A C K is † Hyp. *without* the circle A B C,† ∴ A C is without this last circle; but, because A, C are in the circumference A B C, A C must be * 2 III. within the same circle,* which is absurd, ∴ *one circle cannot touch another on the outside in more than one point;* and it has been shown that they cannot touch on the *inside* in more than one point, ∴ *one circle, &c.* Q. E. D.



PROPOSITION XIV.—THEOREM.

Equal chords (A B, C D) *in a circle are equally distant* *from the centre; and chords equally distant from the centre are equal.*

• 1 III. Take E the centre of the circle A B D C,* and from E draw E F, E G perpen- † 12 I. diculars to A B, C D;† *then if* A B = C D, E F *must be* = E G. For draw E A, E C. Then because E F, from the centre, cuts A B, a chord not through the centre, at right angles, it bisects it,* ∴ • 3 III. A F = F B, ∴ A B is double of A F. For a like reason C D is double of C G. But A B † Hyp. = C D,† ∴ A F = C G. And because E A = E C, ∴ $EA^2 = EC^2$: but $AF^2 + FE^2 = EA^2$, • 47 I. because A F E is a right angle;* and, for a like reason, $CG^2 + GE^2 = EC^2$ ∴ $AF^2 + FE^2 = CG^2 + GE^2$: but $AF^2 = CG^2$, because A F = C G, ∴ $FE^2 = GE^2$, ∴ F E = G E; but chords of a circle are said to be equally distant from the centre when the perpendiculars drawn to them from the centre are equal,† † Def. 3 III. ∴ A B, C D *are equally distant from the centre.*



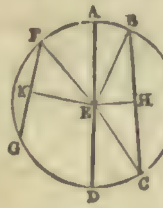
Next, let the chords A B, C D be equally distant from the centre: that is, let the perpendiculars E F, E G be equal: *then shall* A B = C D. For, the same construction being made, it may, as before, be demonstrated that A B is double of A F, and C D double of C G, and that $AF^2 + FE^2 = CG^2 + GE^2$: but $FE^2 = GE^2$, because F E • Hyp. = G E,* ∴ $AF^2 = CG^2$, ∴ A F = C G: but A B, C D are the doubles of A F, C G, as already proved, ∴ A B = C D; ∴ *equal chords, &c.* Q. E. D.

PROPOSITION XV.—THEOREM.

The diameter is the greatest chord in a circle: and of all others, that which is nearer to the centre is always greater than one more remote: and the greater is nearer to the centre than the less.

Let E be the centre of the circle A B C D, and let B C be nearer to it than F G: *the diameter* A D *is the greatest chord, and* B C *is greater than* F G.

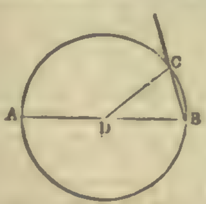
Draw E B, E C. Then because E A = E B and E D = E C, ∴ A D = E B + E C: but E B + E C are greater • 20 I. than B C,* ∴ A D *is greater than* B C. Again, draw E H, E K perpendiculars to B C, F G; then because B C is nearer to the centre than F G,† † Hyp. E H is less than E K; and, as was demonstrated in the preceding proposition, $EH^2 + HB^2 = EK^2 + KF^2$: but EH^2 is *less* than EK^2, because E H is less than E K, ∴ HB^2 is *greater* than KF^2; but B C is the double of H B,* • 3 III. and F G the double of K F, ∴ B C *is greater than* F G.



Next, let B C be greater than F G, then B C *shall be nearer to the centre than* F G; that is, the same construction being made, E H shall be less than E K. Because B C is greater than F G, B H is greater than F K, ∴ BH^2 is greater than FK^2. And $BH^2 + HE^2 = FK^2 + KE^2$, of which BH^2 is greater than FK^2, ∴ EH^2 is *less* than EK^2, ∴ E H is less than EK; that is, B C is nearer to the centre than F G; ∴ *the diameter, &c.* Q. E. D.

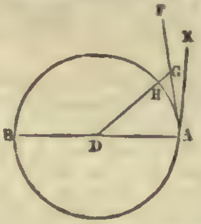
PROPOSITION XVI.—THEOREM.

The straight line drawn at right angles to the diameter (A B) *of a circle* (A B C), *from the extremity of it* (A) *falls without the circle; and no straight line can be drawn from that extremity between the straight line and the circumference, so as not to cut the circle.*



For if A E do not fall without the circle, let a part of it, as A C, fall within the circle; and from the centre D draw D C, to the point C where A E meets the circumference. Then because D A = D C, the angle † 5 I. D A C = D C A;† but D A C is a right angle,* • Hyp. ∴ D C A is a right angle, ∴ D A C + D C A † 17 I. = two right angles, which is impossible,† ∴ a part of A E, *at right angles to* B A, *does not fall within the circle.* And it may be demonstrated, in the same manner, that A E does not fall upon the circumference; ∴ A E *falls without the circle.*

Moreover, between A E and the circumference no straight line can be drawn from A which does not cut the circle. For let A F be supposed to be drawn between them; from D draw D G perpendicular to A F,* • 12 I. and let it meet the circumference in H. Because A G D is a right angle, and D A G less † 17 I. than a right angle,† D A • 19 I. is greater than D G;* but D A = D H, ∴ D H is greater than D G, a part than the whole, which is impossible, ∴ *no straight line can be drawn from* A *between* A E *and the circumference;* ∴ *the straight line, &c.* Q. E. D.



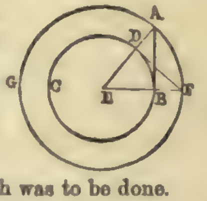
COR.—From this it is manifest that the straight line, at right angles to a diameter of a circle, from an extremity of that diameter, touches the circle; and that it touches it in one point only, because if it met the † 2 III. circle in two points, it would fall within it.† Also it is evident that there can be but one straight line which touches a circle in the same point.

PROPOSITION XVII.—PROBLEM.

To draw a straight line from a given point, either without or in the circumference of a circle (B C D), *which shall touch the circle.*

First let the given point be without the circle as A. • 1 III. Find E the centre,* and draw A E, cutting the circle in D; and with centre E, and radius E A, describe the circle A F G; from D draw D F at right angles to † 11 I. E A,† and draw E B F, A B. A B *shall touch the circle* B C D.

Because E is the centre of the circles B C D, A F G, E A = E F and E D = E B, ∴ the two sides A E, E B are = the two F E, E D, each to each, and the angle E is common to the two triangles A E B, F E D, ∴ the angle E B A • 4 I. = E D F;* but E D F is a right angle, ∴ E B A is a right angle, and E B is a radius; but a straight line from an extremity of a diameter, at right angles to it, † 16 III. Cor. touches the circle,† ∴ A B *touches the circle, and it is drawn from the given point* A; which was to be done.



But if the given point be *in* the circumference, as at D, draw D E to the centre E, and D F at right angles to • 16 III. Cor. D E; D F *touches the circle.**

PROPOSITION XVIII.—THEOREM.

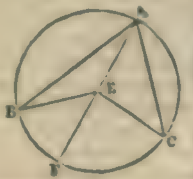
If a straight line touch a circle, the straight line drawn from the centre to the point of contact, shall be perpendicular to the line touching the circle.

This proposition is really included in Prop. XVI.: it affirms that the diameter is perpendicular to the touching line at its extremity: and Prop. XVI. shows that the perpendicular to the diameter at its extremity is the touching line, and the *only* touching line at that extremity. The next proposition is equally superfluous: the only thing proved by either is this—viz., that *a line which is perpendicular to the diameter must have the diameter perpendicular to it.* The two enunciations are retained here only to avoid interruption in the numbering of the propositions.

PROPOSITION XIX.—THEOREM.

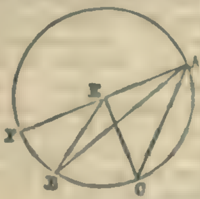
If a straight line touch a circle, and from the point of contact a straight line be drawn at right angles to the touching line, the centre of the circle shall be in that line.

PROPOSITION XX.—THEOREM.



The angle (B E C) *at the centre* (E) *of a circle* (A B C) *is double of the angle* (B A C) *at the circumference upon the same arc* (B C).

Draw A E, and prolong it to F. And first let the centre E be *within* B A C. Because E A = E B, the * 5 I. angle E A B = E B A,* ∴ E A B + E B A is double of E A B; † 32 I. but B E F = E A B + E B A,† ∴ B E F is double of E A B. For a like reason F E C = double of E A C, ∴ B E C *is double of* B A C.

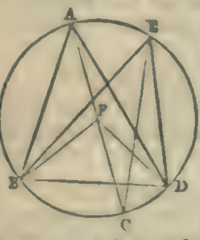


Next let the centre E be *without* B A C. It may be demonstrated, as in the first case, that F E C is double of F A C, and that F E B, a part of the first, is double of F A B, a part of the other, ∴ *the remaining angle* B E C *is double of the remaining angle* B A C; ∴ *the angle at the centre, &c.* Q. E. D.

PROPOSITION XXI.—THEOREM.

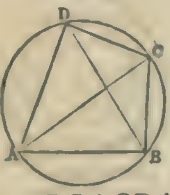
The angles (B A D, B E D) *in the same segment* (B A E D) *of a circle are equal.*

* 1 III. Take F the centre of a circle:* draw F B, F D, as also the diameter A C; and join E, C. Because B F C, at the centre, is upon the same arc B C, as B A C at the circumference, ∴ † 20 III. B F C is double of B A C.† Again, because B F C, at the centre, is upon the same arc B C, as B E C at the circumference, ∴ B F C is double of B E C. But it was shown that B F C is also double of B A C, ∴ B A C = B E C. In like manner it may be proved that C A D = C E D, ∴ *the whole angle* B A D = *the whole angle* B E D; ∴ *the angles, &c.* Q. E. D.



PROPOSITION XXII.—THEOREM.

The opposite angles of any quadrilateral figure (A B C D) *inscribed in a circle* (A B C D), *are together equal to two right angles.*



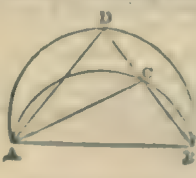
Draw the diagonals A C, B D. Then because the three angles of every triangle are together = two right * 32 I. angles,* ∴ C A B + A B C + B C A = two right angles: but † 21 III. C A B = C D B,† and B C A = B D A, ∴ C A B + B C A = C D A. To each of these add A B C, ∴ A B C + C A B + B C A = A B C + C D A, ∴ A B C + C D A = *two right angles:* and as the *four* * 32 I. angles of a quadrilateral = *four* right angles,* Cor. I. ∴ *the other two opposite angles are also = two right angles;* ∴ *the opposite angles, &c.* Q. E. D.

NOTE.—It appears from the foregoing property, that if one side (as A B) of a quadrilateral in a circle be prolonged, the exterior angle will be equal to the interior and opposite angle (D).

PROPOSITION XXIII.—THEOREM.

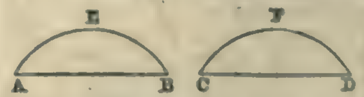
Upon the same straight line (A B), *and on the same side of it, there cannot be two similar segments of circles not coinciding with one another.*

For if it be supposed possible, let A C B, A D B be two similar segments, *not* coinciding with one another. Then, because the circles cut in the two points A, B, they can- * 10 III. not cut in any other point,* ∴ one segment must be within the other. Let A C B be within A D B: draw B C D, as also C A, D A. Then, because the segments are simi- † Hyp. lar,† and that similar segments of circles contain equal * Def. 10 III. angles,* ∴ the angle A C B = A D B, the exterior to † 16 I. the interior and opposite, which is impossible,† ∴ *there cannot be two similar segments of circles upon the same side of the same straight line, which do not coincide.* Q. E. D.



PROPOSITION XXIV.—THEOREM.

Similar segments of circles (A E B, C F D) *upon equal chords* (A B, C D) *are equal to one another.*

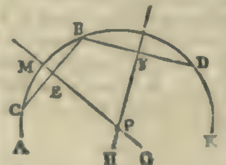


For if the segment A E B be applied to C F D, so that A may be on C, and A B on C D, B shall coincide with D, because A B = C D, ∴ A B coinciding with C D, *the segment* A E B *must coincide with the seg-* * 23 III. *ment* C F D,* *and is* ∴ *equal to it;* ∴ *similar segments, &c.* Q. E. D.

NOTE.—It obviously follows from this, that similar segments of circles upon equal chords have equal arcs.

PROPOSITION XXV.—PROBLEM.

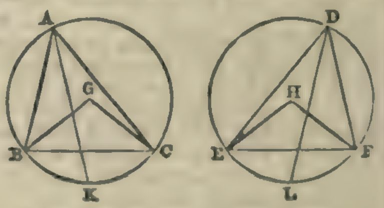
An arc (A B K) *of a circle being given, to describe the circle of which it is an arc.*



Take any point B in the arc, from which draw any two chords B C, B D. Bisect * 10 I. them in E and F,* and † 11 I. draw E G, F H at right angles to B C, B D. These perpendiculars will cut each other in a point P, which will be the centre of the circle. For the centre of the circle to which the arc B C belongs, is in the line E G, bisect- * 1 III. Cor. ing the chord C B at right angles:* it is also in the line F H, bisecting the chord B D at right angles: the centre being thus in *both* the lines E G, F H, must be at P, where they intersect, ∴ *with* P *as centre, and* P M *as radius, if a circle be described, it will be that of which the given arc is a part.* Which was to be done.

PROPOSITION XXVI.—THEOREM.

In equal circles (A B C, D E F) *equal angles stand upon equal arcs, whether they be at the centres or at the circumferences.*



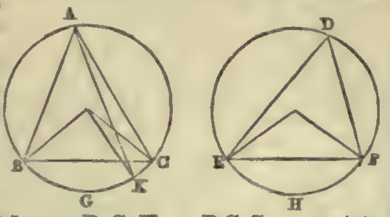
First, let the angles B G C, E H F at the *centres* be equal. Take any point, A, in the arc B A C, and any point, D, in the arc E D F: draw A B, A C, D E, D F, B C, E F. Then, because the circles are equal, the radii G B, G C are equal to the radii H E, H F, each to * Hyp. each; and the angle G = H,* ∴ B C = † 4 I. E F:† and because B A C = E D F,* the seg- * 20 III. ment B A C is similar to the segment E D F;† † Def. 10 III. and they have equal chords, ∴ the seg- * 24 III. ment B A C = segment E D F;* but the whole circle A B K C = the whole circle D E L F, ∴ the remaining segment B K C = E L F, ∴ *the arc* B K C = *arc* E L F.

Next let the angles B A C, E D F at the *circumferences* † 1 III. be equal. Find the centres G, H;† and draw G B, G C, B C; H E, H F, E F: then if B A C be less than a right angle, the angle B G C, at the centre, will stand on the same arc B K C as B A C, and will ∴ * 20 III. be double of B A C.* In like manner E H F will be double of E D F, ∴ the angles G, H at the centres are equal, and ∴, as before proved, the *arcs* B K C, E L F *must be equal.* But if B A C be not less † 9 I. than a right angle, bisect it,† as also the equal angle E D F, by the straight lines A K, D L, then the angles B A K, E D L being equal, and each less than a right angle, the arc B K is, by the first case, = the arc

E L. In like manner K C = L F, ∴ *the arcs* B K C, E L F *are equal,* ∴ *in equal circles, &c.* Q. E. D.

PROPOSITION XXVII.—Theorem.

In equal circles (A B C, D E F) *the angles* (B A C, E D F), *which stand upon equal arcs* (B G C, E H F), *are equal, whether they be at the centres or at the circumferences.*



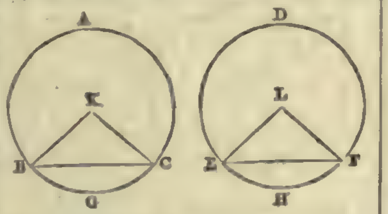
For if not, let one of them, as B A C, be the greater; and make the angle B A K = E D F;* * 23 I. then because in equal circles equal angles stand on equal † 26 III. arcs,† ∴ the arcs B G K, E H F are equal: but B G C = * Hyp. E H F,* ∴ B G K = B G C, a part to the whole, which is impossible, ∴ the angles B A C, E D F cannot be the one greater than the other; that is, *the angles are equal;* ∴ *in equal circles, &c.* Q. E. D.

Note.—The demonstrations of the last two propositions differ considerably from those of Euclid, which, upon examination, will be found to be incomplete, since they exclude the case in which the angles B A C, E D F, at the circumferences, are each not less than a right angle.

It will be observed that the demonstration of the second of these propositions equally applies whether the angles B A C, E D F be at the circumferences, as in the diagrams, or at the centres. These points are left unmarked by letters, in order that, in going over the reasoning, the letters A, D may be mentally transferred to the centres, and thus both cases be included in the the same demonstration.

PROPOSITION XXVIII.—Theorem.

In equal circles (A B C, D E F) *equal chords* (B C, E F) *cut off equal arcs* (B A C, E D F, *and* B G C, E H F) *the greater equal to the greater, and the less to the less.*



* 1 III. Take K, L, the centres of the circles,* and draw K B, K C, L E, L F. Then, because the circles are equal, K B, K C are = L E, L F, each to each, and B C = E F,† † Hyp. ∴ the angle B K C = * 8 I. E L F:\* but equal angles at the centres stand on equal arcs,† ∴ † 26 III. *the arc* B G C = E H F: but the whole cir- * Hyp. cumference A B C = the whole E D F,* ∴ *the remaining part* B A C = *the remaining part* E D F; ∴ *in equal circles, &c.* Q. E. D.

PROPOSITION XXIX.—Theorem.

In equal circles (A B C, D E F) *equal arcs* (B G C, E H F) *are subtended by equal chords* (B C, E F).

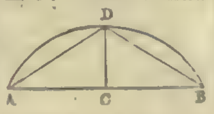
[See preceding diagrams.]

If the arcs are *semi-circumferences,* then B C, E F are *diameters;* and as the circles are equal, these diameters must be equal. But if the arcs be not semi-circumferences, take K, L, the centres of the circles,* and * 1 III. draw K B, K C, L E, L F. Then, because the arc B G C = the arc E H F, the angle B K C = † 27 III. E L F;† and because the circles are equal, K B, K C are equal to L E, L F, each to each, and the * 4 I. angles K, L are also equal, ∴ B C = E F;* ∴ *in equal circles, &c.* Q. E. D.

Note.—It is plain that what is proved in the preceding propositions, as to *equal circles,* necessarily holds in reference to *the same circle.*

PROPOSITION XXX.—Problem.

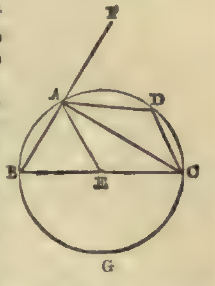
To bisect a given arc (A D B); *that is, to divide it into two equal parts.*



* 10 I. Draw A B and bisect it in C:\* from C draw C D at right angles to A B:† the † 11 I. arc A D B shall be bisected in D. Draw A D, B D. Then, because A C = C B, and C D common to the triangles A C D, B C D, the two sides A C, C D are = the two B C, C D, each to each; and the angle A C D = B C D, each being * 4 I. a right angle, ∴ A D = B D.* But equal chords cut off equal arcs, the greater are equal to the † 28 III. greater, and the less to the less,† ∴ *arc* A D = *arc* B D, each arc being less than a semicircle, because D C, or D C prolonged, passes through the centre; ∴ *the given arc is bisected in* D. Which was to be done.

PROPOSITION XXXI.—Theorem.

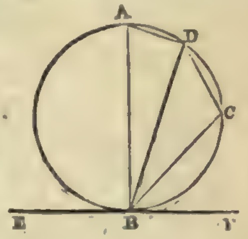
The angle (B A C) *in a semicircle* (B A D C) *is a right angle: the angle in a segment* (A B G C) *greater than a semicircle, is less than a right angle: and the angle* (D) *in a segment* (A D C) *less than a semicircle, is greater than a right angle.*



From the centre, E, draw E A, and produce B A to F. Then, because E B = E A, the * 5 I. angle E A B = E B A;* also because E A = E C, the angle E A C = E C A, ∴ the whole angle B A C = A B C + A C B: but F A C, the exterior angle of the triangle † 32 I. A B C, is = A B C + A C B,† ∴ B A C = F A C, ∴ each is a right * Def. 8 I. angle,* ∴ *the angle* B A C *in a semicircle is a right angle.* Again, because the two angles B, C, of the triangle A B C are together † 17 I. less than two right angles,† and that B A C has been proved to be a right angle, ∴ A B C must be *less* than a right angle, ∴ *the angle* B *in a segment* A B G C, *greater than a semicircle, is less than a right angle.* Lastly, because A B C D is a quadrilateral in a circle, the opposite angles * 22 III. B, D are together = two right angles:* but B has been proved to be *less* than a right angle, ∴ D, *in a segment* A D C *less than a semicircle, is greater than a right angle;* ∴ *the angle, &c.* Q. E. D.

PROPOSITION XXXII.—Theorem.

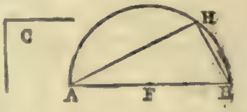
If a straight line (E F) *touch a circle, and from the point of contact* (B) *a straight line* (B D) *be drawn cutting the circle, the angles* (D B F, D B E) *which this line makes with the touching line shall be equal to the angles* (A, C) *in the alternate segments of the circle, each to each.*



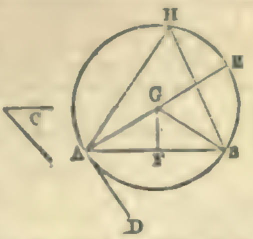
* 11 I. From B draw B A at right angles to E F:* take any point C in the arc D C B, and draw A D, D C, C B. Then, because E F touches the circle in B, and that B A is drawn at right angles to E F, the centre of the circle † 19 III. is in B A,† ∴ A D B, being an angle in a semicircle, is a right angle,* * 31 III. ∴ B A D + A B D † 32 I. = a right angle;† but A B F likewise is a right * Const. angle,* ∴ A B F = B A D + A B D. Take away the common angle A B D, ∴ D B F = A, *the angle in the alternate segment.* Again: because A C is a quadrilateral in a circle A + † 22 III. C = two right angles:† but D B F + D B E * 13 I. = two right angles,* ∴ D B F + D B E = A + C; and it has been proved that D B F = A, ∴ D B E = C, *the angle in the alternate segment;* ∴ *if a straight line, &c.* Q. E. D.

PROPOSITION XXXIII.—Problem.

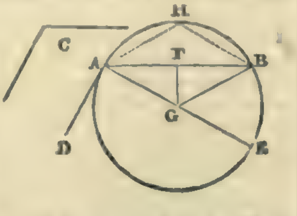
Upon a given straight line (A B) *to describe a segment of a circle capable of containing an angle equal to a given angle* (C).



* 10 I. First let C be a right angle: bisect A B in F,* and with F as centre, and radius F B, describe the semicircle A H B: then *the angle* H, formed by H A, H B, drawn from any point H in the arc, being in a semicircle, † 31 III. *is equal to the right angle* C.†



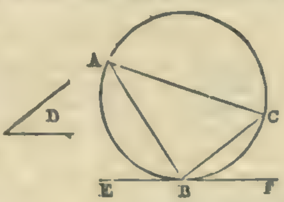
But if C be not a right angle, make B A D = C,* * 23 I. and draw A E at † 11 I. right angles to A D.† * 10 I. Bisect A B in F,* and draw F G at right angles † 11 I. to A B :† F G will meet A E in some point G, because G A F is less than a * Ax 12. right angle ;* and if from G as centre, with radius G A, a circle be described, it will pass through B, and the segment A H B will be that required. For draw G B : then because A F = F B, the two sides A F, F G are = the two B F, F G, each to each ; and the angle † Const. A F G = B F G,† ∴ G A = G B ;* ∴ the * 4 I. circle, with centre G, and radius G A, must pass through B. Again : because from A, an extremity of the diameter A E, A D is drawn at right angles to A E, ∴ A D touches † 16 III. Cor. the circle :† and because A B, drawn from the point of contact, cuts the circle, the angle D A B = H, in the alter- * 32 III. nate segment :* but D A B = C, ∴ H = C ; ∴ *upon* A B *the segment* A H B *of a circle is described, which contains an angle* H = C. Which was to be done.



PROPOSITION XXXIV.—PROBLEM.

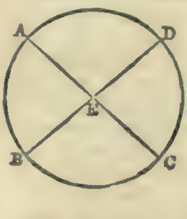
From a given circle (A B C) *to cut off a segment, which shall contain an angle equal to a given angle* (D).

Take any point B in the circumference, and draw E F touching the circle in B,* * 17 III. and make the † 23 I. angle F B C = D.† The segment B A C shall contain an angle A = D. Because E F touches the circle at B, the angle F B C = B A C, in the alternate * 32 III. segment :* but † Const. F B C = D,† ∴ the angle A, in the segment B A C, is = D ; ∴ *from the given circle the segment* B A C *is cut off containing an angle* = D. Which was to be done.



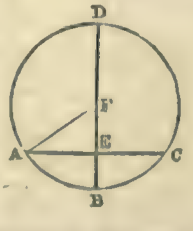
PROPOSITION XXXV.—THEOREM.

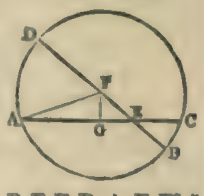
If two chords (A C, B D) *in a circle, cut one another, the rectangle* (A E·E C) *contained by the segments of one of them, is equal to the rectangle* (B E·E D) *contained by the segments of the other.*



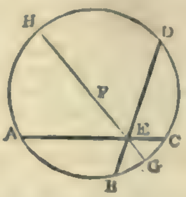
If the chords intersect in the centre E, it is evident that A E, E C, B E, E D, being all equal, *the rectangle* A E·E C = B E·E D.

But if one of them, B D, pass through the centre, and cut the other A C, which does *not* pass through the centre, *at right angles*, in E, then, if B D be bisected in F, F is the centre of the circle ; join A, F. Then, because B D, through the centre cuts A C, not through the centre, at right * 3 III. angles in E, A E = E C.* And because B D is cut into two equal parts in F, and into two unequal parts in E, $B E \cdot E D + E F^2$ † 5 II. $= F B^2$, or $F A^2$;† but * 47 I. $A E^2 + E F^2 = F A^2$,* ∴ $B E \cdot E D + E F^2 = A E^2 + E F^2$. Take away the common square $E F^2$, ∴ $B E \cdot E D = A E^2 = A E \cdot E C$. Again, let B D, which passes through the centre, cut A C, which does not pass through the centre in E, *but not at right angles* ; then, as before, if B D be bisected in F, F is the centre of the circle. Draw A F, and from F draw F G * 12 I. perpendicular to A C,* ∴ † 3 III. A G = G C,† ∴ $A E \cdot E C +$ * 5 II. $E G^2 = A G^2$.* To each of these add $G F^2$, ∴ $A E \cdot E C + E G^2 + G F^2 = A G^2 + G F^2$; but $E G^2$ † 47 I. $+ G F^2 = E F^2$,† and $A G^2 + G F^2 = A F^2$, ∴ $A E \cdot E C + E F^2 =$ * 5 II. $A F^2 = F B^2$; but $F B^2 = B E \cdot E D + E F^2$,* ∴ $A E \cdot E C + E F^2 = B E \cdot E D + E F^2$. Take away $E F^2$, ∴ A E·E C = B E·E D.



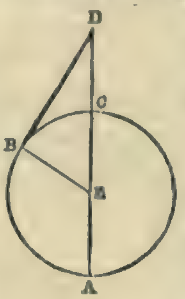


Lastly, let neither of the chords A C, B D pass through the centre. Take the centre F,† † 1 III. and through E, the intersection of the chords, draw the diameter G E F H. Then, because A E·E C = G E·E H, as also B E·E D = G E·E H, as already proved, ∴ A E·E C = B E·E D ; ∴ *if two chords, &c.* Q. E. D.

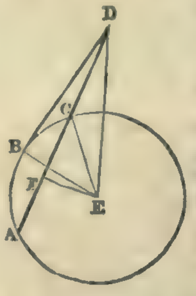


PROPOSITION XXXVI.—THEOREM.

If from any point (D) *without a circle* (A B C) *two straight lines be drawn, one of which* (D A) *cuts the circle, and the other* (D B) *touches it, the rectangle* (A D·D C) *contained by the whole line cutting the circle, and the part without the circle, shall be equal to* ($D B^2$) *the square of the line which touches it* ; that is, $A D \cdot D C = D B^2$.



The line D C A either passes through the centre, or it does not ; first let it pass through the centre E ; and draw E B ; then † 18 III. B is a right angle ;† and because A C is bisected in E, and prolonged to D, $A D \cdot D C + E C^2 =$ * 6 III. $E D^2$;* but E C = E B, ∴ $A D \cdot D C + E B^2 = E D^2$; but $E D^2 = E B^2 + B D^2$, because B is a † 47 I. right angle,† ∴ $A D \cdot D C + E B^2 = E B^2 + B D^2$. Take away $E B^2$, ∴ $A D \cdot D C = B D^2$. But if D C A do not pass through the centre, * 1 III. take the centre E,* and draw E F perpendicular to A C ;† † 12 I. draw also E B, E C, E D. Then because E F, passing through the centre, cuts A C, not through the centre at right * 3 III. angles, it also bisects it,* ∴ A F = F C ; and because A C is bisected in F, and prolonged to D, † 6 II. $A D \cdot D C + F C^2 = F D^2$.† To each of these add $F E^2$, ∴ $A D \cdot D C + F C^2 + F E^2 = F D^2 + F E^2$; but $E D^2 = F D^2 + F E^2$, because E F D is a right angle ;* * 47 I. and, for the same reason, $E C^2 = F C^2 + F E^2$, ∴ $A D \cdot D C + E C^2 = E D^2$; but E C = E B, ∴ $A D \cdot D C + E B^2 = E D^2$; but $E B^2 + B D^2 = E D^2$, because B is a right angle,† † 47 I. ∴ $A D \cdot D C + E B^2 = E B^2 + B D^2$. Take away $E B^2$, ∴ $A D \cdot D C = B D^2$.

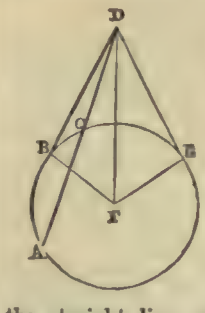


COR.—If from any point without a circle, two straight lines cutting it be drawn, the rectangles of the whole lines and the parts without the circle are equal ; for each rectangle is equal to the square of the line drawn from he point to touch the circle.

PROPOSITION XXXVII.—THEOREM.

If from a point (D) *without a circle* (A B C) *there be drawn two straight lines, one* (D C A) *to cut the circle, and the other* (D B) *to meet it ; and if the rectangle* (A D D C) *of the whole cutting line and the part without the circle be equal to* ($D B^2$) *the square of the line which meets it, the line* (D B) *which meets shall touch the circle.*

* 17 III. Draw D E touching the circle in E :* find



† 3 III. the centre F,† and draw F E, F B, F D: then E is a right * 18 III. angle.* And because D E touches, and D C A cuts the † 36 III. circle, $AD \cdot DC = DE^2$:† * Hyp. but $AD \cdot DC = DB^2$,* ∴ $DE = DB$; also $FE = FB$, ∴ D E, E F are = D B, B F, each to each; and the base F D is common to the two triangles D E F, D B F, † 8 I. ∴ the angle E = B:† but E was shown to be a right angle, ∴ B is a right angle: and B F prolonged is a diameter: but the straight line which is drawn at right angles to a diameter, from an extremity of it, touches the circle,* * 16 III. ∴ D B *touches the circle* A B C; ∴ *if from a point*, &c. Q. E. D.

REMARKS ON BOOK III.

The third book is wholly occupied with propositions concerning the circle. In the definitions we have introduced two terms, the want of which is very much felt in the Elements—the terms *arc* and *chord*. The absence of this latter term has been the occasion of much looseness of expression in certain propositions of Euclid's Third Book: in Proposition I., for instance, as Thomas Simpson has justly noticed, we are directed to "draw within the circle any straight line A B," without the limiting condition that its extremities are to be in the circumference; and the same want of precision is observable in Propositions III. and IV. By "a straight line in a circle," Euclid certainly means exclusively "a straight line in a circle, and terminated both ways by the circumference;" but this should have been expressly stated, and not left to be inferred from observation. Had Definition VII., Book IV. (Simson's Euclid), been placed among the definitions of the third book, the objection here advanced would have been removed; since, according to that definition, "A straight line is said to be placed in a circle, when the extremities of it are in the circumference of the circle;" but it is better to call such a line a *chord*, the name given to it in all other geometrical inquiries.

The demonstration in Proposition I. of Simson's Euclid is imperfect, since all that it proves is, that the centre of the circle must be in the line C E, without determining the particular *point* in that line; the omission is supplied in the present edition.

The enunciation of Proposition VI. in Simson is, "If two circles touch one another *internally*, they shall not have the same centre;" but as it is plain that each circle cannot be *within* the other, the word *internally* should be omitted. If two circles touch *externally*, then, since each must be wholly *without* the other, it is obvious that they cannot have the same centre. In Proposition VII. certain lines are introduced by Euclid—namely, the lines E C, E G—long before they are wanted; and the diagram is thus unnecessarily complicated at the outset of the demonstration. We have already stated (page 549), with a view to an orderly and systematic arrangement of the steps of the argument, that the diagram should not proceed, in advance of the text: the more you depart from this plan, the more you depart from simplicity; since you thus encumber the diagram with lines that serve no purpose but to distract your attention. In demonstrating this seventh proposition without the book, you should commence by exhibiting in your diagram only the lines F B, F C, in addition to the diameter A D: you should then draw E B, for the purpose of proving that F A is greater than F B, whatever line, other than F A, F B may be: one part of the proposition is thus disposed of. The next step is to draw E C, the aid of which is now required—but not till now—to prove that F B, a line nearer to that passing through the centre, is greater than any other line F C more remote: another part of the theorem is thus demonstrated. You may now, if you please, introduce F G, and then draw E G, for the purpose of proving that F D is shorter than any other line drawn from F. We say you may introduce F G *if you please;* for, in strictness, there is no absolute occasion for it; F C, or F B, already drawn, would answer the purpose equally well: of the remaining part of the construction nothing need be said here.

In Proposition VIII. we have actually omitted Euclid's superfluous line—the line corresponding to that which, as just noticed, may be dispensed with in the preceding proposition. As the diagram here is somewhat more complicated, it was thought that the suppression of an unnecessary line from D, and *consequently* of two lines in connection with it from M, would be a desirable relief to it. You will perceive it to be so if you compare the diagram here, with that in other editions of Euclid.

The demonstration of Proposition IX., given in the present edition, is not that of Euclid, though substituted for it by De Chales, and some other editors. In the earlier copies of Euclid, two different demonstrations of this simple theorem are given. They have both been preserved by Gregory, Stone, Williamson, and Bonnycastle. It is the second of these two only that Simson retains; but, as remarked by Williamson, there is a defect in the reasoning, which, however, it is scarcely worth while to remove. The demonstration given in the text is so easy and obvious, that, as Austin justly observes, "we cannot suppose Euclid would have overlooked it." It is probable, therefore, that the demonstrations here discarded are not Euclid's own, but the interpolations of some other writer.

Although it is proved in Proposition XX. that an angle at the centre of a circle is double that at the circumference subtended by the same arc, yet it must not be inferred that to *every* angle at the circumference there corresponds an angle at the centre, upon the same arc, which is double of the former. If the angle at the circumference stand upon a semi-circumference, there can evidently be *no* corresponding angle at the centre upon the same arc; and if the angle at the circumference stand upon an arc greater than a semi-circumference, the angle at the centre, the sides of which terminate in the extremities of the same arc, will stand—not upon *that* arc—but upon the opposite part of the circumference.

The construction of Proposition XXV. is different in the present edition from that given in Euclid, which requires three diagrams: moreover, the "*segment* of a circle," as Euclid has it, need not be given, only the *arc*. Propositions XXVI. and XXVII. differ also in matters of construction from those of Euclid; for, as they at present stand in Simson, they are insufficiently demonstrated; as noticed in the text.

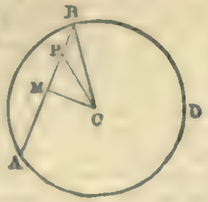
Proposition XXXIII.—In all the editions of Euclid that we have seen, there is a superfluous line (the line B E) introduced into the second of the three diagrams; and in some editions the line B E is also introduced into the third diagram, for what purpose we are unable to conceive; the tendency, though of course not the intention, is to mislead.

The demonstration applies equally to *both* diagrams. In the first, the line B E, which goes to form the angle E, is quite in keeping with the text, as this is really an angle in the segment spoken of. But in the second of these diagrams, the line is not merely superfluous—it is *wrong;* since the angle E, of which it is a side, is an angle in a segment different from that to which the text refers. In order that the proper angle should be exhibited in both diagrams, the vertex of it should be at H, as shown by the dotted lines in this edition, but there is no absolute occasion to introduce this angle at all.

Propositions XXXV. and XXXVI. may be otherwise and more easily established, as follows:—

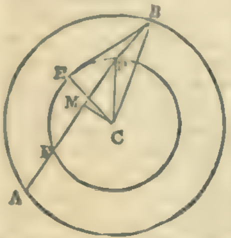
Proposition XXXV.—Let P be any point *within* a circle A B D. It is required to prove that whatever chord, A B, be drawn through P, the rectangle $AP \cdot PB$ will be always the same.

* 1 III. Find the centre C;* and draw C M at right † 12 I. angles to A B;† draw also C P, C B. Then,



* 3 III. because A B is divided equally in M,* and unequally in P, $A P \cdot P B + P M^2$ † 3 II. $= M B^2$.† Add $C M^2$ to each, ∴ $A P \cdot P B + P M^2 + C M^2 = M B^2 + C M^2$; that is, $A P \cdot$ * 47 I. $P B + P C^2 = B C^2$.* Take $P C^2$ from each, ∴ $A P \cdot P B = B C^2 - P C^2$. But $B C^2$ is always the same wherever in the circumference the point B may be, and $P C^2$ is always the same whatever chord be drawn through P, ∴ $B C^2 - P C^2$ is always the same, ∴ $A P \cdot P B$ is always the same, whatever chord (A B) be drawn through P; ∴ if two chords cut one another in any point P, the rectangle contained by the segments of one of them is equal to that contained by the segments of the other.

Proposition XXXVI.—Let B be any point *without* a circle P E F. It is required to prove that whatever line B P F be drawn, *cutting* the circle, the rectangle $B F \cdot B P$ shall be equal to the square of B E, a line drawn *touching* the circle.



* 1 III. Find the centre C,* and draw C B, C P, C E. With this same centre C, and radius C B, describe a circle, and produce B F to meet its circumference in A. Then (last Proposition) $A P \cdot B P = B C^2$ † 47 I. $- P C^2 = B C^2 - E C^2 = B E^2$.† Draw the perpendicular C M to A B; then C M bisects both A B * 3 III. and F P,* ∴ $A F = P B$, ∴ $A P = B F$. But it was proved that $A P \cdot P B = B E^2$; ∴ $B F \cdot B P = B E^2$, which was to be demonstrated.

An obvious corollary follows from this proposition, viz.—

Cor. 1.—Since from any point without a circle *two* † 17 I. lines may be drawn to touch the circle,† these two touching lines must be *equal*.

We shall only further observe that, besides the particulars mentioned above, in which slight departures from the authorised text of Euclid have been made, other modifications, chiefly in the diagrams, have been introduced in certain propositions; but we have nowhere ventured upon any change, where the circumstances of the case did not fully justify and require it.

EXERCISES ON BOOKS I., II., III.

1. Prove the *converse* of Proposition XXII.—Book III.; namely, if the opposite angles of a quadrilateral be together equal to two right angles, a circle may be described about it.

2. A trapezium may be inscribed in a circle, provided two of the opposite sides are parallel, and that the two non-parallel sides are equal.

3. If a quadrilateral be described about a circle, that is, if the four sides touch the circle, one pair of opposite sides will always be equal to the other pair.

4. If from the vertices of the three angles of a triangle, perpendiculars be drawn to the opposite sides, they will intersect in the same point.

5. If two circles cut one another, the line joining the intersections of the circumferences, shall be perpendicular to the line joining the centres.

6. If two circles cut one another, and from one of the points of intersection diameters be drawn, the extremities of these diameters shall be in the same straight line as the other point of intersection.

7. If any two chords of a circle intersect at right angles, the squares upon their four segments will, together, be equal to the square upon the diameter.

8. If two circles touch each other, any straight line through the point of contact will cut off similar segments.

9. If a quadrilateral be described about a circle, the angles subtended at the centre by one pair of opposite sides, will, together, be equal to those subtended by the other pair; that is, to two right angles.

10. Find a point in the prolongation of a diameter of a circle, from which, if a line be drawn to touch the circle, it shall be equal to a given straight line.

11. Two chords A D, B C, are drawn in a semicircle from the extremities of the diameter A B; the chords intersect in P. Prove that the rectangles $A D \cdot A P$, $B C \cdot B P$ are together equal to the square of the diameter.

12. If from any point in the diameter of a semicircle two straight lines be drawn to the circumference, one to the middle of the arc, the other at right angles to the diameter, the squares upon these two lines always amount to the same sum, wherever the point be taken.

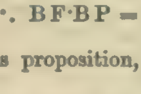
13. From a given point without a circle to draw a straight line to cut it, and to terminate in the circumference, such that the intercepted chord may have a given length, not greater than the diameter of the circle.

CHAPTER IV.

ELEMENTS OF EUCLID.—BOOK IV.

DEFINITIONS.

I.

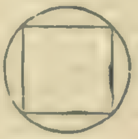


A rectilineal figure is said to be *inscribed* in another rectilineal figure, when all the *vertices* of the former are upon the *sides* of the latter, each upon each.

II.

A rectilineal figure is said to be *described* about another, when all the *sides* of the former pass through the *vertices* of the latter, each through each.

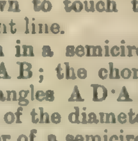
III.



A rectilineal figure is said to be inscribed in a circle, when all the vertices of the former are upon the circumference of the circle.

IV.

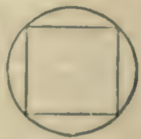
A rectilineal figure is said to be described about a circle when each side of the former *touches* the circumference of the circle.



V.

A circle is said to be inscribed in a rectilineal figure, when the circumference of the circle *touches* each side of the figure.

VI.



A circle is said to be described about a rectilineal figure, when its circumference passes through all the vertices of that figure.

VII.

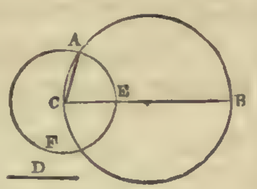
A straight line is said to be *placed in a circle*, when the extremities of it are in the circumference of that circle.*

---

* See *ante*, Book III., Prop. I., III., and IV.

PROPOSITION I.—Problem.

In a given circle (A B C), *to place a straight line equal to a given straight line* (D), *which is not greater than the diameter of the circle.*



Draw B C, any diameter of the circle. Then if C B = D, the thing required is done; but if B C be not = D, • Hyp. it is greater;* make C E = D; and with centre C and radius C E, describe the circle A E F; join C A; C A shall be = D.

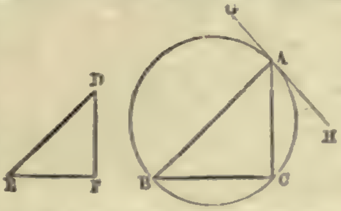
Because C is the centre of the circle A E F, C A = • Const. C E; but D = C E,* ∴ D = C A; *therefore in the circle* A B C, *a straight line, equal to* D, *is placed as required.*

Note.—The enunciation of this proposition might have been as follows:—From a given point, in the circumference of a given circle, to draw a *chord* equal to a given straight line, which is not greater than the diameter.

PROPOSITION II.—Problem.

In a given circle (A B C) *to inscribe a triangle equiangular to a given triangle* (D E F).

Take any point A in the circumference, and draw † 17 III. G A H to touch the circle in that point.† Make • 23 I. the angle H A C = E, and G A B = F,* and draw B C: A B C shall be the triangle required.



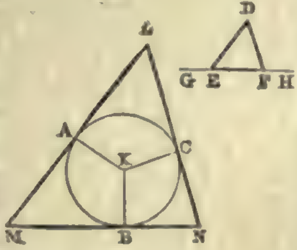
Because H A G touches the circle, and A C is drawn from the point of contact, the angle H A C = B, in the alternate seg- † 22 III. ment:† but H A C = E, ∴ B = E. For a like reason, C = F, ∴ the remaining angle B A C = the • 32 I. remaining angle D;* ∴ *the triangle* A B C, *inscribed in the circle* A B C, *is equiangular to* D E F. Which was to be done.

Note.—If the angle H A C has been made equal to F, instead of E, the resulting triangle would still have been equiangular to D E F: but the construction above furnishes a triangle not only equiangular, but similar in *position* to D E F. Like remarks apply to the next proposition.

PROPOSITION III.—Problem.

About a given circle (A B C) *to describe a triangle equiangular to a given triangle* (D E F).

Prolong E F both ways to G and H: find the • 1 III. centre K of the circle,* and draw any radius K B. Make the angle B K A = D E G, † 23 I. and the angle B K C = D F H:† and through A, B, C, draw L M, M N, N L to touch the • 17 I. circle:* these lines will meet and form a triangle L M N equiangular to D E F.

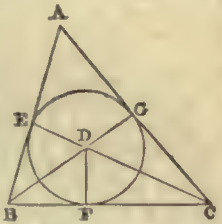


Because L M, M N, N L touch the circle at A, B, C, the lines K A, K B, K C from the centre make the angles at A, B, C *right* † 18 III. angles,† ∴ A M, B M would make with a line joining A, B, angles which are together *less* than two right angles, ∴ A M, • Ax. 12. B M, must *meet.** In like manner A L, C L, meet; as also B N, C N: and because the four angles of the quadrilateral A M B K, are = four right angles, for it can be divided into two triangles, and that two of the angles K A M, K B M, are right angles, ∴ the other two, A K B, A M B make two right angles. But D E G + † 13 I. D E F = two right angles,† ∴ A K B + A M B = D E G + D E F; but A K B = D E G, ∴ A M B = D E F. In like manner it may be proved that L N M = D F E, ∴ the remaining angle L = the remaining angle • 32 I. D;* ∴ the triangle L M N is equiangular to the triangle D E F; *and it is described about the circle.* Which was to be done.

PROPOSITION IV.—Problem.

To inscribe a circle in a given triangle (A B C).

• 9 I. Bisect the angles A B C, B C A* by the straight lines B D, C D, meeting one another in D, from which draw D E perpendicular to one of the sides.† † 12 I. The circle described with centre D, and radius D E, will be inscribed in the triangle.

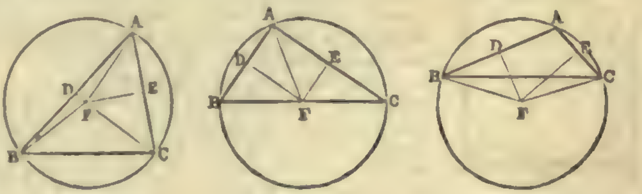


For draw D F, D G, perpendiculars to the other sides:* • 12 I. then, because the angle E B D = F B D, for A B C is † Const. bisected by B D,† and • Ax. 11. that B E D = B F D,* ∴ the triangles E B D, F B D have two angles of the one = two of the other, each to each; and the side B D, opposite to one of the equal angles in each, † 26 I. common to both, ∴ the other sides are equal;† that is, D E = D F. For a like reason, D G = D F, ∴ D E = D G, ∴ D E, D F, D G are all equal; and the circle described with centre D, and *either* of these for a radius, will pass through the extremities of *all;* and will *touch* A B, B C, C A, because the angles at E, F, G • 16 III. are right angles;* ∴ *the circle* E F G *is inscribed in the triangle* A B C. Which was to be done.

PROPOSITION V.—Problem.

To describe a circle about a given triangle (A B C).

• 10 I. Bisect A B, A C in D, E;* and from these points draw D F, E F, at right angles to A B, A C.† † 11 I. Then D F, E F must meet one another, because they make with a line joining D, E, angles on the same • Ax. 12. side, together *less* than two right angles.* Let them meet in F, and draw F A, then a circle described with centre F, and radius F A, will circumscribe the triangle A B C.

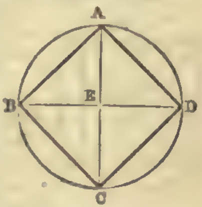


For if the point F be not in B C, draw B F, C F. Then, because A D = D B, and D F is common, and at † 4 I. right angles to A B, A F = F B.† In like manner, it may be shown that C F = A F, ∴ F B = F C, ∴ F A, F B, F C are all equal; ∴ the circle described with centre F, and *either* of these lines for radius, will pass through the extremities of *all, and be circumscribed about the triangle* A B C. Which was to be done.

PROPOSITION VI.—Problem.

To inscribe a square in a given circle (A B C D).

Draw any two diameters A C, B D at right angles to one another: draw A B, B C, C D, D A: the figure A B C D shall be the square required.



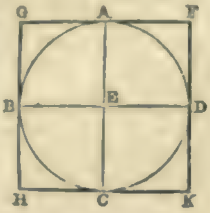
Because E is the centre, E B = E D; also E A is common, and at right angles to B D, ∴ • 4 I. A B = A D.* For a like reason C B, C D are respectively = A B, A D, ∴ the figure A B C D is *equilateral.* It is also *rectangular;* for B D being a diameter of the circle, B A D is a semicircle, ∴ B A D is a right angle.† † 31 III. For the same reason each of the angles A B C, B C D, C D A, like D A B, is a right angle, ∴

the figure is *rectangular*, ∴ it is a *square ; and it is inscribed in the circle* A B C D. Which was to be done.

PROPOSITION VII.—PROBLEM.

To describe a square about a given circle (A B C D).

Draw two diameters, A C, B D, at right angles to one another, and through A, B, C, D, draw F G, G H, H K, K F, touching the circle ;* the * 17 III. figure G H K F shall be the square required. Because F G touches the circle, and E A is drawn from the centre to the point of contact A, the angles at † 18 III. A are right angles.† For a like reason, the angles at B, C, D, are right angles. And because the angle A E B is a right angle, as likewise E B G, G H is * 28 I. parallel to A C ;* for a like reason A C is parallel to F K. In a similar manner may it be proved that G F, H K, are each parallel to B D, ∴ the figures G K, G C, A K, F B, B K, are parallelograms, ∴ G F † 34 I. = H K, and G H = F K ;† and because A C = B D, and that A C = G H = F K ; and B D = G F = H K, ∴ G H, F K, are each = G F or H K, ∴ the figure F G H K is *equilateral*. It is also *rectangular ;* for G E being a parallelogram, and A E B a right angle, * 34 I. G is a right angle ;* and G K, being a parallelogram with a right angle at G, is *rectangular*,† † Cor. 46 I. ∴ it is a *square ; and it is described about the circle* A B C D. Which was to be done.

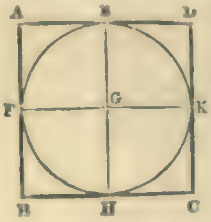


PROPOSITION VIII.—PROBLEM.

To inscribe a circle in a given square (A B C D).

* 10 I. Bisect each of the sides A B, A D in F, E ;* draw E H parallel to A B or D C, and F K parallel to † 31 I. A D or B C ;† then, if with their point of intersection G, as centre, and G F, or G E, as a radius, a circle be described, it will be that required.

Each of the figures A K, K B, A H, H D, A G, G C, B G, G D, being a parallelogram, their opposite sides are * 34 I. equal :* and because A D = A B, and A E = half A D, and A F = half A B, A E = A F, ∴ the sides opposite to these are equal—viz., F G = G E. In like manner, it may be demonstrated that G H = G K, and G H = G F, ∴ the four G E, G F, G H, G K are equal to one another ; and the circle described from centre G, with any one of them for a radius, will pass through the extremities of all, and will *touch* A B, B C, C D, D A, because the angles E, F, H, K are right angles ;† † 16 III. Cor. *the circle is* ∴ *inscribed in the square* A B C D. Which was to be done.

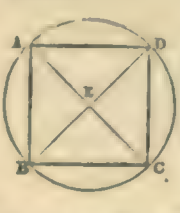


PROPOSITION IX.—PROBLEM.

To describe a circle about a given square (A B C D).

Draw A C, B D, intersecting in E : with E as centre, and E A as radius, describe a circle :—it will be that required.

Because D A = A B, and A C is common to the triangles D A C, B A C, the two sides D A, A C = the two B A, A C, each to each ; and D C = B C, ∴ the * 8 I. angle D A C = B A C ;* that is, the angle D A B is bisected by A C. In like manner, it may be proved that the angles A B C, B C D, C D A, are severally bisected by B D, C A. Again : the angle D A B = A B C, also E A B = half D A B, and E B A = half A B C, ∴ E A B = E B A, † 6 I. ∴ E A = E B.† In like manner, it may be demonstrated that E C, E D = E B, E A, each to each, ∴ the four E A, E B, E C, E D are equal to one another ; and the circle whose centre is E, and radius E A, passes through the extremities of all, *and is* ∴ *described about the square* A B C D. Which was to be done.

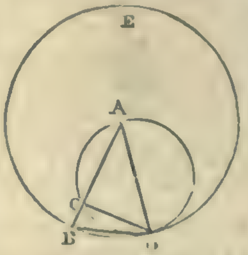


PROPOSITION X.—PROBLEM.

To describe an isosceles triangle having each of the angles at the base double of the third angle.

Take any straight line A B, and divide it in C, so * 11 II. that $A B B C = A C^2$,* and with centre A and radius A B, describe the circle B D E, in which place † 1 IV. B D = A C ;† and draw A D ; the triangle A B D shall be such that each of the angles A B D, A D B shall be double of B A D.

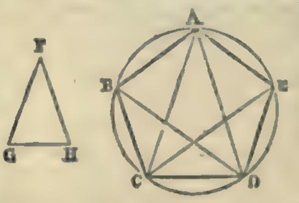
Draw D C ; and about the triangle A C D describe the circle A C D ; then because * Const. $A B \cdot B C = A C^2$,* and A C = B D, ∴ $A B \cdot B C = B D^2$, ∴ B D *touches* the cir- † 37 III. cle† A C D in D, ∴ the angle B D C = D A C ;* * 32 III. to each of these add C D A, ∴ B D A = D A C + C D A ; but the exterior † 32 I. angle B C D = D A C + C D A,† ∴ B D A = * 5 I. B C D ; but B D A = B, because A B = A D,* ∴ B = B C D, ∴ the three angles D B A, B D A, B C D, are equal to one another. Again, because the angle * 6 I. D B C = D C B, D C = D B ;* but D B was made = C A, ∴ C A = C D, ∴ the angle C D A = † 5 I. C A D,† ∴ C D A + C A D = twice C A D ; * 32 I. but B C D = C D A + C A D,* ∴ B C D = twice C A D ; but B C D = B D A = B, as before proved, ∴ each of the angles B D A, D B A is double of B A D, ∴ *an isosceles triangle* A B D *has been described, having each of the angles at the base double of the third angle.* Which was to be done.



PROPOSITION XI.—PROBLEM.

To inscribe an equilateral and equiangular pentagon in a given circle (A B C D).

Describe an isosceles triangle F G H, having each of * 10 IV. the angles G, H, double of F ;* and in the circle inscribe a triangle A C D, equiangular to the triangle F G H, so that the angle C A D may be † 2 IV. = F ;† then each of the angles A C D, A D C is double of C A D. Bisect A C D, A D C, by the straight lines C E, * 9 I. D B ;* and draw A B, B C, D E, E A. A B C D E shall be the pentagon required. Because each of the angles A C D, A D C is double of C A D, and that they are bisected by C E, D B, ∴ the five angles D A C, A C E, E C D, C D B, B D A are equal to one another ; ∴ the five arcs A B, † 26 III. B C, C D, D E, E A are equal to one another,† ∴ the lines A B, B C, C D, D E, E A are equal to one * 29 III. another,* ∴ the pentagon A B C D E is *equilateral*. It is also *equiangular*, for since the arc A B = the arc D E, if to each B C D be added, the whole A B C D = E D C B ; but these arcs subtend the angles † 27 III. A E D, B A E, ∴ A E D = B A E.† For a like reason each of the angles A B C, B C D, C D E = B A E or A E D ; ∴ the pentagon is *equiangular*, ∴ *in the given circle an equilateral and equiangular pentagon has been described.* Which was to be done.



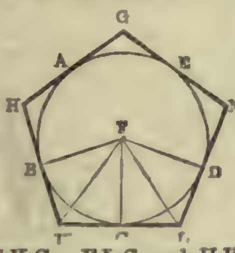
PROPOSITION XII.—PROBLEM.

To describe an equilateral and equiangular pentagon about a given circle (A B C D).

Let the vertices of a pentagon, inscribed in the circle, by last proposition, be at A, B, C, D, E ; so that the arcs A B, B C, C D, D E, E A are equal ; and through these points draw G H, H K, K L, L M, M G, touching

* 17 III. the circle :* the figure GHKLM shall be the pentagon required.

From the centre F draw FB, FK, FC, FL, FD. Then because KL touches the circle in C, FC is perpendicular † 18 III. to KL,† ∴ the angles at C are right angles : for a like reason the angles B, D are right angles. And because FCK is a right angle, $FK^2 =$ * 47 I. $FC^2 + CK^2$:* for a like reason $FK^2 = FB^2 + BK^2$, ∴ $FC^2 + CK^2 = FB^2 + BK^2$; but $FB^2 = FC^2$, ∴ $BK^2 = CK^2$, ∴ BK = CK. Again : because FB = FC, the two sides FB, FK = the two FC, FK ; and BK = CK, as just proved, ∴ the angle BFK = † 8 I. CFK,† and BKF = CKF, ∴ BFC = *twice* CFK, and BKC = *twice* CKF. For a similar reason CFD = twice CFL, and CLD = twice CLF : and because the arc BC = arc CD, the angle BFC = * 27 III. CFD :* and BFC = twice CFK, and CFD = twice CFL, ∴ CFK = CFL ; ∴ in the two triangles FKC, FLC, there are two angles of the one equal to two of the other, each to each, and the side FC, adjacent to equal angles in each, is common to both, * 26 I. ∴ KC = LC,* and the angle FKC = FLC, and KL is twice KC. In a similar manner it may be shown that HK is twice BK, and consequently, since it was proved that BK = KC, and that KL = twice KC, and HK = twice BK, HK = KL. In like manner it may be shown that GH, GM, ML are each = HK or KL : ∴ the pentagon GHKLM is *equilateral.* It is also *equiangular* ; for, since the angle FKC = FLC, and HKL = twice FKC, and KLM = twice FLC, as already proved, ∴ HKL = KLM. And in like manner it may be shown that each of the angles KHG, HGM, GML is = HKL or KLM ; ∴ the five angles GHK, HKL, KLM, LMG, MGH, being equal to one another, the pentagon is *equiangular, and it is described about the circle* A B C D. Which was to be done.

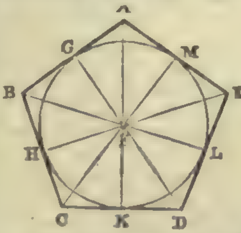


PROPOSITION XIII.—Problem.

To inscribe a circle in a given equilateral and equiangular pentagon (A B C D E).

Bisect the angles BCD, CDE by the straight lines, * 9 I. CF, DF ;* and from the point F, in which they meet, draw FK perpendicular to one of the sides ; then if with F as centre and FK as radius a circle be described, it will touch every side of the pentagon.

† Hyp. Draw FB, FA, FE ; then since BC = CD,† and CF is common to the triangles BCF, DCF, the two sides BC, CF = DC, CF each to each ; and the * 4 I. angle BCF = DCF, ∴ BF = FD,* and the angle CBF = CDF. And because CDE = twice † Const. CDF,† and that CDE = CBA, and CDF = CBF, as just proved, ∴ CBA = twice CBF, ∴ ABF = CBF, ∴ ABC is *bisected* by BF. In a similar manner it may be demonstrated that the angles BAE, AED are bisected by FA, FE. From F draw FG, FH, FL, FM perpendicular to AB, BC, DE, EA ; then because the angle HCF = KCF, and FHC = FKC, being right angles, ∴ in the triangles FHC, FKC, two angles of the one are equal to two of the other, each to each ; and the side FC opposite to one of the equal angles in each is common to both, * 26 I. ∴ FH = FK.* In like manner it may be proved that FL, FM, FG are each = FK, or FH, ∴ the five FG, FH, FK, FL, FM, are equal to one another, ∴ the circle described from centre F with either of them for radius, will pass through the extremities of all ; it will moreover *touch* AB, BC, CD, DE, EA ; since the angles at G, H, K, L, M, are right angles ;† † 16 III. ∴ *the circle is inscribed in the pentagon* ABCDE. Which was to be done.

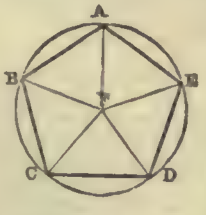


PROPOSITION XIV.—Problem.

To describe a circle about a given equilateral and equiangular pentagon (A B C D E).

Bisect the angles BCD, CDE by the straight lines * 9 I. CF, DF ;* and with the point F, in which they meet, as centre, and either of them as radius, if a circle be described, it will be that required.

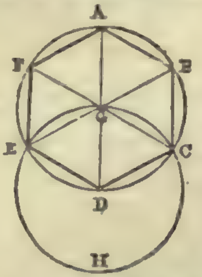
Draw FB, FA, FE. It may be demonstrated, as in the preceding proposition, that the angles CBA, BAE, AED are bisected by FB, FA, FE ; and because the angle BCD = CDE, and that FCD is half BCD, and CDF half CDE, ∴ FCD = † 6 I. FDC, ∴ CF = FD.† In like manner it may be demonstrated that FB, FA, FE are each = FC or FD, ∴ the five FA, FB, FC, FD, FE are equal to one another ; and ∴ the circle described from centre F, with either of them for radius, will pass through the extremities of all, and will ∴ *be described about the pentagon* ABCDE. Which was to be done.



PROPOSITION XV.—Problem.

To inscribe an equilateral and equiangular hexagon in a given circle (A C D F).

* 1 III. Find the centre G of the circle,* and draw the diameter AGD ; from D as centre with radius DG, describe the circle EGCH ; draw EG, CG, and prolong them to B, F ; and draw AB, BC, CD, DE, EF, FA ; ABCDEF shall be the equilateral and equiangular hexagon required. Because G is the centre of the circle ACDF, GE = GD ; and because D is the centre of the circle EGCH, DE = DG, ∴ GE = ED, and the triangle EGD is equilateral, ∴ the angles EGD, GDE, DEG, † 5 I. C. are equal to one another ;† and as they are * 32 I. together equal to two right angles,* ∴ EGD is the third part of two right angles. In a similar manner it may be demonstrated that DGC is the third part of two right angles ; and because GC makes with EB the adjacent angles EGC, CGB, equal to two right † 13 I. angles,† the remaining angle CGB is also the third part of two right angles, ∴ EGD, DGC, CGB, are equal to one another ; and to these are equal the vertical * 15 I. or opposite angles BGA, AGF, FGE ;* ∴ the six angles at G are equal to one another ; consequently the six arcs which subtend them are † 26 III. equal,† and ∴ the six * 29 III. chords of these arcs,* ∴ the hexagon ABCDEF is *equilateral.* It is also *equiangular;* for since the arc AF = ED, add ABCD to each ; ∴ the whole arc FABCD = EDCBA ; and the angle FED stands upon FABCD, and AFE upon EDCBA, ∴ AFE = FED.† † 27 III. In a similar manner it may be demonstrated that the other angles of the hexagon are each of them = AFE, or FED ; ∴ the hexagon is *equiangular ; and it is inscribed in the given circle* ACDF. Which was to be done.

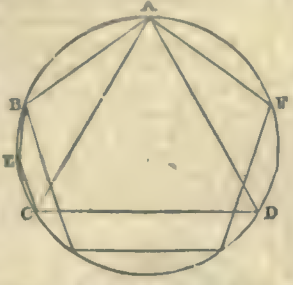


Cor.—From this it is manifest that a side of the hexagon is equal to the radius of the circle. And if through A, B, C, D, E, F lines be drawn touching the circle, an equilateral and equiangular hexagon will be described about it, as may be demonstrated from what has been said of the pentagon : and likewise a circle may be inscribed in a given equilateral and equiangular hexagon, and circumscribed about it, by a method like to that used for the pentagon.

PROPOSITION XVI.—Problem.

To inscribe an equilateral and equiangular quindecagon, or fifteen-sided figure, in a given circle (A B C D).

Let A C be a side of an equilateral triangle inscribed * 2 IV. in the circle,* and A B a side of an equilateral and equiangular pentagon inscribed in the same:† † 11 IV. then of such parts as the whole circumference contains *fifteen*, the arc A B C, being the third part of the circumference, contains *five*; and the arc A B, which is the fifth part of the circumference, contains *three*; ∴ B C, their difference, contains *two* of the same parts. Bisect * 30 III. B C in E,* ∴ B E, E C are each the fifteenth part of the whole circumference; ∴ if the straight lines B E, E C, be drawn, and straight lines equal to them be placed round, in the whole circle, an *equilateral* quindecagon will be inscribed in it; and that it is *equiangular* is plain, because each angle stands upon an arc, equal to the whole circumference diminished by the two arcs which its sides subtend, and which arcs are by construction equal, ∴ *an equilateral and equiangular quindecagon is inscribed in the circle.* Which was to be done.



And in the same manner as was done in the pentagon, if through the points of division made by inscribing the quindecagon, straight lines be drawn touching the circle, an equilateral and equiangular quindecagon will be described about it. And likewise, as in the pentagon, a circle may be inscribed in a given equilateral and equiangular quindecagon, and circumscribed about it.

REMARKS ON BOOK IV.

The propositions in this fourth book are all *problems*, relating chiefly to the construction of regular polygons in and about the circle. From the fourth we learn this theoretical truth; namely, that the straight lines bisecting the three *angles* of a triangle all meet in a point—the centre of the inscribed circle; and from the fifth, that the straight lines bisecting the three *sides* of a triangle also meet in a point—the centre of the circumscribing circle.

As the second proposition shows that a triangle equiangular to any proposed triangle may be inscribed in a circle, we know that an equilateral triangle may be inscribed; and we thus infer that the circumference of a circle may be geometrically divided into *three* equal parts. By bisecting each of these three equal arcs (Proposition XXX., Book III.), we may divide the circumference into *six* equal parts, as otherwise shown in Proposition XV.; and by another series of bisections, into *twelve* equal parts, and so on. The division of the *whole* circumference into *six* equal parts is obviously the division of the semi-circumference into *three;* the division of the whole into *twelve* equal parts is the division of the fourth of it—that is, of a *quadrant*, into *three* equal parts, and so on. We thus see that an arc equal to a fourth part, or to an eighth part, a sixteenth part, &c., of the entire circumference, may be divided geometrically into *three* equal parts. But the general problem to divide *any* arc of a circle into three equal parts, or, which amounts to the same thing, to *trisect an angle*, is a problem that all the geometry in Euclid has been found hitherto inadequate to accomplish. It is one of the great outstanding problems of antiquity; and more thought and labour have been expended upon it, during the last two thousand years, than perhaps any other problem has ever called into exercise. If you now learn this fact for the first time, you will be surprised that a thing apparently so simple as to divide an angle or an arc of a circle into *three* equal parts, should have been found to be a matter of such surpassing difficulty as to have baffled the efforts of the greatest geometers from the time of Euclid to the present day. We draw attention to it here mainly for the purpose of discouraging any fresh attempts by students in geometry to trisect an angle. Novices are very apt to enter upon such attempts from a vague notion that a successful solution of the problem would, in some way or other, advance science. But geometricians know better; and by *them* the inquiry has long been abandoned, not only as a hopeless one, but also as a comparatively useless one. The theorist has no need of this solution, because he is never stopped in any mathematical investigation from the want of it; the practical man has no need of it, for he can avail himself of mechanical methods which effect the trisection of an angle that departs from strict geometrical accuracy, by an amount of error too minute to be detected by his senses, though aided by the most finished instruments of measurement; and these methods he would continue to employ even were the problem ever to be brought within the scope of elementary geometry. You see, therefore, that the inquiry is one of pure curiosity, and nothing more; since the successful issue of it could supply no want either in theory or in practice.

By aid of certain curves beyond the limits of Euclidean geometry, the trisection of an angle may be readily effected, as will be hereafter shown; but what geometricians have been in quest of, is the accomplishment of this trisection by aid merely of the straight line and the circle—the only lines recognised by Euclid. Some have ventured to *say* that, with this limitation as to materials, the problem is impossible; but who can *prove* this? The third part of an angle of course *exists;* and there is therefore no just grounds for affirming that it cannot be found, except by the aid of machinery external to geometry. Till the beginning of the present century, there were the very same grounds for affirming that the circumference of a circle could not be divided into *seventeen* equal parts by common geometry; but in 1801, Gauss, a distinguished German mathematician, showed how this could be effected without going beyond the limits of elementary geometry. The discovery, though of no theoretical or practical value, made a good deal of noise at the time. The work containing this, and several analogous problems, was translated into French by Delisle, under the title of *Recherches Arithmétique;* but the division of the circumference into *seven* equal parts; or, which is the same thing, the problem to inscribe a regular *heptagon*, or seven-sided figure, in a circle, like the trisection of an arc, is not yet accomplished.

From what has now been said, you perceive that Euclid enables us (Proposition II.) to divide the circumference of a circle into 3, 6, 12, &c., equal parts; as also (Proposition VI.) into 4, 8, 16, &c., equal parts; and again (Proposition XI.) into 5, 10, 20, &c., equal parts; and finally (Proposition XVI.), into 15, 30, 60, &c., equal parts;—all these subdivisions of the circumference being obtained by the propositions here referred to, and the repeated application of Proposition XXX., Book III. As just observed, Gauss has extended Euclid's instructions, and taught us how to divide the circumference into 17, 34, 68, &c., equal parts; as also into other parts, in like manner excluded from Euclid's divisions—namely, into 257, 65537, &c.; each part, by repeated bisections, giving rise to a new series of subdivisions as above. And by combining some of these with the subdivisions of Euclid—as Euclid himself has combined the divisions into three parts and into five parts, in Proposition XVI., to get the division into fifteen parts—other sections of the circumference may be obtained. But the actual constructions, even in the simplest of these additional cases—the division, namely, into seventeen equal parts, are so very complicated as to be of no avail in actual practice; they are interesting merely as showing that this part of the Euclidean geometry is really susceptible of extension; and we have occupied your attention in this brief account of the speculations of geometers in reference to the division of the circumference, chiefly that you might see sufficient reason why so few of these divisions are accomplished by Euclid, and why he should pass at once from the six-sided polygon (Proposition XV.) to that of fifteen sides (Proposition XVI.), without anything being said as to the intermediate polygons of 7, 9, 11, 13, and 14 sides respectively. You now know that the omission arose from his inability to inscribe any of these polygons in a circle.

ON THE QUADRATURE OF THE CIRCLE.

Intimately connected with the researches just adverted to, is the problem of the quadrature of the circle, which, like that of the trisection of an angle, has for ages occasioned the fruitless expenditure of much valuable time and thought. We shall endeavour to give you here some notion of the meaning and object of this celebrated problem, not only because it is a matter of such historical interest, that you ought to know something about it; but because, moreover, in certain elementary writings on the subject, the thing is put before the student in an erroneous form; and, consequently, a wrong impression as to the real character of the problem is conveyed.

The problem of *squaring the circle*, as it is popularly called, has a twofold meaning—namely, the *geometrical* quadrature, and the *numerical* quadrature. In the first of these senses the problem is to construct a square that shall be equal in surface to a given circle; in the second, the problem is to express the numerical measure of the surface of a circle when the measure or length of its diameter is given in numbers. The former of these is the more ancient form of the problem; and all that can be fairly said of it is—as was said of the trisection of an angle—that the solution has never been effected; a square equal to a circle has never yet been constructed. We have no grounds for affirming that this construction is *impossible*, for the equivalent square *exists*. You may readily satisfy yourself of this by the following reflections:—The square on the *diameter* of the circle would be too great, and the square on the chord from an extremity of the diameter, to cut off a fourth part of the circumference, would be too small, since the former square would be circumscribed about the circle, and the latter inscribed in it; the circle therefore is in magnitude somewhere *between* the two. Conceive, now, the smaller of these two squares to expand continuously, still retaining its character as a square, till it arrives at the larger square in magnitude; then, as all intermediate magnitudes are thus reached and passed through, and as the circle is *one* of these intermediate magnitudes, it necessarily follows that our expanding square must, at a particular stage of its progress, have exactly attained the magnitude of the circle; so that if its progress could be arrested at that stage, or—to drop this idea of progression—if the individual square could be isolated and exhibited, the problem of the geometrical quadrature of the circle would be solved. It is plain, therefore, that there is nothing visionary or absurd in the search after this square, as if it were a thing that had no existence; although some very able geometers have, strangely enough, condemned the inquiry on these grounds. The only sound reasons for abandoning the investigation are these two; namely—first, that the problem has been earnestly and laboriously attempted, by the profoundest geometers, for thousands of years, and *they* have been obliged to abandon it in despair; and secondly, that the successful solution of it would be of no theoretical or practical value if furnished. As far as *utility* is concerned, the other form of the problem of the quadrature of the circle is by far the more important; that is, to discover the numerical measure of the surface of a circle from the measured length of its diameter being given. But, under this aspect of it, the accurate solution of the problem is really impracticable; it can be *proved* to be so; and the proof will be given in a subsequent part of the present mathematical course. It is just as impracticable as it is to assign accurately the square-root of 2; and, in fact, this square-root does repeatedly enter into the approximative numerical process. You will require to know something of *Proportion*, in the sense in which the term is employed by Euclid, before that process can be fully explained to you. This subject, together with the sixth book of Euclid, forms the object of the chapter next following; and at the end of it you will find the principles upon which the approximative quadrature of the circle depends, clearly exhibited; and the mode of computation pointed out. The plan is to compute first the surface of the inscribed four-sided equilateral figure or square; then the inscribed eight-sided figure; then the sixteen-sided figure; and so on, till the inscribed polygon differs insensibly from the circle. *How* the surfaces of these successive polygons are computed one after another, must be deferred for the present; but some of the *results* are exhibited in the margin, where the radius of the circle, whose surface is approximated to, is regarded as 1; that is, 1 inch, 1 foot, 1 yard, or *one* any measure.

No. of sides.	Surface of pol.
4	2
8	2·8284271
16	3·0614674
32	3·1214451
64	3·1365485
128	3·1403311
256	3·1412772
512	3·1415138
1024	3·1415729
2048	3·1415877
4096	3·1415914
8192	3·1415923
16384	3·1415925
32768	3·1415926

It appears, from the above table, that the surface of an inscribed regular polygon of 32768 sides is 3·1415926, which is correct as far as the decimals extend; this number, therefore, may be taken for the numerical measure of the circle itself; for it is plain that a regular polygon of so many thousand sides would be undistinguishable from, and therefore *practically* identical with, the circle in which it is inscribed. But, by continuing to double the number of sides of the polygon, the approximation to the circle may be pushed to any extent. De Lagny computed the decimals true to 128 places; and eighty more have been recently added on by Dr. Rutherford. It is observed by Montucla, that if we suppose a circle whose diameter is a thousand million times the distance of the sun from the earth, the *approximative* measure of the circumference, as computed by De Lagny, would differ from the *true* measure by a length less than the thousand millionth part of the thickness of a hair.

There is obviously no use, as far as practical purposes are concerned, in extending the approximation to anything like this extreme degree of nearness. The earlier computers were no doubt induced to carry on the decimals in the expectation that they would at length terminate; but, as already observed, and as will be hereafter proved, the decimals will go on for ever. It is right to infer, therefore, that the *exact* numerical measure of the surface of a circle does not exist, though a geometrical square equal to it does exist. The exact numerical value of $\sqrt{2}$ does not exist; yet $\sqrt{2}$ represents the diagonal of a square whose side is 1, which diagonal is of course an existent geometrical line.

EXERCISES ON BOOKS I.—IV.

1. Prove that if a pair of opposite angles of a quadrilateral be equal to two right angles, a circle may be described about it.—(Converse of Proposition XXII., Book III.)

2. If the diagonals of a quadrilateral divide one another, so that the rectangle contained by the parts of the one is equal to the rectangle contained by the parts of the other, then a circle may be described about the quadrilateral: required the proof.

3. If two opposite sides of a quadrilateral be prolonged to meet, and if it be found that the rectangle contained by one of the lines thus produced, and the part produced, are equal to the rectangle contained by the other line and the part produced, then a circle may be described about the quadrilateral: required the demonstration.

These two theorems are virtually the converses of Propositions XXXV. and XXXVI. of Book III.

4. If a circle be described about the square B E (see the Diagram to Proposition XLVII., Book I.), its circumference shall pass through the point where A D, F C intersect, and also through the point where A E, K B intersect: required the proof.

5. If an equilateral triangle be constructed on one side

of a given line, and on the other side two equilateral triangles, one on each half of the line, then the two lines drawn from the vertex of the larger triangle to the vertices of the smaller triangles will trisect the given line: required the proof.

6. Divide a given triangle into three equal parts by lines drawn from the vertices of the triangle to a point within it.

7. Inscribe a circle in a rhombus.

8. Prove that the square circumscribing a circle is double of the square inscribed in the same.

9. If a circle be inscribed in a right-angled triangle, and another be circumscribed about it, prove that the sum of the sides containing the right angle will be equal to the sum of the diameters.

10. From a given point in the arc of a circle, to draw a tangent thereto without first finding the centre of the circle.

11. The straight line bisecting any angle of a triangle cuts the circumference of the circumscribing circle in a point which is equidistant from the extremities of the opposite side, and from the centre of the inscribed circle: required the proof.

12. If from any point within an equilateral and equiangular polygon perpendiculars be drawn to the several sides, the sum of these perpendiculars will always be the same, wherever the point from which they are drawn be taken.

13. Through a given point within a circle it is required to draw the shortest chord possible.

CHAPTER V.

PROPORTION.

A TREATISE INTENDED AS A SUBSTITUTE FOR EUCLID'S BOOK V.

INTRODUCTORY.—In the foregoing portion of elementary geometry, we have given you the "Elements of Euclid," substantially, in all their integrity: the modifications we have introduced are for the most part merely of a verbal character; but while condensing the language we have been careful to preserve the spirit and rigour of the original. In the few instances in which we have thought an improvement might be introduced, or a defect supplied, we have not hesitated to offer the suggestion, and to propose the emendation: what little is done in this way is sufficiently detailed in the Remarks appended to the several books. You will, of course, submit these to your own judgment—always remembering that in matters connected with geometery, nothing is to be taken upon trust; mere opinion, unsupported by reasonings—reasonings which elevate it into proof—must be regarded, *in this subject*, as of but little worth.

We are now going to depart altogether from Euclid's method of exposition, and to place before you a treatise on Proportion, constructed on a different plan. We have come to this determination only after mature deliberation. It would, of course, be a much easier task to transfer Euclid's fifth book into these pages. We could find very little to remark upon in it, as the ancient Geometer has displayed so much sagacity and penetration in this, the most elaborate of all his writings, that he has left to the moderns little or no room for improvement: it must be studied just as it is (in Simson's restoration), or else be superseded in instruction by a treatise of equal generality, but of geater simplicity. You will understand, therefore, that we do not displace Euclid's fifth book because of its imperfections, or because of its inadequacy to completely accomplish its objects; but solely because of its great *difficulty* to a beginner. We will endeavour to give you here some notion of the cause of this difficulty. The subject of Euclid's fifth book is PROPORTION—*universal* proportion: that is, not *numerical* proportion merely, but proportion in reference to all magnitudes and quantities whatever, whether numbers, lines, surfaces, solids, or concrete quantities of any kind. With proportion *in numbers* you are already familiar:—this will be a help. You are also somewhat acquainted with proportion in *Algebra:* this will be a greater help; for proportion in Geometry really accomplishes no more for things in general, than the same doctrine in arithmetic and algebra accomplishes for what the notation of those sciences specially represents; and if this kind of proportion would do for geometry, the fifth book of Euclid would become a very easy matter indeed. But the obstacle to this is, that geometrical magnitudes, when compared together, are in many cases found to be *incommensurable;*—that is to say, two such magnitudes may be quite incapable of a common measurement—they may be of a nature not to admit of being *both* measured by one and the same unit of measurement, however minute the measuring unit be taken; and, consequently, *both* cannot be represented by *numbers.* We have already adverted to an instance of this kind* in the side and diagonal of a square, and to another in the diameter and circumference of a circle. You may divide the side of a square into as many equal parts as you please—from two parts to as many millions. In every case each part is, of course, a *measure* of the side; so that by applying such part, progressively, from one extremity of the side onwards towards the other extremity, that other extremity would at last be accurately reached.

But if the same measure, however small it be taken, be applied in like manner to the diagonal, the remote extremity of *it* can never be accurately reached; either an unmeasured *smaller* portion will still be left, or else the applied measure will overlap and project *beyond* that extremity. It is thus that these two lines are *incommensurable.* That they are so, could not have been found out by such practical or experimental tests as those here adverted to for illustration; they must be proved to be so by geometrical reasoning.

It may be as well to caution you here that you must not speak of a line or quantity, *by itself*, as being incommensurable; this would be absurd. The diagonal of a square is not itself incommensurable, since it has, of course, its third part, fourth part, hundredth part, &c., and is therefore *measurable* by each of those parts; but as none of them will *also* measure the *side*, the two, considered together, are incommensurable; there exists no measure common to *both.* In the same way in reference to the circle—the circumference itself is not incommensurable any more than the diameter; for each has its fourth part, sixth part, &c.; but it is incommensurable with its diameter; no length whatever can measure *both.* The circumference of a circle may be ten feet and some fraction of a foot; the diameter will necessarily be more than three feet; but the exact fraction of a foot, besides, it is not in the power of numbers to express.

Now although Euclid makes no mention of incommensurable quantities in his fifth book, he was well aware of their existence; and therefore, to render his theorems on proportion general, he had to take care that this class of quantities should be comprehended in his reasonings. But proportion limited to numbers, or to the symbols for numbers, would necessarily exclude incommensurables; he therefore had to proceed quite independently of arithmetic, and to secure to his propositions such a universality that each theorem should rigorously apply, whether the quantities or magnitudes spoken of be measurable, or beyond the powers of numerical representation. He has executed his difficult task with consummate ability; for, as Dr. Barrow remarks, "there is nothing, in the whole body of the Elements, of a more subtile invention—nothing more solidly established, and more accurately handled, than the doctrine of proportionals."

---

* See *ante*, p. 569.

It is on account of the subtleties here adverted to, and which are of too refined a character for the generality of young students to comprehend, that we have resolved to replace the fifth book by the following treatise. We cannot promise that you will find the study of it *easy;* but it will certainly be much *less difficult* than the corresponding portion of Euclid's work; and you will enter upon it with considerable advantage, if you have read Arithmetical and Geometrical Progression in the chapter on Algebra.

DEFINITIONS.

I. Of two unequal magnitudes, of the same kind, the greater is said to *contain* the less as many times as there are parts in the greater equal to the less.

This definition is intended to convey the sense in which the word *contain* is to be understood in what follows. You will carefully observe that the term is not restricted by any condition as to whether or not the greater quantity leave any *remainder* after taking the less from it as often as possible. Thus 8 is said to contain 2 as often as 9 contains it, though there is a remainder in the latter case, and no remainder in the former.

II. One magnitude is said to be a *multiple* of another when it is equal to a certain number of times that other *exactly.* And the less of the two is in this case said to be a *sub-multiple* of the greater, or a *measure* of the greater.

Thus 8 is a multiple of 2, because 8 is equal to a certain number of times 2 *exactly;* namely, *four* times 2. And 2 is a sub-multiple of 8, or, as we should say in arithmetic, a *factor* of 8. Remember that a sub-multiple, or *measure* of any magnitude, is a smaller magnitude of the same kind which measures the former (the *multiple*) *exactly*, without leaving any remainder. 2 is not a sub-multiple or measure of 9; which is the same as saying, that 9 is not a multiple of 2.

III. Magnitudes—two or more—which have a *common measure*—that is, which are multiples of some other magnitude—are said to be *commensurable.* But if it be *impossible* that any such common measure can exist, then the magnitudes are said to be *incommensurable.*

All sets of abstract numbers, and of concrete quantities, like in kind, that can be accurately denoted by numbers, are commensurable; that is, they have a common measure. The expression, "common measure," as employed in arithmetic and algebra, is not synonymous with the geometrical meaning. In arithmetic we should say that the pairs of numbers 3, 7; 4, 11; 5, 12, &c., have no common measure; but even here a qualifying exception is always tacitly made: it is this—namely, *except unit.* All whole numbers contain 1 an exact number of times; though it is agreed in arithmetic that 1 shall not be recognised as a common measure. Geometry makes no such exception: whatever quantity is contained in another, an exact number of times, is a measure of that other. In like manner, 3½, 7¼, would not be regarded as having a common measure in arithmetic; yet as the first number contains ¼ exactly 14 times, and the second contains ¼ exactly 29 times, ¼ is a common measure of the two numbers according to the above definition of the term. And whatever numbers be compared together, whether they be whole or fractional, it will be found that there always exists some smaller number—either whole or fractional—that will exactly measure both. Suppose, for instance, the proposed numbers, when brought to a common denominator, have (say) 12 for the common denominator, then each denotes so many *twelfths:* that is, $\frac{1}{12}$ is a common measure of both. We do not say anything here about such expressions as $\sqrt{2}$, $\sqrt{3}$, $\sqrt{7}$, &c.; geometrical rigour forbids our calling what these symbols stand for, definite numbers, as they involve an endless series of fractions or decimals, and can only be valued *approximately;* yet they may be accurately represented by *lines*, as Euclid has himself shown in a Book not now read (Book X.) We could not speak of any number being contained in $\sqrt{2}$ a certain number of times *exactly*, because $\sqrt{2}$ itself is not determinable exactly.

IV. *Equimultiples*, or *like multiples*, of two or more magnitudes, are those larger magnitudes which contain those of which they are multiples—each of each—*the same number of times.*

For instance, the numbers 8 and 12 are equimultiples of 2 and 3; for the former contain these, respectively, the same number of times—namely, *four* times. In like manner, 7½ and 10 are equimultiples of 2½ and 3⅓; for the former numbers contain these, respectively, *three* times.

V. And *like sub-multiples* are those which are contained in their respective multiples the same number of times.

Thus, in the instances just adduced, 2 and 3 are like sub-multiples or like measures of 8 and 12; 2½ and 3⅓ are like sub-multiples or measures of 7½ and 10.

VI. Four magnitudes are said to be *proportionals*, or to form a *proportion*, when the first cannot be contained in any multiple of the second, oftener than the third is contained in a *like multiple* of the fourth, nor the third in any multiple of the fourth, oftener than the first in a *like multiple* of the second.

The first and third of four such magnitudes are called *antecedents*, and the second and fourth their *consequents.* The definition affirms that an antecedent must be contained in each multiple of its consequent as often as the other antecedent is contained in a like multiple of its consequent, but not oftener.

VII. When four magnitudes are in proportion, the first antecedent is said to have the same *ratio* to its consequent that the second antecedent has to *its* consequent.

This term *ratio* has been the source of very considerable embarrassment to Geometers since the time of Euclid, and has been productive of much metaphysical disquisition and controversy. We think that on this subject, as well as in reference to the theory of parallel lines, mathematicians too often overlook the fact that the fundamental notions of geometry really exist in the mind anterior to, and independently of, the definitions of the science. These, for the most part, do not originate those notions, but only give to them the necessary degree of clearness and precision. If one pair of magnitudes be submitted to our contemplation, and then another pair be brought into comparison with them, as well as with each other, the mind is at once capable of forming a notion as to whether the *relative magnitudes* of the individuals of the first pair be the same or not as the relative magnitudes of those of the second pair: the *absolute* magnitudes of the individuals of one pair may be very different from the absolute magnitudes of those of the other pair; yet the former two may have the same *relation to one another*, as to magnitude, as the latter two; and the mind is quite capable of recognising and understanding this sameness of relation, or of *ratio*, as it is called above, before any *name* is given to the conception. It is this *equality of ratios* of two magnitudes brought into comparison with other two, that renders the *four* proportionals.

That the foregoing definition of proportion (Def. VI.) includes numerical proportion, in Arithmetic, will be obvious upon a little consideration. Proportion limited to numbers may be defined thus:—

Four numbers are proportionals when the first is contained *exactly*, as often in some multiple (any *one* multiple being sufficient) of the second, as the third is contained in a *like* multiple of the fourth.

It is plain that if this condition have place, the four numbers must be proportionals according to the common arithmetical notion; for it follows of necessity, that the quotient of the second by the first must then be the same as that of the fourth by the third, and consequently that the quotient of the first by the second must be the same as that of the third by the fourth.*

Definition VI., above, is, however, free from the restriction implied in the term *exactly*, which is introduced here into the particular case of it, applying exclusively to *numerical* proportion; since the general form of the definition admits of such restrictive qualification when numbers only are concerned; incommensurables being then excluded.

Four magnitudes not fulfilling the conditions of Definition VI. would evidently violate even this arithmetical condition of proportion. There can be no such things as proportionals out of the restrictions of the former definition; so that all proportionals, whether among commensurables or incommensurables, must be included in the general Definition VI.

VIII. The first and last of four proportionals are called the *extremes*, and the two intermediate ones the *means.*

IX. The magnitudes themselves are called the *terms* of the proportion; and those are called *homologous* or *like* terms which have the same *name;*—the *antecedents* forming one pair of homologous terms, and the *consequents* another pair.

X. Magnitudes, more than two, are said to form a *continued proportion* when each *consequent* in succession is taken for the *antecedent* of the term next following.

Thus, if A is to B, as B is to C, as C is to D, &c.; then A, B, C, &c., are in continued proportion.

XI. If the continued proportionals be but *three* in number, the middle one is called the *mean* term, and the others the *extremes.*

AXIOMS.

I. Equimultiples of the same magnitude, or of equal magnitudes, are equal to one another; so also are equi-sub-multiples.

II. A multiple of a greater magnitude exceeds a like multiple of a less; and a sub-multiple of a greater exceeds a like sub-multiple of a less.

---

* See Arithmetic, p. 416.

III. The magnitude of which a multiple or sub-multiple is greater than a like multiple or sub-multiple of another, is greater than that other.

IV. Of any two magnitudes of the same kind, a multiple of one may be taken so great as to exceed the other.

Marks and Signs used for Abbreviation.

1. To express that four magnitudes, A, B, C, D, are proportionals, they are arranged thus: $A : B :: C : D$; and this expression is read, "as A is to B, so is C to D;" or, "A is to B, as C is to D."

2. And to express that magnitudes A, B, C, D, E, &c., form a series of continued proportionals, they are arranged thus: $A : B :: B : C :: C : D :: D : E$, &c., which is read, "as A is to B, so is B to C, and C to D, and D to E," &c.

3. Besides the marks $+$ and $-$ for addition and subtraction, the mark $\backsim$ is sometimes employed, to denote the *difference* of the two quantities between which it is placed; it is useful for this purpose when it is not stated *which* of the two quantities is the greater of the two; thus $A \backsim B$ means simply the difference between A and B, or rather between the things denoted by these letters, without any assertion as to which is the greater. The double mark $\overset{+}{\backsim}$ between two quantities signifies "the sum or difference" of those quantities. Thus by $6 \overset{+}{\backsim} 2$ we should understand "8 or 4."

4. The terms "greater than" and "less than" being of frequent use in what follows, convenient symbols for them are introduced: when $>$ is placed between two quantities it implies that the first of them is *greater than* the second; and when $<$ is placed between them, it denotes that the first of them is *less than* the second. Thus $A > B$ asserts that A is *greater than* B, or that A *exceeds* B; and $A < B$ affirms that A is *less than* B, or that B *exceeds* A.

5. In the following propositions, magnitudes (whether lines, surfaces, or solids) will be represented by the capital letters, A, B, C, &c. They may, indeed, be taken to represent any quantities whatever, whether abstract or concrete; as the reasonings will be found to apply without restriction as to the nature of the things represented by the letters. But when *multiples* of these quantities are taken (that is, when they are multiplied by *numbers*), these numbers will be represented by the small letters; and, in general, by m, n, p, q.

PROPOSITION I.—Theorem.

If any number of magnitudes be equimultiples of as many others, each of each, whatever multiple any one of the former is of the corresponding one of the latter, the *same multiple* is the *sum* of all the former, and of the *sum* of all the latter.

First, let there be but *two* magnitudes mA, mB, any equimultiples whatever of two others, A, B; the *sum* of the former shall be *the same* multiple of the *sum* of the latter.

For the sum of the former is $mA + mB$; that is, $m(A + B)$; and the sum of the latter is $A + B$; and $m(A + B)$ is *the same multiple* of $A + B$, that mA is of A, or mB of B.

Next, let there be *three* magnitudes mA, mB, mC, equimultiples of the three A, B, C.

The *sum* of the former three is $mA + mB + mC$; that is $m(A + B + C)$, and the *sum* of the latter three is $A + B + C$; and $m(A + B + C)$ is *the same multiple* of $A + B + C$, that mA is of A, or mB of B, or mC of C. And in the same manner is the proposition proved, when there are four magnitudes equimultiples of other four; when there are five magnitudes, six magnitudes, or any number of magnitudes, $\therefore$ *if any number of magnitudes*, &c. Q. E. D.

PROPOSITION II.—Theorem.

If, in any proportion, an antecedent and its consequent be respectively the same as an antecedent and its consequent in *another* proportion, the remaining antecedent and consequent in the former, together with the remaining antecedent and consequent in the latter, will form a proportion.

Let the two proportions be—

$$\begin{matrix} A : B :: C : D \\ A : B :: E : F, \end{matrix} \text{ then } C : D :: E : F.$$

For (Def. VI.) m being any whole number whatever, C is contained in mD as often as A is contained in mB, but not oftener.

In like manner E is contained in mF as often as A is contained in mB, but not oftener.

Therefore C cannot be contained oftener in mD than E is contained in mF; nor can E be contained oftener in mF, than C is contained in mD; and m is any whole number whatever, $\therefore$ (Def. VI.) *the four magnitudes*, C, D, E, F, *are proportionals*, $\therefore$ *if in any proportion, &c.* Q. E. D.

PROPOSITION III.—Theorem.

If, in any proportion, equimultiples of the antecedents and equimultiples of the consequents be taken; if the multiple of one of the antecedents be greater than that of its consequent, the multiple of the other antecedent will be greater than that of *its* consequent.

Let the proportion be—

$$A : B :: C : D.$$

If $mA > nB$, then $mC > nD$, and conversely; m and n being any whole numbers whatever.

For A is contained in mA exactly m times; but, by hypotheses, nB is *less* than mA, $\therefore$ A is contained in nB *less* than m times. But (Def. VI.) C is contained no oftener in nD, than A is contained in nB, $\therefore$ C is contained in nD, less than m times.

But C is contained in mC exactly m times, $\therefore$ C is contained in mC *oftener* than it is contained in nD, $\therefore$ $mC \quad nD$.

In like manner, if the hypothesis be that $mC > nD$, may it be shown that $mA > nB$, $\therefore$ *if in a proportion*, &c. Q. E. D.

Cor.—Since m and n may be any whole numbers whatever, let each be $= 1$: then it follows that:—

In a proportion, if one antecedent be greater than its consequent, the other antecedent will be greater than its consequent.

PROPOSITION IV.—Theorem.

In any proportion, according as one antecedent is greater than, less than, or equal to its consequent, so will the other antecedent be greater than, less than, or equal to *its* consequent.

It has already been proved (Prop. III., Cor.) that if one antecedent be *greater* than *its* consequent, the other antecedent will be *greater* than *its* consequent. Let the proportion be:—

$$A : B :: C : D.$$

1st. If $A < B$, then $C < D$, and conversely. Let $B - A = P$; then a number m exists such that $mP > A$ (Ax. 4), $\therefore$ mB must contain A *oftener* than it contains B. But mD contains C *as often* as mB contains A (Def. VI.), $\therefore$ mD contains C *oftener* than mB contains B; that is, oftener than m times, $\therefore$ $C < D$. Consequently, if $A < B$ then $C < D$. And in like manner may it be shown that if $C < D$ then $A < B$.

2nd. If $A = B$ then $C = D$, and conversely.

For when $A = B$, if it were possible that $C > D$, or $C < D$, or, when $C = D$, if it were possible that $A > B$, or $A < B$, the foregoing conclusions would be contradicted, $\therefore$ *in any proportion, &c.* Q. E. D.

PROPOSITION V.—Theorem

If four magnitudes be such, that whatever equimultiples of the antecedents, and whatever equimultiples of the consequents be taken, the multiple of one antecedent cannot be greater than that of its consequent, without the multiple of the other antecedent being greater also than that of its consequent, the four magnitudes are proportionals.

Let the four magnitudes be A, B, C, D. If they are *not* proportional, one of the antecedents, as A, must be contained in some multiple mB of its consequent *oftener* than C is contained in mD (Def. VI.) Therefore, p being any whole number, A must be contained oftener in pmB than C is contained in pmD.

Let nA be the *greatest* multiple of A that does not *exceed* pmB; then nA is not $> pmB$, and A is contained in nA, and in pmB the same number of times, namely, n times. Therefore C is contained in pmD less than n times. But C is contained in nC exactly n times, $\therefore$ $nC > pmD$. Consequently, of the four magnitudes, equimultiples of the antecedents, and equimultiples of the consequents, may be taken, as below :—

$$\begin{array}{cccc} A : & B : : & C : & D \\ nA & pmB & nC & pmD \end{array}$$

such that $nC > pmD$, and yet nA *not* $> pmB$: but, by hypothesis, this is impossible: therefore the magnitudes cannot be other than proportionals; $\therefore$ *if four magnitudes*, &c. Q. E. D.

PROPOSITION VI.—THEOREM.

In any proportion, if like multiples of the antecedents, and like multiples of the consequents, be taken, the results will form a proportion.

Of the four proportionals, let equimultiples of antecedents and of consequents be taken as below, m, n, p, and q being *any* whole numbers :—

$$\begin{array}{cccc} A : & B : : & C : & D \\ mA & nB & mC & nD \\ pmA & qnB & pmC & qnD \end{array}$$

Then (Prop. III.) if $pmA > qnB$, it must follow that $pmC > qnD$; or if $pmC > qnD$, that $pmA > qnB$. But pmA, pmC, are *any* equimultiples of mA, mC; and qnB, qnD, are *any* equimultiples of nB, nD. Consequently (Prop. V.),

$$mA : nB : : mC : nD.$$

Therefore, *in any proposition*, &c. Q. E. D

NOTE.—Either m or n may of course be *unit*; as also in every case where the multiples are unrestricted.

In Proposition V. it was demonstrated that—"If four magnitudes be such that whatever equimultiples of the antecedents, and whatever equimultiples of the consequents be taken, the multiple of one antecedent cannot be greater than that of its consequent, without the multiple of the other antecedent being greater also than *its* consequent, the four magnitudes are proportionals." It is now proved that these multiples themselves are also proportionals. Consequently (Prop. IV.), according as the first multiple is greater than, less than, or equal to the second, so will the third multiple be greater than, less than, or equal to the fourth multiple. And this is the condition which constitutes Euclid's criterion of proportional magnitudes, as embodied in his celebrated *fifth* definition, which, in the version of Playfair, is expressed as follows :—

Euclid's Definition of Proportionals (Def. V.)

If there be four magnitudes, and if any equimultiples whatsoever be taken of the first and third, and any equimultiples whatsoever of the second and fourth, and if according as the multiple of the first be greater than the multiple of the second, equal to it, or less, the multiple of the third also is greater than the multiple of the fourth, equal to it, or less; then the four magnitudes are proportionals. This definition of Euclid is deduced here as a *theorem*; but in what follows it will be referred to as "Def. V., page 573."

PROPOSITION VII.—THEOREM.

The terms of any proportion form also a proportion when they are taken INVERSELY; that is, the second term is to the first as the fourth is to the third, or the second has the same ratio to the first that the fourth has to the third.

Let the proportion be $A : B : : C : D$; then also $B : A : : D : C$.

For (Prop. VI.) $mA : nB : : mC : nD$.

And (Prop. IV.) according as nB is greater than, less than, or equal to mA, so is nD greater than, less than, or equal to mC; and m, n are any whole numbers whatever. But when this is the case in reference to four magnitudes B, A, D, C, they are proportionals. (Def. V., page 573).

$$\therefore B : A : : D : C.$$

Hence *the terms of any proportion*, &c. Q. E. D.

COR.—Therefore a consequent is contained as often in a multiple of its antecedent, as the other consequent is contained in a like multiple of its antecedent, but not oftener. (Def. VI.)

PROPOSITION VIII.—THEOREM.

In any proportion, if equimultiples of the first two terms be taken, and also equimultiples of the last two, the results will form a proportion.

Let the proportion be $A : B : : C : D$; then also

$$mA : mB : : nC : nD$$

By Def. VI., $A : B : : mA : mB$; and $C : D : : nC : nD$

But $A : B : : C : D$; $\therefore$ (Prop. II.) $C : D : : mA : mB$

and therefore, by the same prop., $mA : mB : : nC : nD$; $\therefore$ *in any proportion*, &c. Q. E. D.

PROPOSITION IX.—THEOREM.

In a proportion consisting of *homogeneous* magnitudes—that is, magnitudes all of the same kind—if one antecedent be greater than the other, the consequent of the former will be greater than the consequent of the latter.

Let the magnitudes forming the proportion $A : B : : C : D$ be all of the same kind, and let $A > C$; then also $B > D$. For let $A - C = P$; then (Ax. 4) there exists some number m, such that $mP > D$, and consequently such that mA contains D oftener than mC contains D.

But by taking the terms of the proportion inversely (Prop. VII.)

$$\begin{array}{cc} B : A : : & D : C \\ mA & mC \end{array}$$

$\therefore$ mA does not contain B oftener than mC contains D (Def. VI.), $\therefore$ mA contains D oftener than it contains B, therefore $B > D$ $\therefore$ *in a proportion*, &c. Q. E. D.

COR. I.—In a proportion consisting of *homogeneous* magnitudes, if one *consequent* be greater than the other, the *antecedent* of the former will be greater than that of the latter.

This follows from the present proposition by *inversion*; and, consequently, in a proportion whose terms are all homogeneous, if one antecedent be greater than, less than, or equal to the other antecedent, the consequent of the former will be greater than, less than, or equal to the consequent of the latter, and conversely.

COR. II.—Therefore (Prop. II.) if two proportions have three corresponding terms in each equal, each to each, the fourth terms will be equal.

NOTE.—It must be carefully observed that Proposition IX., as also X. and XI. following, apply only when the magnitudes are all four of the same kind. There can be no such relation as that implied in the word *ratio* between things of different kinds. In the other propositions hitherto discussed, it is necessary only that the first and second of the magnitudes be of the same kind, and that the third and fourth be also of the same kind. The latter pair, however, may differ in kind from the former pair: one pair may be lines, or numbers, and the other pair surfaces, or solids: but no *ratio* can exist between *heterogeneous* quantities, or quantities unlike in kind.

PROPOSITION X.—THEOREM.

If any number of *homogeneous* magnitudes be proportionals, then as one antecedent is to its consequent, so is the sum of all the antecedents to the sum of all the consequents.

First, let there be *four* proportionals, and let any equimultiples of the antecedents, and any equal multiples of the consequents, be taken thus :—

$$\begin{array}{cccc} A : & B : : & C : & D \\ mA & nB & mC & nD \end{array}$$

It is to be proved that

$$A : B : : A + C : B + D$$

By Prop. III. if $mA > nB$, then $mC > nD$; consequently, if $mA > nB$, then also $(mA + mC) > (nB + nD)$.

And conversely, if $(mA + mC) > (nB + nD)$, then $mA > nB$. For, from the first proportion, if this were not the case, neither could $mC > nD$; and, consequently, neither could $(mA + mC) > (nB + nD)$; $\therefore$ if this latter condition have place, so, of necessity, must the condition $mA > nB$.

$\therefore$ (Prop. V.) $A : B :: A + C : B + D$.

Next let there be six proportionals,

$$A : B :: C : D :: E : F.$$

It has already been proved, in reference to the last four, that

$$C : D :: C + E : D + F$$
$$\text{But } C : D :: A : B.$$

$\therefore$, (Prop. II.) $A : B :: C + E : D + F$.

Consequently, by the first case above,

$$A : B :: A + C + E : B + D + F.$$

And in a similar way as the proof for six proportionals has been derived from that for four, so may the proof for eight be derived from that for six; and so on for any number of proportionals; $\therefore$ *if any number of homogeneous magnitudes, &c.* Q. E. D.

PROPOSITION XI.—Theorem.

If the terms of a proportion are all of the *same kind*, they also form a proportion when taken ALTERNATELY; that is, the first is to the third as the second is to the fourth. Let the homogeneous proportionals be

$$A : B :: C : D; \text{ then also } A : C :: B : D.$$

For let any equimultiples of A, B, and any equimultiples of C, D, be taken and arranged as below,

$$\begin{array}{ccccccccccccccc} A & : & B & :: & C & : & D; & & A & : & C & :: & B & : & D \\ mA & & mB & & nC & & nD; & & mA & & nC & & mB & & nD \end{array}$$

Then (Prop. VI.) $mA : mB :: nC : nD$; $\therefore$ (Prop. IX.) if $mA > nC$, then $mB > nD$; and if $mB > nD$, then $mA > nC$.

$$\therefore \text{(Prop V.) } A : C :: B : D.$$

Hence, *if the terms of a proportion, &c.* Q. E. D.

PROPOSITION XII.—Theorem.

If in any proportion an antecedent be a multiple or submultiple of its consequent, the other antecedent will be a like multiple or submultiple of *its* consequent.

Let A, B, C, D be four proportionals, such that $A = mB$, then will $C = mD$. For since

$$A : B :: C : D$$

$\therefore$ (Prop. VI.) $A : mB :: C : mD$; but $A = mB$, $\therefore$ $C = mD$ (Prop. IV.)

Again, let the proportionals be such that $B = mA$; then will $D = mC$.

For by inversion (Prop. VII.) $B : A :: D : C$ and (Prop. VI.) $B : mA :: D : mC$, but $B = mA$ $\therefore$ $D = mC$.

$\therefore$ *if in any proportion, &c.* Q. E. D.

COR.—When the proportionals are *homogeneous*, if one antecedent be a multiple of the other, the consequent of the former will be a like multiple of the consequent of the latter.

PROPOSITION XIII.—Theorem.

In any proportion, the sum of an antecedent and its consequent is to either term, as the sum of the other antecedent and consequent is to the like term.

$$\begin{array}{rlllll} \text{Let the proportion be} & A & : B & :: & C & : D \\ \text{then} & A+B & : A & :: & C+D & : C \\ \text{also} & A+B & : B & :: & C+D & : D \end{array}$$

For A cannot be contained oftener in mB than C is contained in mD (Def. VI), $\therefore$ A cannot be contained oftener in $m(A + B)$ than C is contained in $m(C + D)$. Nor can C be contained oftener in $m(C + D)$ than A is contained in $m(A + B)$; for if it could, C would be contained in mD oftener than A in mB, which is impossible (Def. VI.) $\therefore$ $A : A + B :: C : C + D$.

Again, by inversion, $B : A :: D : C$; therefore, as just proved, $B : A + B :: D : C + D$; consequently inverting the two proportions now deduced,

$A + B : A :: C + D : C$, and $A + B : B :: C + D : D$.

$\therefore$ *in any proportion, &c.* Q. E. D.

COR.—If the proportionals are *homogeneous*, then, by alternation (Prop. XI.),

$A + B : C + D :: A : C$; and $A + B : C + D :: B : D$.

PROPOSITION XIV.—Theorem.

In any proportion, the difference between an antecedent and its consequent is to either term, as the difference between the other antecedent and consequent is to the like term.

Let $A : B :: C : D$ be any proportion; then taking any antecedent and consequent, as A, B, suppose first that $B > A$, and consequently (Prop. IV.) that $D > C$.

Take any equimultiples of B, D, and the same of $B-A$, $D-C$; and arrange the terms as usual—

$$\begin{array}{ccccccc} A & : & B & :: & C & : & D \\ & & mB & & & & mD \\ A & : & B-A & :: & C & : & D-C \\ & & mB-mA & & & & mD-mC \end{array}$$

Then (Def. VI.) A cannot be contained oftener in mB than C is contained in mD; but A is contained in mA just as often as C is contained in mC, namely, m times, without remainder. Therefore, A cannot be contained in $mB-mA$ oftener than C is contained in $mD-mC$.

In like manner may it be shown that C cannot be contained in $mD-mC$ oftener than A is contained in $mB-mA$; $\therefore$ (Def. VI.)

$$A : B-A :: C : D-C; \therefore \text{(Prop. XIII.)}$$
$$B : B-A :: D : D-C$$

And inverting these two proportions (Prop. VII.),

$B-A : A :: D-C : C$, and $B-A : B :: D-C : D$ which proves the theorem when $A > B$.

Next let $A > B$, and consequently (Prop. IV.) $C > D$.

By inversion, $B : A :: D : C$: $\therefore$ as proved above, $A-B : B :: C-D : D$, and $A-B : A :: C-D : C$, which proves the theorem when $A > B$; $\therefore$ $A \backsim B : A :: C \backsim D : C$; and $A \backsim B : B :: C \backsim D : C$ $\therefore$ *in any proportion, &c.* Q. E. D.

PROPOSITION XV.—Theorem.

If there be three magnitudes and other three, such that, whichever set be taken, the first in that set is to the second, as the second in the other set is to the third; then if the first in one set be greater than the third, the first in the other set also will be greater than the third.

Let the two sets of magnitudes be—

$$\left.\begin{array}{l} A, B, C \\ D, E, F \end{array}\right\} \text{ such that } \left\{\begin{array}{l} A : B :: E : F \\ D : E :: B : C \end{array}\right.$$

If $A > C$ then must $D > F$; and if $D > F$, then $A > C$. Let $A > C$: and take mA, mC, such equimultiples of A, C that mA may contain B *oftener* than mC contains B (Ax. 4); take also mE, the same multiple of E. Then since by the second proportion mE contains D only *as often* as mC contains B, $\therefore$ mA contains B *oftener* than mE contains D.

But mE contains F as often as mA contains B (Prop. VII., Cor.), therefore mE contains F *oftener* than mE contains D, $\therefore$ $D > F$. So that if $A > C$, then must $D > F$.

And in like manner may it be demonstrated that if $D > F$ then must $A > C$; $\therefore$ *if there be three magnitudes, &c.* Q. E. D.

PROPOSITION XVI.—Theorem.

If there be three magnitudes and other three such that whichever set be taken, the first in that set is to the second, as the second in the other set is to the third; then the first in the one set will be to the third, as the first in the other set is to the third.

Let the two sets of magnitudes be—

$$\left.\begin{matrix}A, B, C\\ D, E, F\end{matrix}\right\}\text{ such that }\left\{\begin{matrix}A : B :: E : F\\ D : E :: B : C\end{matrix}\right.$$

it is to be proved that A : C :: D : F.

Of A, B, D take any equimultiples, mA, mB, mD, and of C, E, F, any equimultiples, nC, nE, nF; then

$$\left.\begin{matrix}\text{(Prop. VIII.) } mA : mB :: nE : nF,\\ \text{and (Prop. VI.) } mD : nE :: mB : nC\end{matrix}\right\}\quad\left\{\begin{matrix}mA, mB, nC\\ mD, nE, nF.\end{matrix}\right.$$

Hence the first of the three magnitudes, on the right, are related to the other three, as in Proposition XV.; $\therefore$ if $mA > nC$, then $mD > nF$; or if $mD > nF$, then $mA > nC$. Consequently, (Prop. V.) A : C :: D : F; $\therefore$ *if there be three magnitudes*, &c. Q. E. D.

Cor.—If to one of the above sets a *fourth* magnitude P be *annexed*, and to the other set, a *fourth* magnitude Q be *prefixed*, such as to furnish an additional proportion, Q : D :: C : P; then, from the hypotheses, and the foregoing conclusion, namely, that—

$$\left.\begin{matrix}A, B, C, P\\ Q, D, E, F\end{matrix}\right\}\text{ are such that }\left\{\begin{matrix}A : C :: D : F\\ Q : D :: C : P,\end{matrix}\right.$$

it follows that A, C, P are related to Q, D, F, as in the proposition; and therefore that A : P :: Q : F. And in this way may the proposition be extended to any number of magnitudes.

PROPOSITION XVII.—Theorem.

If there be two sets of magnitudes, the number being the same in each set, such that the first is to the second in the one set, as the first to the second in the other set, the second to the third in the former set, as the second to the third in the latter set, and so on: then as the first magnitude in the one set is to the last, so is the first magnitude in the other set to the last.

First, let there be *three* magnitudes in each set, namely—

$$\left.\begin{matrix}A, B, C\\ D, E, F\end{matrix}\right\}\text{ such that }\left\{\begin{matrix}A : B :: D : E\\ B : C :: E : F,\end{matrix}\right.$$

then it is to be proved that A : C :: D : F.

Take any equimultiples, mA, mD of A, D; and any equimultiples nC, nF, of C, F; then (Props. VI. and VII.),

$$\left.\begin{matrix}B : mA :: E : mD\\ \text{and } B : nC :: E : nF\end{matrix}\right\}\quad\left\{\begin{matrix}A,\ C,\ D,\ F\\ mA, nC, mD, nF.\end{matrix}\right.$$

Let $mA > nC$, then (Ax. 4) a multiple pmA of mA, may be taken so great that pmA will contain B *oftener* than pnC will contain B. But pmD contains E as often as pmA contains B (Def. V.); while pnF contains E *only as often* as pmC contains B, $\therefore$ pmD contains E oftener than pnF contains E, $\therefore$ $mD > nF$; so that if $mA > nC$ then $mD > nF$. In like manner it may be proved, by interchanging A, C, with D, F, and also interchanging B with E, that if $mD > nF$, then $mA > nC$; $\therefore$ A : C :: D : F.

Next let there be *four* magnitudes in each set—namely,

$$\left.\begin{matrix}A, B, C, P\\ D, E, F, Q\end{matrix}\right\}\text{ such that }\left\{\begin{matrix}A : C :: D : F\\ C : P :: F : Q,\end{matrix}\right.$$

then it is to be proved that A : P :: D : Q. And this is done as in the first case, since the three magnitudes A, C, P are related, by the foregoing proportions, to the three D, F, Q, as that case supposes; $\therefore$ A : P :: D : Q. And in like manner may the case for *five* magnitudes be deduced from this for *four;* and so on for any number of magnitudes in each set; $\therefore$ *if there be two sets of magnitudes*, &c. Q. E. D.

Cor.—If the consequents in one proportion be the antecedents in another, a third proportion may be formed, having the same antecedents as the first, and the same consequents as the second; thus if—

$$\left.\begin{matrix}A : B :: C : D\\ \text{and } B : K :: D : L\end{matrix}\right\}\text{ then } A : K :: C : L.$$

Note.—It will be observed that, in the last three propositions, the magnitudes in each set are *all of the same kind;* but that those in one set, need not be of the same kind as those in the other sets.

PROPOSITION XVIII.—Theorem.

In any proportion, the sum of the first two terms is to their difference, as the sum of the other two is to their difference.

Let A : B :: C : D; then $A + B : A \backsim B :: C + D : C \backsim D$.

For (Prop. XIII.) $A + B : A :: C + D : C$, and (inverting Prop. XIV.) $A : A \backsim B :: C : C \backsim D$.

Consequently (Prop. XVII., Cor.) $A + B : A \backsim B :: C + D : C \backsim D$, $\therefore$ *in any proportion*, &c. Q. E. D.

PROPOSITION XIX.—Theorem.

If the antecedents in one proportion be the same as those in another, then the first antecedent is to the sum or difference of the first consequents, as the second antecedent is to the sum or difference of the second consequents.

Let the proportions be A : B :: C : D; and A : E :: C : F; it is to be proved that $A : B \underset{\backsim}{+} E :: C : D \underset{\backsim}{+} F$.

Inverting the first of the given proportions (Prop. VII.)

$$\left.\begin{matrix}B : A :: D : C\\ \text{but } A : E :: C : F\end{matrix}\right\}\begin{matrix}\therefore \text{ (Prop. XVII., Cor.)}\\ B : E :: D : F.\end{matrix}$$

Consequently (Props. XIII., XIV.) $B : B \underset{\backsim}{+} E :: D : D \underset{\backsim}{+} F$; and, comparing this with the first of the given proportions,

$A : B \underset{\backsim}{+} E :: C : D \underset{\backsim}{+} F$; $\therefore$ *if the antecedents*, &c. Q. E. D.

Cor.—If the terms are all *homogeneous*, then by alternation, $A : C :: B \underset{\backsim}{+} E : D \underset{\backsim}{+} F$; and $B : D :: B \underset{\backsim}{+} E : D \underset{\backsim}{+} F$.

PROPOSITION XX.—Theorem.

In a proportion whose terms are homogeneous, the sum of the greatest and least terms exceeds the sum of the other two.

Let A : B :: C : D; and first let an antecedent, A, be the greatest term; then will D be the least (Prop. IX.); and it is to be proved that $(A + D) > (B + C.)$

By Prop. XIV., and inversion, $A : A - B :: C : C - D$: but by hyp. $A > C$, $\therefore$ (Prop. IV.) $(A - B) > (C - D)$. To each of these unequals add $B + D$, then $(A + D) > (B + C)$.

Next, let a consequent, B, be the greatest: then by inverting the proportion, B : A :: D : C; and since by hyp. B is the greatest of these, C is the least, and $\therefore$ as just proved $(B + C) > (A + D)$; $\therefore$ *in a proportion*, &c. Q. E. D.

Cor.—If the proportion be A : B :: B : C, then $(A + C) > 2\,B$; that is, the sum of *the extremes*, in three proportionals, exceeds twice the *mean*.

The three propositions following, though of no application in the Sixth Book of Euclid, will be found useful in the consideration of *incommensurable quantities*.

PROPOSITION XXI.—Theorem.

If a magnitude measure each of two others, it will also measure their sum and difference.

Let A, B be any two magnitudes, and let C be a third magnitude which measures each; that is, such that $A = mC$ and $B = nC$, m and n being whole numbers. Then $A + B = mC + nC = (m + n)\,C$; also $A \backsim B = mC \backsim nC = (m \backsim n)\,C$: but C is contained in the former $m + n$ times *exactly*, and in the latter $m \backsim n$ times exactly, $\therefore$ C measures both $A + B$, and $A \backsim B$; $\therefore$ *if a magnitude*, &c. Q. E. D.

Cor.—If C measure B, and also $A + B$ and $A - B$, it must likewise measure A: for the sum of $A - B$ and B is A, and the difference of $A + B$ and B, is A; and as shown above, C measures both this sum and difference.

PROPOSITION XXII.—Problem.

Two magnitudes of the same kind being given to find their greatest common measure.

Let the two given magnitudes be A, B: it is required to find the greatest magnitude that will measure both. Let A be the greater of the two magnitudes, and from it take the greatest possible multiple of B (viz., *m*B), leaving a remainder C, less, of course, than B. In like manner take from B the greatest possible multiple of C (viz., *n*C), leaving a remainder D, less than C. In like manner take from C the greatest possible multiple of D (viz., *p*D), leaving a remainder E less than D; and so on, as in the margin: the greatest common measure will be that remainder which exactly measures the preceding one: for instance, if E measure D so that *q*E = D, then E is the greatest common measure of A and B.

B)A(M
*m*B
——
C)B(*n*
*n*C
——
D)C(*p*
*p*D
——
E)D(*q*
*q*E
——
&c.

For every common measure of A and B, as it measures B, will measure *m*B; consequently, as it at the same time measures A, it will measure A — *m*B, by last proposition; that is, it will measure C. This being the case, it must also measure *n*C, and therefore, last proposition, it must measure B — *n*C; that is, it must measure D: for similar reasons it must measure E; and so on. Consequently every measure of A and B *also* measures each of the remainders C, D, E, &c.; and as these remainders become less and less, it follows that that must be the *greatest* common measure which is exactly *equal* to the last of these remainders, and at which the operation terminates. But if the operation never terminate, the diminishing series of remainders being continued without end, then, as there is no *last* remainder, there can be no common measure at all—in other words, the magnitudes A, B will be *incommensurable*.

PROPOSITION XXIII.—THEOREM.

If one magnitude contain another, and leave a remainder, such that the greater of the two magnitudes is to the less, as the less is to that remainder, then the two magnitudes will be incommensurable. Let A, B be the two magnitudes, such that the greater A contains the less B, *m* times, leaving a remainder C; that is, such that A — *m*B = C; then if A : B : : B : C, the magnitudes A, B will be *incommensurable*.

For let C, D, E, &c., be the successive remainders in the operation for finding the common measure (Prop. XXII.) Then C cannot measure B, for then B would measure A, so that there would not be any *remainder* (Prop. XII.); but C is contained as often in B as B is contained in A (Def. VI.) Let *m*B be the greatest multiple of B which is contained in A, and take *m*C, an equimultiple of C: then (Prop. VIII.) A : B : : *m*B : *m*C, and (Props. XIV. and XI.) A : B : : A — *m*B : B — *m*C: but by hypothesis A — *m*B = C, and B — *m*C = D: therefore A : B : : C : D; and since A : B : : B : C, ∴ (Prop. II.) B : C : : C : D; hence D cannot measure C, inasmuch as C cannot measure B, (Prop. XII.)

Let now *n*C be the greatest multiple of C in B, and take *n*D, an equimultiple of D: then, from what is proved above, C : D : : D : E; hence E cannot measure D, inasmuch as D, as just proved, cannot measure C. And the reasoning is the same for every successive remainder; so that no remainder can ever measure the preceding remainder; and therefore the operation for the common measure can never terminate; that is, the two magnitudes A, B are *incommensurable*, ∴ *if one magnitude* &c. Q. E. D.

The operation explained in Prop. XXII. is that actually performed on a pair of *numbers*, when the object is to ascertain whether those numbers have a common measure, and to discover the *greatest* common measure.

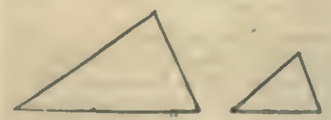
In this *arithmetical* process, should a remainder ever become 1, we conclude that no common measure of the two numbers exists; because *in Arithmetic*, as remarked at page 571, 1 is not regarded as an arithmetical common measure. When the two numbers have no factor in common, a unit-remainder must always occur to apprise us of the fact, after a finite number of steps of the work; since the remainders—all whole numbers—go on continually *diminishing*. But in magnitudes not susceptible of numerical representation, the operation referred to could not be practically applied—as long as *any* remainder occurred, so long must the work be continued; and therefore, in the case of incommensurable magnitudes, it would be endless, even if we could practically carry forward the steps. But the proposition just established, furnishes a geometrical test of incommensurability that may be readily appealed to, as will be seen in the proposition respecting the side and diagonal of a square, at the end of the Sixth Book. It will also be shown hereafter, by aid of the present theorem, that if a line be divided, as in Prop. XI., Book II., the two parts of that line will be incommensurable; and therefore that it would be quite impossible to express *both* by numerical values of their lengths.

CHAPTER VI.

ELEMENTS OF EUCLID.—BOOK VI.

DEFINITIONS.

I.



Similar rectilineal figures are those which have the several angles in one equal to those in the other, each to each, and the sides *about* the equal angles—that is, which *include* the equal angles, proportionals.

II.

Two sides of one figure are said to be *reciprocally proportional* to two sides of another, when one of the sides of the first is to one of the sides of the second as the remaining side of the second is to the remaining side of the first.

III.

A straight line is said to be cut in *extreme and mean ratio*, when the whole is to the greater segment as the greater segment is to the less.

IV.

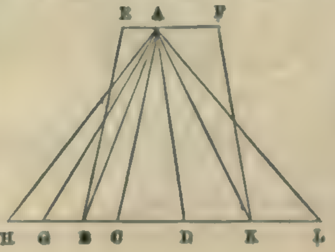
The *altitude* of any figure is the straight line drawn from its vertex perpendicular to the base, or opposite side, and terminating in that side, or the side prolonged.

Thus the perpendicular A D, drawn from the vertex A to the base B C, is the altitude of the triangle A B C, in Proposition VIII. in this book.

PROPOSITION I.—THEOREM.

Triangles and parallelograms of the same altitude are to one another as their bases.

Let the triangles A B C, A D K, and the parallelograms E C, F D, have the same altitude: then as the base B C is to the base DK, so is the triangle A B C to the triangle A D K, and the parallelogram E C to the parallelogram F D.



Produce B K both ways to H and L, and make B G, G H., &c., any number of

3 I. them, each equal to B C; and K L, &c., any number of them, each equal to D K; and draw A G, A H, &c., and A L, &c.; then the triangles A B C, A G B, †38 I. A H G, &c., are all equal;† and if the base of the triangle which is the sum of all these be *m* times B C, the triangle itself will be *m* times the triangle *38 I. A B C.* In like manner if D L be *n* times D K, the triangle A D L will be *n* times A D K.

base B C : base D K : : triangle A B C ; triangle A D K,
m. B C : *n*. D K : : *m*. A B C : *n*. A D K

Hence if *m*. B C = *n*. D K, then *m*. A B C = *n*. A D K; if *m*. B C > *n*. D K, then *m*. A B C > *n*. A D K; and if *m*. B C = *n*. D K, then *m*. A B C = *n*. A D K, and *m*, *n*. are any whole numbers whatever, ∴ (Def. A., page 573).

base B C : base D K : : triangle A B C : triangle A D K.

And because the parallelogram E C is double of the triangle A B C, and the parallelogram F D double of the triangle A D K, ∴ triangle A B C : triangle A D K : : †8 V. parallelogram E C : parallelogram F D;† and, comparing this proportion with the last, base B C : base *2 V. D K : : parallelogram E C : parallelogram F D,* ∴ *triangles and parallelograms*, &c. Q. E. D.

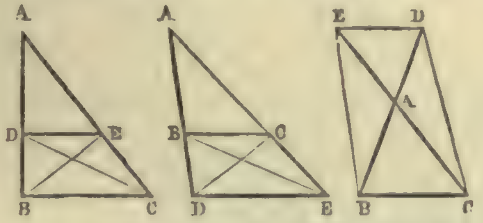
COR.—If triangles or parallelograms have *equal* altitudes, they are to one another as their bases.

For if the figures be so placed as to have their bases in the same straight line, and perpendiculars be drawn from the vertices to the bases, the straight line joining the vertices will be parallel to that in which are the *23 I. bases,* since the perpendiculars are both equal †28 I. and parallel;† and ∴ if the above construction be made, the demonstration will be the same.

PROPOSITION II.—THEOREM.

If a straight line (D E) *be drawn parallel to one of the sides* (B C) *of a triangle, it shall cut the other sides, or these produced, proportionally; and if the sides, or the sides produced, be cut proportionally, the straight line which joins the points of section shall be parallel to the remaining side of the triangle.*

For draw B E, C D. Then the triangle B D E = C D E,



because they are on the same base D E, and are between *37 I. the same parallels D E, B C;* and A D E is another triangle, ∴ B D E : A D E : : C D E : A D E. †1 VI. But B D E : A D E : : B D : D A.† For a similar reason C D E : A D E : : C E : E A,

2 V. ∴ B D : D A : : C E : E A.

Again, let the sides A B, A C, or these produced, be cut proportionally in the points D, E; that is, so that B D : D A : : C E : E A; and draw D E; *D E shall be parallel to B C.*

The same construction being made, because

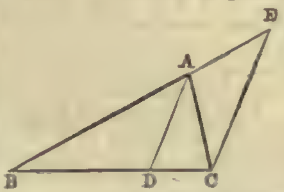
B D : D A : : C E : E A, and B D : †1 VI. D A : : B D E : A D E,† and C D E : A D E : : C E : *1 VI. E A.* } ∴ (2 V.) B D E : A D E : : C D E : A D E.

But as the consequents are equal the antecedents are †9 V. Cor. 1. equal,† ∴ triangle B D E = triangle C D E; and they are on the same base D E, and are between the same parallels, ∴ *D E is parallel to B C*; ∴ *if a straight line*, &c. Q. E. D.

PROPOSITION III.—THEOREM.

If an angle (B A C) *of a triangle, be divided into two equal angles, by a straight line which cuts the opposite base, the segments of the base* (B D, D C) *shall be to each other as the remaining sides of the triangle; and if the segments of the base are to each other as the remaining sides of the triangle, the straight line drawn from the vertex to the point of section, shall divide the vertical angle into two equal angles.*

31 I. Draw C E parallel to D A; and let B A produced meet C E in E. Because A C meets the parallels A D, E C, the angle A C E = C A D;† †29 I. but by hypothesis, C A D = B A D; ∴ B A D = A C E. Again, because B E meets the parallels A D, E C, the angle B A D *29 I. = A E C;* but it was proved that A C E = B A D, ∴ A C E = A E C, and ∴ A E = A C; and since A D is parallel to E C, a side of the triangle B C E; †2 VI. ∴ B D : D C : : B A : A E;† but A E = A C,



∴ B D : D C : : B A : A C.

Next let B D : D C : : B A : A C; and draw A D; the angle B A C shall be divided into two equal angles by A D.

The same construction being made, A D is parallel to *Const. E C,* and because

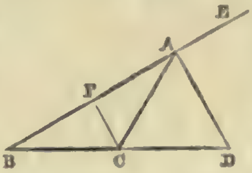
B D : D C : : B A : A C, and †2 VI. B D : D C : : B A : *9 V. Cor. A E,† } ∴ (2 V.) B A : A C : : B A : A E, ∴ A C = A E,*

and consequently the angle A E C = A C E; but A E C †29 I. = B A D,† and A C E = C A D,* ∴ B A D = *29 I. C A D, that is, *the angle B A C is divided into two equal angles by A D*; ∴ *if an angle*, &c. Q. E. D.

PROPOSITION A.—THEOREM.

If the outward angle (C A E) *of a triangle* (A B C) *made by producing one of its sides, be divided in two equal angles, by a straight line* (A D) *which cuts the base produced, the segments* (B D, D C) *between the dividing line and the extremities of the base, are to each other as the remaining sides of the triangle; and if the segments of the base produced are to each other as the remaining sides of the triangle, the straight line drawn from the vertex to the point of section, divides the outward angle of the triangle into two equal angles.*

31 I. Through C draw C F parallel to A D. Then because A C meets the parallels A D, F C, the angle A C F †29 I. = C A D;† but (hyp.) C A D = D A E, ∴ D A E = A C F. Again, because F E meets the parallels A D, F C, the angle D A E = C F A;* *29 I. but as just proved, D A E = A C F ∴ C F A = †6 I. A C F; ∴ A C = A F.† And because A D is parallel to F C, a side of the triangle B C F, ∴ B D : D C : : B A : A F; but A C = A F, ∴



B D : D C : : B A : A C.

Next, let B D : D C : : B A : A C; and draw A D; the angle C A D shall be equal to D A E.

The same construction being made, because

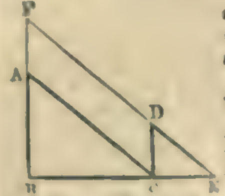
B D : D C : : B A : A C, and *2 VI. B D : D C : : B A : A F,* } ∴ (2 V.) B A : A C : : B A : A F, ∴ A C = A F,

†5 I. ∴ the angle A F C = A C F;† but A F C = *29 I. E A D, and A F C = C A D,* ∴ E A D = C A D; ∴ *if the outward angle*, &c. Q. E. D.

PROPOSITION IV.—THEOREM.

The sides about the equal angles of equiangular triangles (A B C, D C E) *are proportionals; and those which are opposite to the equal angles are* homologous *sides; that is, are the antecedents, or the consequents of the ratio.*

Let the angle A B C = D C E; A C B = D E C; and consequently B A C = C D E; and let the triangle D C E be placed so that its side C E may be contiguous to B C, and in the same straight line with it; then the angle

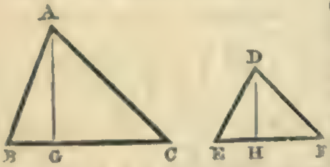


† Hyp. B C A = C E D.† Add to each the angle B; then B C A + B = C E D + B; but the former two are less than two right angles,* * 17 I. ∴ C E D + B, are less than two right angles, ∴ B A, E D, † Ax. 12 if produced will meet;† let them be produced and meet in F. Then because the angle B = * 28 I. DCE, BF is parallel to CD;* and because A C B = D E C, A C is parallel to F E; ∴ † 34 I. F C is a parallelogram,† ∴ A F = C D, and A C = F D; and because A C, C D are respectively parallel to F E, B F, sides of the triangle F B E, ∴ (1 VI.)

B C : C E : : B A : A F and B C : C E : : F D : D E } or since A F = C D, and F D = A C { B C : C E : : B A : C D; B C : C E : : A C : D E

* 2 V. ∴ B A : C D : : A C : D E.* Alternating these three proportions, B C : B A : : C E : C D; B C : A C : : C E : D E; B A : A C : : C D : D E. ∴ *the sides about the equal angles, &c.* Q. E. D.

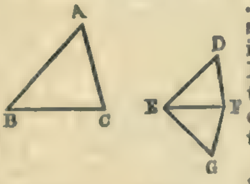
Cor.—In similar triangles (A B C, D E F), the bases (B C, E F) are to one another as the altitudes (A G, D H). For since the angles B, E are equal, as also the right angles G, H, the triangles A B G, D E H are equiangular, ∴ A B : A G : : D E : D H; but B C : A B : : E F : E D;* * Def. 1 VI. ∴ B C : A G : : E F : D H;† hence, alter- † 15 V. Cor. nately, the bases are as the altitudes.



PROPOSITION V.—Theorem.

If the sides of two triangles (A B C, D E F), *about two angles* (B, C) *of one, and two angles* (E, F) *of the other, be proportionals, the triangles shall be equiangular; and the equal angles shall be those which are opposite to homologous sides.*

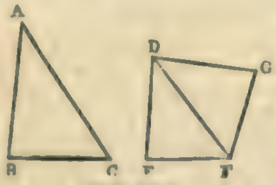
At the points E, F, in the straight line E F, make the angle F E G = B, and E F G = C; then the remaining angle G = A, and ∴ the triangles A B C, G E F, are equi- * 4 VI. angular, ∴ A B : B C : : G E : E F;* but (hyp.) † 2 VI. A B : B C : : D E : E F; ∴ D E : E F : : G E : E F;† ∴ D E = G E. For a like reason D F = F G. And because in the triangles D E F, G E F, D E = G E, and E F common, the two sides D E, E F are equal to the two G E, E F, each to each, and D F = G F; ∴ * 8 I. the angle D E F = G E F,* and the angle D F E = G F E, and E D F = E G F. And because D E F = G E F, and † Const. G E F = B,† ∴ D E F = B. For a like reason D F E = C, and ∴ D = A; ∴ *the triangle* D E F *is equiangular to* A B C; ∴ *if the sides, &c.* Q. E. D.



PROPOSITION VI.—Theorem.

If two triangles (A B C, D E F) *have an angle* (A) *of one, equal to an angle* (E D F) *of the other, and the sides about them proportionals, the triangles shall be equiangular, and shall have those angles equal which are opposite to the homologous sides.*

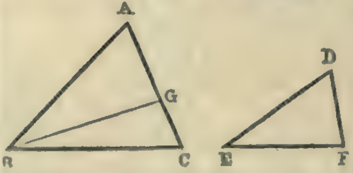
At the points D, F, in the straight line D F, make the angle F D G equal to either of the angles A, or E D F; and the angle D F G equal to C; then the remaining angle G = B, and ∴ the triangles A B C, D G F are equiangular; ∴ B A : A C : : G D * 4 VI. : D F;* but (hyp) B A : A C : : E D : : D F; ∴ E D : D F : : G D : D F;† ∴ † 2 V. E D = G D; ∴ in the triangles E D F, G D F, the two sides E D, D F = * Const. G D, D F, each to each, and the angle E D F = G D F;* ∴ E F = F G†, and the angle D F G = D F E, † 4 I. and G = E;* but D F G = C (const.) D F E = * 4 I. C; but E D F = A (const.), ∴ E = B; ∴ *the triangles* A B C, D E F *are equiangular;* ∴ *if two triangles, &c.* Q. E. D.



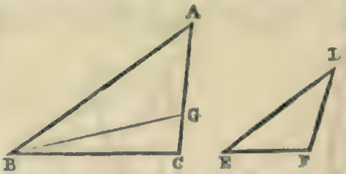
PROPOSITION VII.—Theorem.

If two triangles (A B C, D E F) *have an angle* (A) *of the one, equal to an angle* (D) *of the other, and the sides about two* (A B C, D E F) *proportionals; then if each of the remaining angles* (C, F) *be either less, or not less, than a right angle, the triangles shall be equiangular, and shall have those angles equal, about which the sides are proportionals.*

First let each of the angles C, F be *less* than a right angle: the angles A B C and E shall be equal, and ∴ the angle C to the angle F. For if A B C be not equal to E, one of them, as A B C, must be the greater. At the point B, in A B, make the angle A B G = E; then because A = D (hyp.) the remaining angle A G B must be * 32 I. = F;* ∴ the triangles A B G, D E F are equiangular, ∴ A B : B G : : D E : E F. But (hyp.) A B : B C : : D E : E F, ∴ A B : B C : : A B : B G, ∴ B C = B G,† and ∴ † 9 V. Cor. 1. B G C = B C G; but (hyp.) B C G is less than a right angle, ∴ B G C is less than a right angle; ∴ A G B must be *greater* than a right angle: but it was proved that A G B = F; ∴ F is greater than a right angle; but (hyp.) it is *less* than a right angle; which is absurd; ∴ the angles A B C, E are not unequal, that is, they are equal; and, as A = D (hyp.) ∴ C = F ∴ *the triangles* ABC, DEF *are equiangular.*



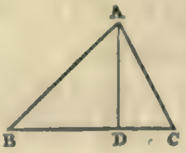
Next, let C, F be each *not less* than a right angle: the triangles shall also in this case be equiangular. For if it be denied, then, the same construction being made, it may be proved, as above, that B C = B G; and that ∴ the angle B G C = C: but (hyp.) C is not less than a right angle: ∴ B G C is not less than a right angle ∴ two angles of the triangle B G C are together not less than two right angles: which is impossible; ∴ *the triangle* A B C, *as in the first case, is equiangular to* D E F. ∴ *if two triangles, &c.* Q. E. D.



PROPOSITION VIII.—Theorem.

In a right-angled triangle (A B C), *if a perpendicular* (A D) *be drawn from the vertex of the right angle to the base, the triangles* (A B D, A C D) *on each side of it are similar to the whole triangle* (A B C) *and to one another.*

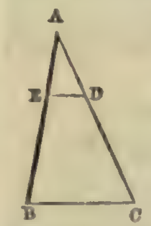
Because the angle B A C = A D B, each being a right angle, and that B is common to the two triangles A B C, A B D, ∴ the * 32 I. angle A C B = B A D;* ∴ the triangles A B C, A B D are equi- † 4 VI. and Def. 1. angular, ∴ they are similar.† In like manner it may be demonstrated that the triangles A B C, A C D are similar; ∴ *the triangles* A B D, A C D *being both similar to* A B C, *are similar to each other;* ∴ *in a right-angled triangle, &c.* Q. E. D.



Cor.—From this it is manifest that the perpendicular from the vertex of the right angle of a right-angled triangle to the base, is *a mean proportional* between the segments of the base; and also that each side about the right angle is a mean proportional between the base, and the segment of it adjacent to that side: for in the tri- * 4 VI. angles B D A, C D A, B D : D A : : D A : D C;* in the triangles A B C, D B A, B C : B A : : B A : B D; and in the triangles A B C, A C D, B C : C A : : C A : C D.

PROPOSITION IX.—PROBLEM.

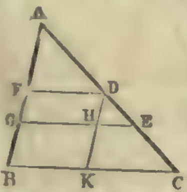
From a given straight line (A B) *to cut off any part required.*



From A draw a straight line A C, making any angle with A B; and in it take any point D; and take A C, the same multiple of A D, that A B is of the part to be cut off. Draw B C, and D E * 31 I. parallel to it,* then A E shall be the part required to be cut off. Because E D is parallel to B C, a side of the triangle A B C, ∴ C D : D A : : B E : E A; † 13 V. ∴ A C ; A D : : A B : A E ;† but * Const. A C is a multiple of A D,* ∴ A B is the same multiple of A E; that is, whatever part of A D is of A C, the same † 7 V. Cor. part is A E of A B,† ∴ *from* A B, *the part required,* A E *is cut off.* Which was to be done.

PROPOSITION X.—PROBLEM.

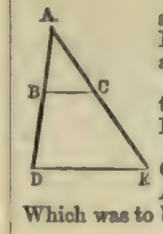
To divide a given straight line (A B) *similarly to a given divided straight line* (A C).



Let A C, placed so as to make any angle with A B, be divided in the points D, E. Draw B C; and through the points D, E draw D F, E G parallels to it; A B shall be divided in F, G similarly to A C. Through D draw D H K, parallel to A B: then each of the figures F H H B is a parallelogram, ∴ D H = * 34 I. F G,* and H K = G B; and because H E is parallel to K C, a side of the triangle DKC, ∴ C E : † 2 VI. E D : : K H : H D ;† but K H = B G, and H D = G F; ∴ C E : E D : : B G : G F. Again, because F D is parallel to G E, a side of the triangle A G E, ∴ E D : D A : : G F : F A : and it was before proved that C E : E D : : B G : G F; ∴ *the given straight line is divided similarly to* A C. Which was to be done.

PROPOSITION XI.—PROBLEM.

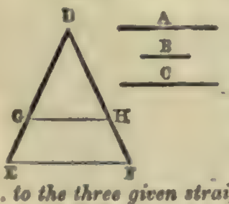
To find a third proportional to two given straight lines (A B, A C).



Let the lines be placed so as to make any angle A, and produce them to D, E. Make B D = A C; draw B C, and through D draw D E parallel to it:* * 31 I. C E shall be a third proportional to A B, A C. Because B C is parallel to D E, ∴ A B : B D : : A C : C E; but B D † Const. = A C ;† ∴ A B : A C : : A C : C E; ∴ *to the two given straight lines* A B, A C, *a third proportional* C E *is found.* Which was to be done. Q. E. D.

PROPOSITION XII.—PROBLEM.

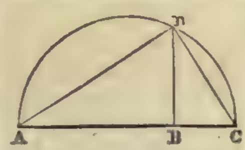
To find a fourth proportional to three given straight lines (A, B, C).



Take two straight lines D E, D F, making any angle D; and upon these take D G = A, G E = B, and D H = C. Draw G H, and E F parallel to it: F H shall be a fourth proportional to A, B, C. Because G H is parallel to E F, ∴ D G : G E : : D H : H F; but D G = A, G E = B, and D H = C,* * Const. ∴ A : B : : C : H F, ∴ *to the three given straight lines* A, B, C, *a fourth proportional* H F *is found.* Which was to be done.

PROPOSITION XIII.—PROBLEM.

To find a mean proportional between two given straight lines.

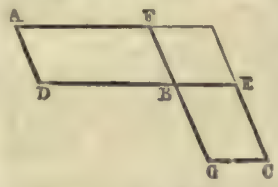


Let the parts A B, B C be equal to the two given straight lines: it is required to find a mean proportional between them. Upon A C describe the semicircle A D C, and from B draw B D perpendicular * 11 I. to A C;* B D shall be a mean proportional between A B, B C.

Draw A D, C D. Then because † 31 I. the angle A D C, in a semicircle is a right angle,† and that in the right-angled triangle A D C, D B is drawn from the vertex of the right angle perpendicular to the base, D B is a mean proportional between A B, B C,* * 8 VI. Cor. ∴ *between* A B, B C, *a mean proportional* D B, *is found.* Which was to be done.

PROPOSITION XIV.—THEOREM.

Equal parallelograms (A B, B C) *which have an angle* (B) *of the one equal to an angle of the other, have their sides about the equal angles reciprocally proportional: and parallelograms that have an angle of the one equal to an angle of the other, and the sides about those angles reciprocally proportional, are equal to one another.*



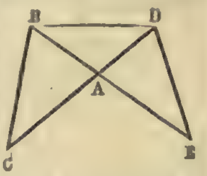
Let the sides D B, B E, be placed in the same straight line; then because F B D + F B E = two right angles, and that F B D = G B E (hyp.), ∴ G B E + F B E = two right angles; ∴ F B, B G are in one straight line. It is to be proved that DB : BE : : GB : BF. Complete the parallelogram F E. Then because A B = B C, AB : FE : : BC : FE; but AB : FE : : DB : BE,* * 1 VI. and B C : F E : : † 2 V. G B : B F, ∴ D B : B E : : G B : B F ;† ∴ *the sides of the equal parallelograms* A B, B C, *about their equal angles are reciprocally proportional.*

Next, let the sides about the equal angles be reciprocally proportional; namely: D B : B E : : G B : B F; then is A B = B C. Because D B : B E : : G B : B F, and DB : BE : : AB : F E, and GB : BF : : BC : FE,* * 1 VI. ∴ A B : F E : : B C : FE,† ∴ A B = B C, ∴ † 2 V. *equal parallelograms, &c.* Q. E. D.

PROPOSITION XV.—THEOREM.

Equal triangles (A B C, A D E), *which have an angle* (A) *of the one equal to an angle of the other, have their sides about the equal angles reciprocally proportional; and triangles which have an angle of the one equal to an angle of the other, and their sides about those angles reciprocally proportional, are equal to one another.*

Let the triangles be placed so that their sides, C A, A D may be in one straight line; then it may be proved, as in last proposition, that E A, A B are in one straight line. It is to be proved that C A : A D : : E A : A B.



Draw B D. Then because the triangles A B C, A D E are equal, ∴ triangle A B C : triangle A B D : : triangle A D E : triangle A B D; but triangle ABC : triangle ABD : : C A * 1 VI. : AD,* and triangle ADE : triangle A B D : : E A : A B, con- † 2 V. sequently† C A : A D : : E A : A B; ∴ *the sides of the equal triangles* A B C, A D E, *about the equal angles are reciprocally proportional.*

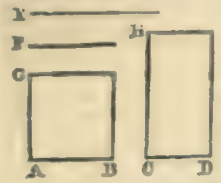
Next, let the sides of the triangles, A B C, A D E, about the equal angles be reciprocally proportional; namely, C A : A D : : E A : A B; then is triangle A B C = triangle A D E.

Draw BD as before. Then, because C A : A D : : E A : A B, and C A : A D : : triangle A B C : triangle ABD,* * 1 VI. and E A : A B : : triangle A D E : triangle A B D; ∴ triangle A B C : triangle A B D : : triangle † 2 V. A D E : triangle A B D ;† and the consequents * 9 V. Cor. being equal, the antecedents are equal,* ∴ *triangle* A B C = *triangle* A D E; ∴ *equal triangles, &c.* Q. E. D.

PROPOSITION XVI.—THEOREM.

If four straight lines (AB, CD, E, F) *are proportionals, the rectangle contained by the extremes* (A B, F) *is equal to that contained by the means* (CD, E): *and if the rectangle contained by the extremes be equal to that contained by the means, the four straight lines are proportionals.*

From A, C draw A G, C H, perpendiculars to A B, • 11 I. C D;* make A G = F, and C H = E, and † 31 I. complete the parallelograms B G, D H.† It is to be proved that these rectangles are equal.



Because A B : C D :: C H : A G, ∴ the sides of the parallelograms about the equal angles A, C, are reciprocally proportional; they are therefore equal to one • 14 VI. another;* and B G is the rectangle contained by A B, F, and D H the rectangle contained by C D, E; ∴ AB·F = C D·E. And if AB·F = CD E, then shall A B : C D :: E : F. The same construction being made, the rectangle B G = D H; and as they are equi- † 14 VI. angular also, ∴ A B : C D :: C H : A G;† that is A B : C D :: E : F; ∴ *if four straight lines, &c.* Q. E. D.

NOTE.—The next proposition is merely a corollary to this: it is that particular case of it in which the *means* are equal.

PROPOSITION XVII.—THEOREM.

If three straight lines be proportionals, the rectangle contained by the extremes is equal to the square of the mean, and if the rectangle contained by the extremes is equal to the square of the mean, the three straight lines are proportionals.

COR.—The first of the three proportionals (A, B, C) is to the third, as the square of the first to the square of the second.

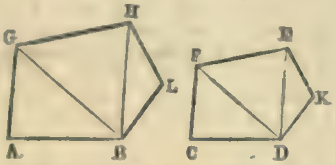
• 1 VI. For* A : C :: rectangle A·A : rectangle A·C; but A·C = B^2, ∴ A : C :: A^2 : B^2.

PROPOSITION XVIII.—PROBLEM.

Upon a given straight line (A B) *to describe a rectilineal figure similar, and similarly situated, to a given rectilineal figure.*

First, let the given rectilineal figure, C, D, E, F have *four* sides: it is required to describe on A B a figure similar, and similarly situated to C, D, E, F.

Draw D F; and at the points A, B, in A B, make the angle A = C, and ABG = CDF; then AGB = CFD;† † 32 I. ∴ the triangles F C D, G A B, are equiangular. At the points G, B in G B, make the angle B G H = D F E, • 32 I. and G B H = F D E; then G H B = F E D;* ∴ the triangles F D E, G B H are equiangular.



Because the angle A G B = C F D, and B G H = D F E; ∴ A G H = C F E. For like reasons A B H = C D E, ∴ since A = C, and G H B = F E D, *the figures* A B H G, C D E F, *are equiangular.* Moreover these figures have their sides about the equal angles proportionals; G A B, F C D being equiangular triangles, ∴ B A : A G † 4 VI. :: D C : C F; and A G : G B :: C F : F D;† also by reason of the equiangular triangles B G H, D F E, G B : G H :: F D : F E; ∴ A G : G H :: C F : F E. In like manner it may be proved that A B : B H :: C D : D E, and G H : H B :: F E : E D; ∴ *the equiangular figures* A B H G, C D E F *have their sides about the equal* • Def. 1 VI. *angles proportionals,* ∴ *they are similar.**

Next, let the given rectilinear figure C D K E F have *five* sides. Draw D E; and upon A B describe the figure A B H G, similar and similarly situated, to the quadrilateral C D E F, by the former case: and at the points B, H, in B H, make the angle H B L = E D K, and • 32 I. B H L = D E K, then L = K.*

Because the figures A B H G, C D E F are similar, the angle G H B = F E D; and B H L was made = D E K; ∴ G H L = F E K. For like reasons A B L = C D K; ∴ *the figures* A B L H G, C D K E F, *are equiangular.* And because the figures A B H G, C D E F are similar, ∴ G H : H B :: F E : E D; but H B : H L :: E D : E K, ∴ G H : H L :: F E : E K. For like reasons A B : B L :: C D : D K, and B L : L H :: D K : K E; ∴ *the equiangular figures* A B L H G, C D K E F *have their sides about the equal angles proportionals,* ∴ *they are similar.* And in like manner may a rectilineal figure of *six* sides, similar to a given one, be described upon A B; and so on. Which was to be done.

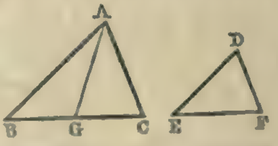
PROPOSITION XIX.—THEOREM.

Similar triangles (A B C, D E F) *are to one another, as the squares of their homologous sides.*

The triangles being similar, having the angle B = E, • Def 9 V. and the side B C homologous to E F,* that is such that A B : B C :: D E : E F, it is to be proved that tri·A B C : tri·D E F :: BC^2 : EF^2.

† 11 VI. Take B G, a third proportional to B C, E F;† so that B C : E F :: E F : B G; and draw G A.

Then because A B : B C :: D E : E F, alternately,* • 11 V. A B : D E :: B C : E F, but B C : E F :: E F † 2 V. : B G (Const.), ∴ A B : D E :: E F : B G;†



but triangles which have the sides about two equal angles reciprocally proportional are • 15 VI. *equal,** ∴ ABG = D E F. And because B C : E F :: E F : B G, ∴ B C : B G :: BC^2 : EF^2;† † 17 VI. Cor. but B C : B G :: triangle A B C : triangle • 1 VI. A B G;* ∴ triangle A B C : triangle A B G :: BC^2 : EF^2, but A B G = D E F, ∴ triangle A B C : triangle D E F :: BC^2 : EF^2; ∴ *similar triangles, &c.* Q. E. D.

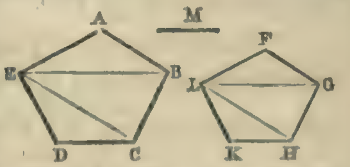
COR.—If three straight lines be proportionals, then as the first is to the third, so is any triangle upon the first, to a similar and similarly situated triangle upon the second.

PROPOSITION XX.—THEOREM.

Similar polygons may be divided into the same number of similar triangles, which are to one another as the polygons themselves: and the polygons are to one another as the squares of their homologous sides.

Let A B C D E, F G H K L be similar polygons, and let A B be the side homologous to F G.

From E, L draw the diagonals. Because the polygons are similar, the angle B A E = G F L, and B A : A E :: G F : F L; ∴ the triangles A B E, F G L have an angle in one equal to an angle in the other, and the sides about those equal angles proportionals, ∴ the triangles are • 6 & 4 VI. equiangular and similar,* ∴ the angle A B E = F G L: but since the polygons are similar, the whole angle A B C = the whole angle F G H, ∴ the remaining angle E B C = L G H.



Also E B : B A :: L G : G F, and from the similar polygons, A B : B C :: F G : G H; ∴ E B : B C :: L G : G H,† that † 17 V. Cor. is, the sides about the equal angles E B C, L G H are proportionals; • 6 VI. ∴ the triangles E B C, L G H are similar.* For like reasons the triangle E C D, L H K are similar, ∴ *the polygons are divided into the same number of similar triangles.* It is now to be proved that these triangles are, each to each, as the polygons themselves, and that these are to each other as the squares of their like sides.

Because the triangles A B E, F G L are similar, as • 19 VI. also B E C, G L H, ∴

$$\left.\begin{array}{l}\text{triangle } ABE : \text{triangle } FGL :: BE^2 : GL^{2*}\\ \text{triangle } BEC : \text{triangle } GLH :: BE^2 : GL^2\end{array}\right\}\therefore ABE$$

† 2 V. : F G L :: B E C : G L H.†

In like manner, because the similar triangles B E C, G L H, as also the similar triangles E C D, L H K, are as EC^2 to LH^2, ∴ B E C : G L H :: E C D : L H K, ∴ A B E : F G L :: B E C : G L H :: E C D : L H K. Con-

* 10 V. sequently,* A B E : F G L : : polygon A B C D E : polygon F G H K L ; but A B E : F G L : : A B^2 : FG^2,† † 19 VI. .·. (2 V.) *the polygons are to one another as the squares of their homologous sides* A B, F G ; *similar polygons, &c.* Q. E. D.

Cor.—It follows from this and the corollary to Prop. XIX., that if three straight lines be proportionals, the first is to the third as any rectilineal figure upon the first, to a similar and similarly described figure upon the second.

PROPOSITION XXI.—Theorem.

Rectilineal figures (A B) *which are similar to the same rectilineal figure* (C) *are also similar to one another.*

Because A is similar to C, they are equiangular, and * Def 1 VI. have also their sides about the equal angles proportionals.*

Again, because B is similar to C, they also are equiangular, and have their sides about the equal angles proportionals, .·. A, B are each of them equiangular to C, and have their sides about the equal angles of each of them and of C proportionals ; .·. A, C are equiangular, and have their sides about the equal angles propor- † 2 V. tionals ;† .·. A, B *are similar figures* ; .·. *rectilineal figures, &c.* Q. E. D.

PROPOSITION XXII.—Theorem.

If four straight lines (A B, C D, E F, G H) *are proportionals, the similar rectilineal figures, similarly described upon them, are also proportionals: and if the similar and similarly described rectilineal figures upon four straight lines are proportionals, the straight lines themselves also are proportionals.*

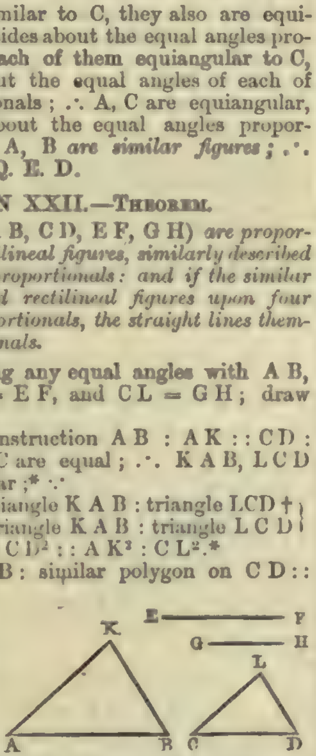
Draw A K, C L, making any equal angles with A B, C D ; make also A K = E F, and C L = G H ; draw K B, L D.

By hypothesis and construction A B : A K : : C D : C L ; and the angles A, C are equal ; .·. K A B, L C D * 6 VI. are equiangular ;* .·.

† 19 VI. A B^2 : C D^2 : : triangle K A B : triangle L C D †
A K^2 : C L^2 : : triangle K A B : triangle L C D

* 2 V. .·. A B^2 : C D^2 : : A K^2 : C L^2.*

But a polygon on A B : similar polygon on C D : : A B^2 : C D^2 ; and polygon on A K : similar polygon on C L : : A K^2 : C L^2 ; .·. polygon on A B : sim. polygon on C D : : polygon on E F : sim. polygon on G H.



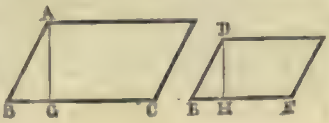
Again, let the last proportion have place, then A B : C D : : E F : G H.

Make equal angles at A and C, as before, as also A K = E F ; and as A B is to C D, so make A K to C L ;† † 12 VI. then the triangles K A B, L C D are equian- * 6 VI. gular ;* and .·., as proved above, A B^2 : C D^2 : : A K^2 : C L^2 ; but A K = E F, .·. A B^2 : C D^2 : : E F^2 : C L^2. But by hyp., the polygons on A B, C D, E F, G H are proportionals, and therefore, since similar poly- † 20 VI. gons are as the squares of their like sides† A B^2 : * 9 V. Cor. 2. C D^2 : : E F^2 : G H^2 ; .·. C L = G H.* But by construction, the four lines A B, C D, A K, C L, are proportionals ; .·. *the four lines* A B, C D, E F, G H *are proportionals* ; .·. *if four straight lines, &c.* Q. E. D.

PROPOSITION XXIII.—Theorem.

Equiangular parallelograms (A C, D F) *are to each other as the rectangles of their containing sides* (A B·B C *and* D E·E F).

Draw A G, D H, perpendiculars to B C, E F. Then because parallelograms on the same base and between the same parallels are equal, A C = A G·B C, and D F = D H·E F. Also the rectangles A G B C, A B·B C having the same altitude B C, are to each other as their bases, A G, A B. In like manner, the rectangles D H·E F, D E· * 1 VI. E F are to each other as their bases D H, D E.* But the triangles A B G, D E H having the angles at B and G respectively equal to those at E and H, are equi- † 4 VI. angular ; .·. A G : A B : : D H : D E.† .·. A G·B C : A B·B C : : D H·E F : D E·E F, and alternately* * 11 V. A G·B C : D H·E F : : A B·B C : D E·E F ; that is, *the parallelograms* A C, D F *are to each other as the rectangles* A B·B C, D E·E F *of their containing sides* ; .·. *equiangular parallelograms, &c.* Q. E. D.



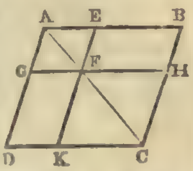
PROPOSITION XXIV.—Theorem.

Parallelograms (E G, H K) *about the diagonal* (A C) *of a parallelogram* (D B) *are similar to the whole, and to one another.*

Because D C, G F are parallels, the angle A D C = † 29 I. A G F ;† and because B C, E F are parallels, A B C = A E F ; and each of the angles B C D, E F G is equal to the opposite angle D A B ; .·. B C D = E F G ; .·. the parallelograms B D, E G are *equiangular.* And because the angle A B C = A E F, and that B A C is common to the two triangles B A C, E A F, .·. they are equiangular ; .·. A B : B C : : A E : * 4 VI. E F ;* that is, the opposite sides of parallelograms being equal,

A B : A D : : A E : A G
D C : C B : : G F : F E
C D : D A : : F G : G A

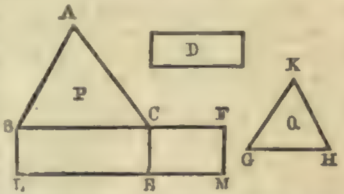
.·. the sides of the equiangular parallelograms B D, E G, about the equal angles, are proportionals : the parallelograms are therefore similar. For like reasons, the parallelograms B D, H K are similar ; .·. *each of the parallelograms* E G, H K *is similar to* B D : *they are therefore similar to each other* ;* * 21 VI. .·. *parallelograms, &c.* Q. E. D.



PROPOSITION XXV.—Problem.

To describe a rectilineal figure which shall be similar to one (P) *and equal to another given rectilineal figure* (D).

Upon B C, a side of the given figure, describe the † 45 I. Cor. parallelogram B E = P ;† and upon C E describe the parallelogram C M = D, and having the angle F C E = C B L ; then L B C + E C B = two right angles, .·. F C E + E C B = two right angles, .·. B C, C F are in a straight * 14 I. line ;* so also for like reasons are L E, E M. Between B C, C F find † 13 VI. a mean proportional G H ;† and upon it describe the rectilineal figure Q, similar and similarly * 18 VI. situated to the figure P,* Q shall be the figure required.

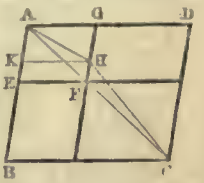


Because B C : G H : : G H : C F, .·. B C : C F : : P : † 20 VI. Cor. Q ;† but B C : C F : : B E : E F ; .·. P : Q : : B E : E F ; and P = B E, .·. Q = E F ; but E F = D, .·. Q = D, *and it is similar to* P. Which was to be done.

PROPOSITION XXVI.—Theorem.

If two similar parallelograms (B D, E G) *have a common angle* (at A) *and be similarly situated, they are about the same diagonal.*

For if not, let, if possible, the parallelogram B D have its diagonal A H C in a different straight line from A F, the diagonal of E G ; and let G F, or G F prolonged, meet A H C in H, and draw H K parallel to D A, or C B. Then B D, K G being about the same diagonal are similar, .·. D A : A B : : G A : A K ; but B D, E G * Hyp. are similar ;* .·. D A : A B : : G A : A E ; .·. G A : A E : : G A : A K ; .·. A K = A E which is impossible ; .·. B D, K G are *not* about the same diagonal, that is, the diagonal of B D



cannot be in a different straight line from that of E G, .·. *the parallelograms are about the same diagonal ; .·. if two similar parallelograms, &c.* Q. E. D.

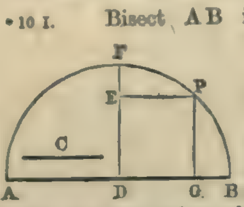
PROPOSITION XXVII.—THEOREM.

Of all the rectangles contained by the segments of a given straight line, the greatest is the rectangle of the two EQUAL *parts of the line ; that is, the square of half the line.*

This is an obvious corollary from Proposition V., Book II., as already noticed at page 553. The corresponding Proposition of Euclid is long and complicated, and Propositions XXVIII., XXIX., are still more so. Playfair, in his edition of the Elements, has therefore replaced these three Propositions by others of a simpler character; and his example is followed here; but the demonstrations of the next two Propositions will be found still simpler than those of Playfair.

PROPOSITION XXVIII.—PROBLEM.

To divide a given straight line (A B), *so that the rectangle contained by its segments may be equal to a given square* (C^2), *not greater than the square of half the line.*



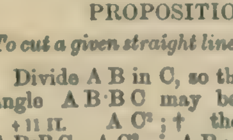
• 10 I. Bisect A B in D ;* then must A D be either = C, or ⁊ C. If A D = C, the thing required is done ; but if A D ⁊ C, draw D F perpendicular to A B, † † 11 I. and make D E = C, as also D F = A D. With centre D and radius D F describe a circle ; the circumference must pass through the points A, B, because D A, D F, D B are (by Const.) equal. Draw E P, parallel to A B, meeting the circumference in P ; and draw P G parallel to E D ; then G will be the point of division required.

• 34 I. For (Const.) E G is a rectangle, .·. P G = E D ;* but E D = C (Const.) .·. P G = C : but A G·G B = † 13 VI. P G^2,† .·. A G·G B = C,² .·. *A B is divided in* G, *so that* A G·G B = C^2 ; which was to be done.

PROPOSITION XXIX.—PROBLEM.

To prolong a given straight line (A B), *so that the rectangle contained by the segments between the extremities of the given line, and the point to which it is prolonged, may be equal to a given square* (C^2).

Bisect A B in D, draw B E perpendicular to it, and make B E = C ; draw D E, and with centre D and radius D E, describe a circle meeting A B prolonged in G, F ; then will A G·G B = C^2. Because D is the centre of the circle F E G, D F = D G ; and (Const.) D A = D B, .·. A F = B G. To each of these add A B, then • 13 VI. F B = A G. But F B·B G = B E^2,* .·. A G·G B = B E^2 = C^2, .·. A B *is prolonged to* G, *so that* A G·G B = C^2 ; which was to be done.



PROPOSITION XXX.—PROBLEM.

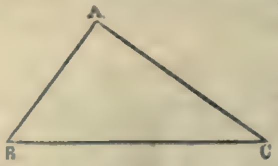
To cut a given straight line (AB) *in extreme and mean ratio.*

Divide A B in C, so that the rectangle A B·B C may be equal to † 11 II. A C^2 ; † then because A B·B C = A C^2, .·. A B : A C : : A C : • 17 VI. B C ;* .·. A B is cut in extreme and mean † Def. 3 VI. ratio ; † which was to be done.

NOTE.—An example is here furnished of the way in which pairs of *incommensurable* lines may be found at pleasure. It was proved (Prop. XXIII., Book V.), that if two lines A B, A C, are such that A B : A C : : A C : B C (= A B − A C), then A B, A C, are incommensurable. It would be impossible, therefore, to express the two lines A B, A C, accurately by *numbers* ; and it is thus that a theory of proportion, sufficiently comprehensive for the demands of geometry, could never be rigorously established by aid of numbers only : the bases of the proposed triangles in Proposition I. of this book, might, for aught we know to the contrary, be related as the lines A B, A C above ; and therefore could not be numerically expressed.

PROPOSITION XXXI.—THEOREM.

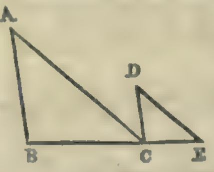
In a right-angled triangle (A B C) *the rectilineal figure described upon the side* (B C) *opposite to the right angle, is equal to the similar and similarly situated figures described upon the sides* (A B, A C) *containing the right angle.*



• 20 VI. For figure on AB : figure on AC : : AB^2 : AC^2 ;* therefore fig. on A B + fig. on A C : fig. on A C : : A B^2 † 13 V. + A C^2 : A C^2, † that is, fig. on A B + fig. on A C : fig. on A C : : B C^2 : A C^2. But fig. on B C : fig. on A C : : B C^2 : A C^2 ; • 2 V. consequently,* fig. on A B + fig. on A C : fig. on A C : : fig. on B C : fig. on A C, .·. the consequents being equal, the antecedents † 9 V. Cor. are equal, † .·. *fig. on* A B + *fig. on* A C = *fig. on* B C ; .·. *in a right-angled triangle, &c.* Q. E. D.

PROPOSITION XXXII.—THEOREM.

If two triangles (A B C, D C E) *which have two sides* (B A, A C) *of the one proportional to two sides* (C D, D E) *of the other be joined at an angle, so as to have their homologous sides* (A B, D C, and A C, D E) *parallel to one another, the remaining sides* (B C, C E) *shall be in a straight line.*



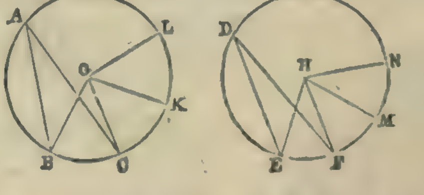
Because A B is parallel to D C, and A C meets them, the angle B A C = A C D ; for a similar reason C D E = A C D ; .·. B A C = C D E. And because the triangles A B C, D C E have an angle A = D, and the sides about those angles proportional, namely, B A : A C : : • Hyp. C D : D E,* the triangles † 6 VI. A B C, D C E, are equiangular ; † .·. angle A B C = D C E ; and it was proved that B A C = A C D, .·. A C E = A B C + B A C. Add A C B to each, .·. A C E + A C B = A B C + B A C + A C B = two right angles ; that is, at the point C, in A C, the two straight lines C B, C E, on opposite sides of it, make the adjacent angles A C E, A C B, together equal to two right angles ; .·. C B, C E *are in a straight line ; .·. if two triangles, &c.* Q. E. D.

PROPOSITION XXXIII.—THEOREM.

In equal circles (A B L, D E N), *angles* (B G C, E H F) *at the centres or* (B A C, E D F) *at the circumferences are to one another as the arcs* (B C, E F) *upon which they stand ; and so also are the sectors* (B G C, E H F).

NOTE.—In the following demonstration, by "the angle B G L" must be understood "the sum of the angles B G C, C G K, &c. ;" and by "the angle E H N," "the sum of the angles E H F, F H M, &c."

Take any number of arcs, C K, K L, each equal to B C ; and any number F M, M N, each equal to E F ; and draw G K, G L ; H M, H N ; then the angles at G • 27 III. are all equal,* .·. whatever multiple B L is of B C, the same multiple is the angle B G L of B G C. For a similar reason, whatever multiple E N is of E F, the same multiple is the angle E H N of E H F ; also if



B L = E N, then B G L = E H N ; if B L ⁊ E N, then B G L ⁊ E H N ; and if B L ∠ E N, then B G L ∠ E H N. Consequently (Def. V., p. 573) B C : E F : : B G C : E H F ; and since the angles A, D, are the halves of B G C, E H F, each of each, .·. B C : E F : : A : D ; .·. *the angles are as the arcs on which they stand.*

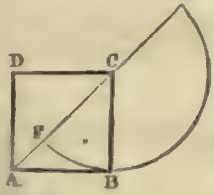
Again, the sectors B G C, C G K, K G L are equal; for it is manifest that, if applied to one another, they would coincide; in like manner, the sectors E H F, F H M, M H N, are also equal; consequently, if in the preceding demonstration "sectors" are substituted for "angles," the conclusion will be that B C : E F : : sector B G C : sector E H F. $\therefore$ *in equal circles, &c.* Q. E. D.

We shall conclude this chapter with two supplementary propositions of interest.

1. *The diagonal and side of a square are incommensurable.*

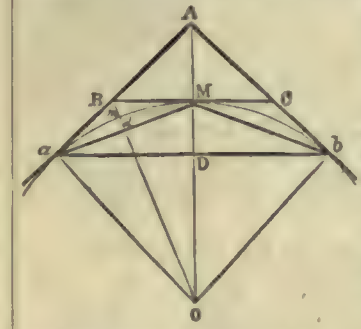
Let B D be a square: the diagonal A C is incommensurable with its side A B.

With C as centre, and C B as radius, describe the semicircle F B E: then A B C being a right angle, A B touches the circle (16 III.); $\therefore$ (36 III.) $AE \cdot AF = AB^2$ $\therefore$ (17 VI.) A E : A B : : A B : A F; $\therefore$ (23 V.) the lines A E, A B are incommensurable, $\therefore$ A C, A B, are also incommensurable; for if these had a common measure, that measure would likewise measure A C + AB, that is AE; so that B A E would have a common measure, which is shown to be impossible: $\therefore$ the diagonal and side of a square are incommensurable.



2. *The surface of a regular inscribed polygon, and that of a similar circumscribed polygon being given, to find the surfaces of regular inscribed and circumscribed polygons of double the number of sides.*

Let *ab* be a side of an *inscribed* polygon: the touching line *a*A, *b*C will each be half a side of the similar *circumscribed* polygon, as it is evident from what has been shown in reference to the inscribed and circumscribed pentagon in Propositions XI. and XII. of Book IV., and from what is said at the close of Prop. XVI. Let the surfaces of these two polygons be given. The chords *a*M, *b*M, drawn to the middle of the arc *a*M*b*, will be sides of an inscribed polygon of double the number of sides, and the touching line, B M C, will be a side of a similar circumscribing polygon, as is evident.



For brevity, let the surface of the inscribed polygon, whose side is *ab*, be represented by *p*, and that of the corresponding circumscribed polygon by P; also let the inscribed and circumscribed polygons of double the number of sides be denoted by p' and P'.

It is evident that the space O*a*D, is the same part of *p*, that O*a*A is of P,—that O*a*M is of p',—and that O*a*BM is of P'; for each of these spaces must be repeated exactly the same number of times to complete the polygon to which it belongs: consequently, since magnitudes are as their like multiples or sub-multiples, whatever proportions exist among these spaces, must also exist among the polygons of which they are sub-multiples. Now the right angled triangles OD*a*, OA*a* are similar, $\therefore$ O D : O*a* : : O*a* : O A; that is, O D : O M : : O M : O A; and since triangles of the same altitude are to one another as their bases, and that the altitude *a*D is the same for the triangles OD*a*, OM*a*, OA*a*, it follows, from the proportion just deduced, that O D*a* : O M*a* : : O M*a* : O A*a*; that is, the numerical measure of the surface of the triangle OM*a* is a mean proportional between the measures of OD*a*, OA*a*; consequently *the surface of the polygon p' is a mean proportional between the surfaces of p and P.*

Again, the right-angled triangles O D*a*, B M A, are also similar, $\therefore$ O D : O*a* : : B M : B A; that is, O D : O M : : *a*B : B A; consequently, since the altitude *a*D is the same for the triangles O D*a*, O M*a*, and the altitude O*a*, the same for the triangles O*a*B, O B A, and that triangles of the same altitude are to each other as their bases, it follows that O D*a* : O M*a* : : O*a*B : O B A; $\therefore$ (13 and 6 V.) OD*a* + O M*a* : 2O D*a* : : O*a*B + O B A : 2O*a*B; $\therefore p + p' : 2p :: P : P'$

The two conclusions now obtained are sufficient to enable us to compute the surfaces of inscribed and circumscribed regular polygons of 8, 16, 32, &c. sides, from having the surfaces of the inscribed and circumscribed squares already given. Thus, let the radius of the circle be numerically represented by 1, then if the given inscribed and circumscribed polygons (*p*, P) be *squares*, the side of the former will be $\sqrt{2}$, and that of the latter 2; and their surfaces will be 2 and 4 respectively; and, from what is proved above, the surface of the regular eight-sided *inscribed* polygon (p') will be a mean between the two squares *p*, P, $\therefore p' = \sqrt{8} = 2{\cdot}8284271$. Again, for the surface of the eight-sided *circumscribed* polygon (P') the proportion $p + p' : 2p :: P : P'$, gives,

$$= \frac{2p.\ P}{p + p'} = \frac{16}{2 + \sqrt{8}} = \frac{16}{4{\cdot}8284271} = 3{\cdot}3137085$$

And from these numerical expressions for the surfaces of inscribed and circumscribed polygons of eight sides, we may evidently, by repeating the operation, and substituting the values just obtained for *p* and P, deduce the numerical expressions for the surfaces of the sixteen-sided polygons, and so on to any extent: the results are as in the following table, which was in part given at page 569.

No. of sides.	Surf. of ins. pol.	Surf. of circ. pol.
4	2·0000000	4·0000000
8	2·8284271	3·3137085
16	3·0614674	3·1825979
32	3·1214451	3·1517249
64	3·1365485	3·1441184
128	3·1403311	3·1422236
256	3·1412772	3·1417504
512	3·1415138	3·1416321
1024	3·1415729	3·1416025
2048	3·1415877	3·1415951
4096	3·1415914	3·1415933
8192	3·1415923	3·1415928
16384	3·1415925	3·1415927
32768	3·1415926	3·1415926

From these numerical values for the surfaces of the inscribed and circumscribed polygons, it appears that when the number of the sides is so great as 32768, the two polygons differ so little from one another, that their numerical measures, as far as seven places of decimals, are absolutely the same. Now the circle, with which these polygons are connected, is manifestly *between the two*, as to amount of surface; being greater than the inscribed polygon, and less than the circumscribed one; consequently the surface of the circle must differ *less* from that of either polygon than the polygons differ from each other; and as the polygons themselves differ in numerical measure only, after the seventh decimal of the number 3·1415926, &c., it follows that this number, as far as the decimals extend, is the numerical expression for the surface of a circle whose radius is 1. By carrying on the foregoing process, the expression for the surface is found to be 3·141592653589793, &c.

CHAPTER VII.

PLANES:

BEING THE FIRST TWENTY-ONE PROPOSITIONS OF THE ELEVENTH BOOK OF EUCLID'S GEOMETRY.

INTRODUCTION.—The figures, lines, angles, &c., the properties of which form the subject of the First Six Books of Euclid's Geometry, are supposed to lie in one plane, or to be in space of two dimensions.* The following pages contain a few elementary propositions on the relations between lines, angles, &c., which do not lie in one plane, but are in solid space,—or space of *three dimensions.*† The student will find the following propositions very easy, *when once he has distinctly conceived the meaning of their enunciations.* The figures which are given to each proposition cannot represent the proposition to the eye so perfectly as in the former books, in consequence of their having to be drawn in perspective. It is hoped, however, that the shading introduced into the diagrams will aid the student in conceiving the proposition they belong to.

* i.e., of length and breadth.

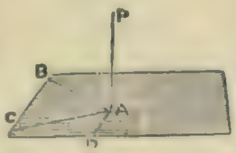
† i.e., of length, breadth, and thickness.

It is to be added, that, as in Plane Geometry, we are allowed to draw lines in any direction, and to produce them to any extent, so in solid Geometry we are allowed to draw planes in any direction, and to produce them to any extent. Moreover, two lines intersect in a point; in like manner it will be shown that two planes intersect in a line. Also, as we may suppose, a line to revolve round a point till it comes to a point on its plane, so we may suppose a plane to revolve round a given line until it comes to a given point situated anywhere in space.

DEFINITIONS.

I.

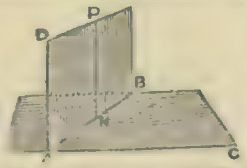
A straight line is perpendicular, or at right angles to a plane, when it makes right angles with every straight line in that plane which meets it.



Thus, if B D be a plane, P A a line perpendicular to it. Through A draw any lines A B, A C, A D . . . . in that plane, then will P A B, P A C, P A D, &c., be right angles.

II.

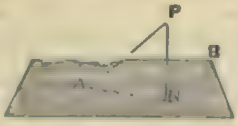
A plane is perpendicular to a plane, when a straight line drawn in one plane perpendicular to the intersection of the planes is at right angles to the other plane.



Thus, let A B D, A B C, be two planes, let the former be perpendicular to the latter, and let A B be the line of intersection of the planes in the plane A B D, draw P N at right angles to A B. Then is P N at right angles to the plane A B C.

III.

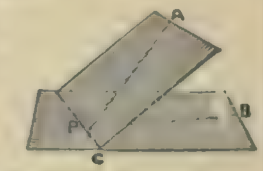
The inclination of a straight line to a plane, is the acute angle contained by that straight line, and another drawn from the point in which the first line meets the plane, to the point in which a perpendicular to the plane drawn from any point of the first line above the plane meets the same plane.



Thus, let A N B be a plane, A P a line meeting the plane in A; from P draw P N perpendicular to the plane, and meeting the plane in N. Join A N, then the angle P A N is the inclination of the line P A to the plane A N B.

IV.

The inclination of a plane to a plane, is the acute angle contained by two straight lines drawn from any one point of their common section at right angles to it, one upon one plane, the other upon the other.



Let P A C, P B C be two planes intersecting in the line P C. From P in the former plane, draw P A at right angles to P C; and from the same point P on the latter plane, draw P B at right angles to P C. Then if B P A be an acute angle, this is the inclination of the planes to each other.

V.

Two planes have the same inclination to one another which two other planes have, when the said angles of inclination are equal to one another.

VI.

Parallel planes are such as do not intersect, though produced ever so far in all directions.

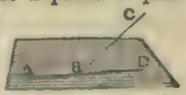
VII.

A solid angle is that which is made by the meeting of more than two plane angles, which are not in the same plane, in one point.

PROPOSITION I.—THEOREM.

One part (A B) *of a straight line* (A B C) *cannot be in a plane, and another part* (B C) *be above it.*

For let us suppose this possible, then since the straight line A B is in the plane, it can be produced in that plane: let it be produced to D. Now, suppose a plane to pass through the straight line A D, and let it be turned round that line, till it comes to the point C. Then because B and C are in the plane, the straight line B C is in it:* ∴ there are two straight lines A B C, A B D in the same plane, having a common segment A B, which is impossible.† Q. E. D.



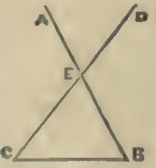
* 6 Def. I.

† Cor. 11 I.

PROPOSITION II.—THEOREM.

Two straight lines (A B, C D) *which cut one another (in the point* E) *are in one plane. And three straight lines* (B C, C E, E B) *which meet one another, are in one plane.*

Let any plane pass through E B, and let the plane be turned about E B produced if necessary, until it pass through the point C. Then because the points C and E are in this plane, the line C E is in it.* For the same reason the straight line B C is in the same plane, and by the hypothesis E B is in it; ∴ the three straight lines B C, C E, E B are in one plane. But A B is in the same plane as E B, and D C as E C.† Also A B and D C are in the same plane. Q. E. D.



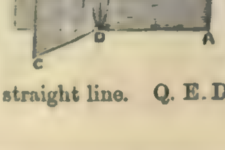
* 6 Def. I.

† 1 XI.

PROPOSITION III.—THEOREM.

If two planes (A B, B C) *cut one another, their common section* (D B) *is a straight line.*

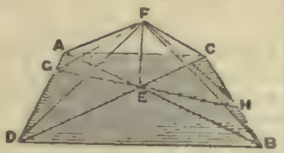
For, if not, since D, B are points in the plane A B, draw the straight line D F B in that plane, and similarly draw the line D E B in the plane B C. Then because these two straight lines have the same extremities, they enclose a space, which is absurd;* ∴ the common section B D cannot but be a straight line. Q. E. D.



* 3 I. Ax. I.

PROPOSITION IV.—THEOREM.

If a straight line (E F) *be at right angles to each of two straight lines* (A B, C D) *at their point of intersection* (E), *it shall also be at right angles to the plane* (A D B C), *which passes through them, i.e., to the plane in which they are.*

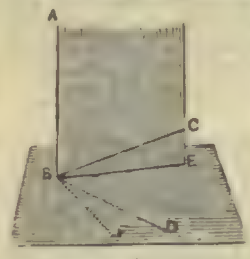


Take the straight lines E A, E B, E C, E D equal to each other. Join A D and B C. In the plane A D B C draw through E any line G E H, meeting A D and B C in G and H; we are to show that F E is perpendicular to G H. For join F A, F B, F C, F D, F G, F H. Now, because in the triangles A E D, B E C, the sides A E, E D = the sides C E, E B, and the angle A E D
• 15 I. = angle C E B,* ∴ A D = B C, and angle D A E
† 4 I. = angle E B C.† Again, in triangles A G E,
• 15 I. E B H we have the angle A E G = angle B E H;* and by what we have proved, angle G A E = E B H, and the side A E = side E B; ∴ G E = E H, and A G =
† 26 I. B H.† Again, since the sides A E, E F are equal to the sides D E, E F each to each, and the right
• Ax. 11 I. angle A E F = the right angle D E F;* ∴
† 4 I. A F = D F.† Similarly A F = F B, and E = F C. Hence in the triangles D A F, B C F we have the sides D A, A F = to the sides C B, B F, each to each, and the base D F = the base F C; ∴ the angle D A F =
• 8 I. the angle F B C.* Again, in the triangles G A F, H B F we have (by what we have already proved) the sides G A, A F = the sides H B, B F, each to each, and the angle G A F = angle H B F; ∴ base G F = base
† 4 I. F H.†

Hence (by what we have now proved), in the triangles G E F, H E F we have the sides G E, E F = the sides H E, E F, each to each, and the base F G = the base
• 8 I. F H, ∴ the angle G E F = the angle H E F,*
† 8 Def. I. which are therefore each right angles.† The same proof applies to any other line drawn through E, in the plane A B C. Hence E F is perpendicular to the
• 1 Def. XI. plane.* Q. E. D.

PROPOSITION V.—THEOREM.

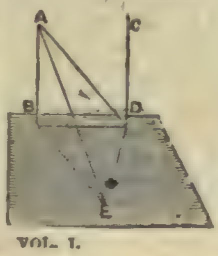
If three straight lines (B C, B D, B F) *meet all in one point* (B), *and a straight line* (B A) *stands at right angles to each of them at that point, these three straight lines are in one and the same plane.*



For if not, suppose the plane which passes through B F and B D not to pass through B C, and suppose the plane passing through A B and B C to cut the former plane in B E, then the straight lines B F, B D, B E are in the same plane, viz., the one passing through B D, B F, and A B is at right angles to B D, B E, and ∴ is also at
• 4 XI. right angles to B E.* Now, the angle A B C is a
† 11 Ax. I. right angle, ∴ angle A B C = angle A B F,† and they are both in the same plane, which is impos-
• 9 Ax. I. sible.* ∴ B C, B D, B F must be in the same plane. Q. E. D.

PROPOSITION VI.—THEOREM.

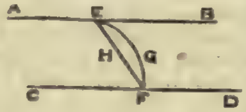
If two straight lines (A B, C D) *are at right angles to the same plane* (B D E), *they shall be parallel to one another.*



B, D are the points in which the lines meet the plane. Join B D, and at D draw D E in the plane perpendicular to B D. Make D E = A B. Join A D, B E, A E. Now, since A B is perpendicular to plane, A B D and A B E are right angles, then in triangles A B D, B D E the sides A B, B D = sides D E, D B, each to each, and angle A B D = angle B D E, each being a right angle, ∴ B E
• 4 I. = A D.* Then in triangles A D E, A B E, the sides A D, D E = the sides E B, B A, each to each, and the base A E common, ∴ angle A B E = angle A D E.†
† 8 I. But angle A B E is a right angle, ∴ A D E is a right angle. Now, because C D is perpendicular to the
• 3 Def. XI. plane, C D E is a right angle;* so that E D is at right angles to the three lines B D, A D, C D,
† 5 XI. which are therefore in the same plane;† but the plane which contains A D, D B contains A B,* ∴
• 2 XI. A B, B D, D C are in the same plane; now, angles A B D and B D C are right angles, and are ∴ together equal to two right angles, ∴ A B is parallel to
† 28 I. C D.† Q. E. D.

PROPOSITION VII.—THEOREM.

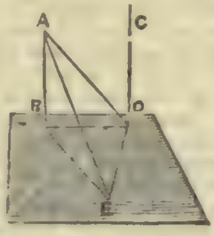
If two straight lines (A B, C D) *are parallel, the straight line drawn from any point* (E) *in the one, to any point* (F) *in the other, is in the same plane with the parallels.*



For if not, suppose E G F to be the straight line joining them, and suppose it do not fall in the plane. Since E and F are points in the plane, we can join them by a straight line, which lies wholly in the plane. Let this line be E H F. Then E H F and E G F are two straight lines, inclosing a space, which is impossible. Q. E. D.

PROPOSITION VIII.—THEOREM.

If two straight lines (A B, C D) *are parallel, and one of them* (A B) *is at right angles to a given plane* (B D E), *the other shall also be at right angles to the same plane.*



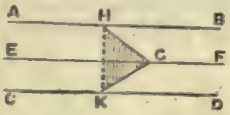
Let the lines meet the plane in B and D. Join B D. Then A B, B D, D C are in one
• 7 XI. plane.* Draw D E at right angles to B D, and in the
† 11 I. plane B D E.† Take A B = D E. Join A D, A E, B E. Now, A B being perpendicular to the plane, is perpendicular to B D
Def. XI. and B E.* Now, B D meets the parallel lines A B, C D, ∴ the angles A B D, B D C are together equal to two right an-
† 29 I. gles.† But A B D is a right angle, ∴ B D C is a right angle.

Again, in triangles A B D, B D E, the sides A B, B D = the sides E D, D B, and the right angle A B D = the
• 4 I. right angle B D E; ∴ A D = B E.* Hence in triangles A B E, A D E we have the sides A B, B E = the sides E D, D A, and the base A E is common, ∴
† 8 I. angle A B E = angle A D E.† But A B E is a right angle, ∴ A D E is a right angle; ∴ E D is at right angles to the lines B D and D A, and ∴ is at right angles
• 4 XI. to the plane passing through them,* and ∴ since C D is in the same plane with A D, B D, angle C D E is
† Def. XI. a right angle.† But we have already seen that B D C is a right angle, ∴ C D is at right angles to the
• 4 XI. plane passing through B D, D E,* i.e., is at right angles in the plane B D E. Q. E. D.

PROPOSITION IX.—THEOREM.

If two straight lines (A B, C D) *are each parallel to the same straight line* (E F), *but not both in the same plane with it, they are parallel to one another.*

For, take any point G in E F, and from G in the
• 11 I. plane AB, EF draw GH perpendicular to EF;*



and likewise from G in plane E F, C D, draw G K perpendicular to E F.

Then because G F is at right angles to G H and G K, it is at right angles to the plane
† 4 XI. H G K;† and since G F is at right angles to the plane H G K, and H B is parallel to G F, ∴ H B is
• 8 XI. at right angles to H G K.* Similarly K D is at right angles to H G K, ∴ H B and K D are parallel,†

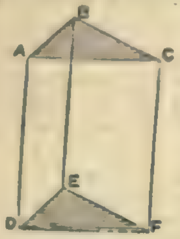
† 6 XI. or A B and C D are parallel to each other. Q. E. D.

PROPOSITION X.—THEOREM.

If two straight lines (A B, B C) *meeting one another be parallel to two others* (D E, E F) *also meeting one another, the latter two not being in the same plane with the former two, then the former two contain an angle* (A B C) *equal to the angle* (D E F) *contained by the latter two.*

We suppose that A B is parallel to D E, and B C to E F. Take B A = E D, and B C = E F, and join B E, A D, C F, A C, D F.

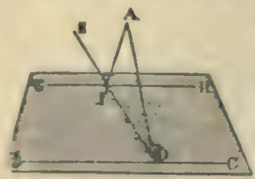
Then because A B is equal and parallel to D E, and their extremities are joined towards the same points B E and A D; ∴ B E is equal and
* 33 I. parallel to A D.* Similarly B E is equal and parallel to C F, and
† Ax. 1 I. ∴ A D is equal† and paral-
* 9 XI. lel* to C F. But the extremities of A D, C F are joined towards the same points by A C, and
† 33 I. D F, and therefore A C = D F.† Hence in triangles A B C, D E F we have the sides A B, B C = the side D E, E F, each to each, and the base A C = the base D F, ∴ the angle
* 8 I. A B C = the angle D E F.* Q. E. D.



PROPOSITION XI.—PROBLEM.

From a given point (A) *above a plane* (B C H) *to draw a line perpendicular to that plane.*

In the plane draw any line B C. From A draw A D
* 12 I. perpendicular to B C.* In the given plane from
† 11 I. D draw E D perpendicular to B C.† From A
* 12 I. draw A F perpendicular to E D,* then A F is the line required.

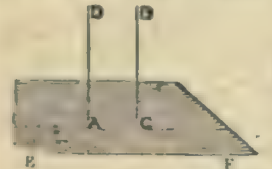


From through F draw G H,
† 31 I. parallel to BC.† Now, since B C is perpendicular to E D and A D, it is perpendicular to the plane passing
* 4 XI. through them,* ∴ G H is also perpendicular to the plane passing through E D
† 8 XI. and A D,† and ∴ is perpendicular to F A ;* ∴
* Def. XI. the angle A F G is a right angle. But, by construction A F D is a right angle, then since A F is perpendicular to the lines F G, F D it is also perpendicular
† 4 XI. to the plane passing through them,† *i. e.*, is perpendicular to the plane B C H. Which was to be done.

PROPOSITION XII.—PROBLEM.

From a given point (A) *in a given plane* (E F) *to draw a line perpendicular to that plane.*

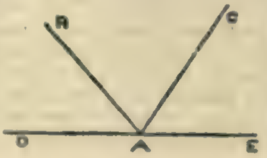
Take any point B above the plane, and from B draw B C perpendicular to the
* 11 XI. plane.* From A draw A D parallel to
† 33 I. B C ;† then because A D and B C are parallel, and B C is perpendicular to the plane, ∴ A D is also perpendicular to the
* 8 XI. plane.* Which was to be done.



PROPOSITION XIII.—THEOREM.

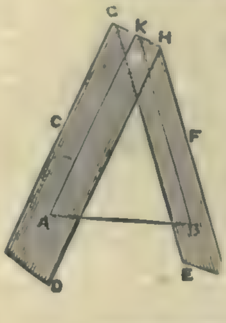
From the same point (A) *of a given plane, there cannot be two straight lines* (A B, A C) *at right angles to the plane, upon the same side of it ; and there can be but one perpendicular drawn to a plane from a given point above it.*

For, if possible, suppose A B, A C to be at right angles to a given plane. Suppose the plane which contains A B and A C to intersect the given plane in D E. Then C A, B A, D A, are in the same plane. Now C A is perpendicular to every line in the
* Def. XI. plane,* and ∴ to A D, ∴ C A D is a right angle. For the same reason B A D is a right angle, ∴
† Ax. 11 I. C A D = B A D,† which is absurd. Also from the same point above a given plane, two perpendiculars cannot be drawn to it, for if they could they would be parallel to one another,*
* 6 XI. which is absurd. Q. E. D.



PROPOSITION XIV.—THEOREM.

Planes (D C, E F) *to which the same straight line* (A B) *is perpendicular are parallel to each other.*

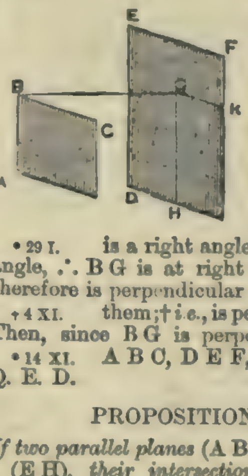


For if not, the planes must intersect ; let them intersect in the straight line H G, in which take any point K. Join K A, K B. Then K A is in the plane D C, ∴ K A B is a right angle.*
* Def. XI. Similarly A B K is a right angle, ∴ the two angles K A B, A B K of the triangle A B K, are equal to two right angles, which is absurd,† ∴
† 17 I. the two planes cannot intersect, and therefore are pa-
* Def. XI. rallel.* Q. E. D.

PROPOSITION XV.—THEOREM.

If two straight lines (A B, B C) *meeting one another be parallel to two other straight lines* (D E, E F) *which meet one another but are not in the same plane with the former two, then the plane passing through the former two* (A B, B C) *is parallel to the plane passing through the latter two* (D E, E F).

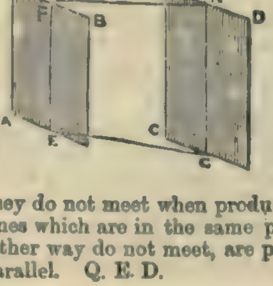
For, from B draw B G perpendicular to the plane
* 11 XI. A B C,* meeting the plane D E F in G. In this plane and through G, draw G H, G K, parallel to
† 31 I. D E, E F.† Then, since E D is parallel both to A B and G H, ∴ A B is
* 9 XI. parallel to G H.* Similarly G K is parallel to B C. Again, because B G is perpendicular to the plane A B C, it is perpendicular to
† Def. XI. A B,† ∴ A B G is a right angle ; but because A B is parallel to G H, A B G and B G H are together equal to two right angles,* ∴ B G H
* 29 I. is a right angle, Similarly B G K is a right angle, ∴ B G is at right angles to G H and G K, and therefore is perpendicular to the plane passing through
† 4 XI. them;† *i.e.*, is perpendicular to the plane D E F. Then, since B G is perpendicular to both the planes
* 14 XI. A B C, D E F, these planes are parallel.* Q. E. D.



PROPOSITION XVI.—THEOREM.

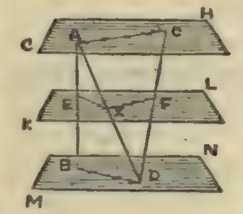
If two parallel planes (A B, C D) *are cut by a third plane* (E H), *their intersections with it* (E F, G H) *are parallels.*

For if not, they will meet when produced either on the side F H or E G ; let them be produced on the side F H, and meet in K. Then, since G H is in the plane C D, G H when produced is in
* 1 XI. that plane,* ∴ G H K is in the plane C D. Similarly E F K is in the plane A B, ∴ the plane A B meets the plane C D, for they have a common point K, and therefore is not parallel to it, which is contrary to the hypothesis, ∴ E F and G H do not meet when produced on the side F H. Similarly they do not meet when produced on the side E G. But lines which are in the same planes, and being produced either way do not meet, are parallel, ∴ E F and G H are parallel. Q. E. D.



PROPOSITION XVII.—Theorem.

If two straight lines (A B, C D) *are cut by parallel planes* (G H, K L, M N, *in points* A C, E F, B D), *they are cut in the same ratio,* (*i. e.,* A E : E B :: C F : F D).



For, join A D meeting K L in X, and join A C, E X, X F, and B D. Then, because the plane A B D cuts the parallel planes K L, M N in the lines E X and B D, these are parallels.* • 16 XI. Similarly A C is parallel to X F; now because E X is parallel to B D, and A C to X F, we have,

† 2 VI. A E : E B :: A X : X D†

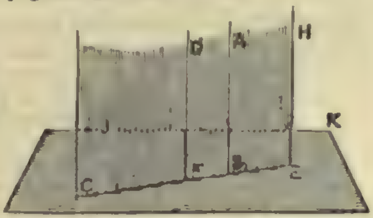
and A X : X D :: C F : F D

∴ A E : F B :: C F : F D. Q. E. D.

PROPOSITION XVIII.—Theorem.

If a straight line (A B) *be at right angles to a plane* (C K), *every plane that passes through the line is at right angles to the plane.*

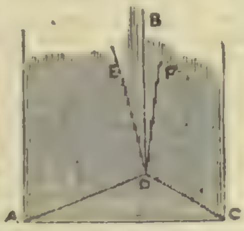
Let C H be any plane passing through A B, and let it intersect C K in the line C E. From any point F in C E, and in the plane C H, draw F G at right angles • 11 I. to C B.* Then, because A B is perpendicular to the † Def. XI. plane it is perpendicular to C E,† ∴ A B F is a right angle. But G B F is also a right angle, ∴ G F B and F B A are together equal to two right angles; • 28 I. ∴ G F is parallel to B A,* and A B is perpendicular to the plane C K, ∴ G F is perpendicular to † 8 XI. the plane C K;† similarly any other line in C H drawn perpendicular to C E is perpendicular to the plane C K, ∴ plane C H is perpendicular to plane C K. In like manner it can be proved that any other plane passing through A B is perpendicular to C K. Q. E. D.



PROPOSITION XIX.—Theorem.

If two planes (A B, B C) *which cut one another* (*in the line* B D) *be each perpendicular to a third plane* (A D C), *the common section* (B D) *is also perpendicular to the same plane.*

Let plane A B intersect plane A D C in A D, and let plane B C intersect plane A D C in D C. Then, if B D is not perpendicular to A D C, from point D in plane A B, draw D E perpendicular to A D,* • 11 I. and similarly in B C draw D F perpendicular to D C. Then, because plane A B is perpendicular to A D C, we have E D perpendicular to † Def. XI. A D C,† similarly F D is perpendicular to A D C; ∴ from the point A D in the plane A D C, two lines D E, D F are drawn perpendicular to that plane, • 13 XI. which is absurd :* ∴ B D is perpendicular to the third plane A D C. Q. E. D.



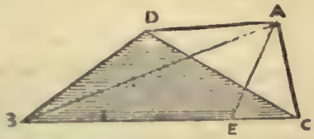
PROPOSITION XX.—Theorem.

If a solid angle (*at* A) *be contained by three plane angles* (B A C, C A D, D A B), *any two of them are greater than the third.*

If the three plane angles are equal, any one of them is clearly less than the other two.

If the three angles are not equal, let B A C be that which is not less than either of the other two.

At A in B A, and in plane B A C, make the angle B A E = angle • 23 I. B A D,* make A E = A D, through E draw B E C, meeting A B and A C in B and C. Join D B, D C.

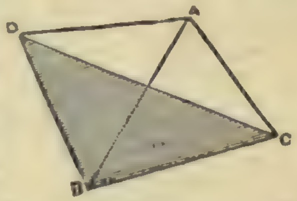


Then in triangles B A D, B A E, the sides B A, A D = the sides B A, A E each to each, and the angle B A D = † 4 I. the angle B A E, ∴ the base B D = base B E.† Now, the sides B D, D C are together greater than B C;* • 20 I. *i. e.,* greater than B E, C E; taking away the equals B D, B E, we have left D C greater than E C.† † 5 Ax I. Then in the triangles E A C, D A C, we have the sides D A, A C = the sides E A, A C, each to each. But the base D C is greater than the base E C, ∴ the • 25 I. angle D A C is greater than the angle E A C.* To each of these add the equals D A B, B A E. Then the two B A D, D A C are together greater than B A C.* † 4 Ax. I. Q. E. D.

PROPOSITION XXI.—Theorem.

Every solid angle (A) *is contained by plane angles, which, together, are less than four right angles.*

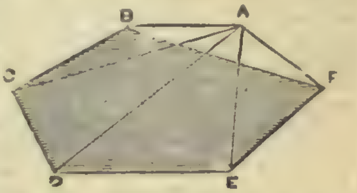
First, let the angle (A) be contained by three plane angles B A C, C A D, D A B. Join B C, C D, D B. Now, since the angles of any triangle are together equal to two right • 32 I. angles,* we have the angles of any three triangles together equal to six right angles, ∴ B A C + C A D + D A B + A B C + B C A + A C D + C D A + A D B + D B A = six right angles.



Now, because D is a solid angle, C D A + A D B are † 20 XI. greater than C D B.* Similarly D B A + A B C are greater than D B C, and B C A + A C D are greater than B C D.

∴ B A C + C A D + D A B + C D B + D B C + B C D are less than six right angles. Now, B C D is a triangle, and ∴ C D B + D B C + B C D = 2 right angles, ∴ B A C + C A D + D A B are together less than four right angles. But these contain the solid angle A, ∴ when three angles contain a solid angle, they are together less than four right angles. Q. E. D.

Next, suppose the angle A to be contained by any number of plane angles. Then all these plane angles are together less than four right angles; for supposing the lines containing the angle to be cut by a plane, so that we obtain a polygon B C D E F instead of the triangle in the first case. As before, we can easily prove that the angles containing the solid angle, together with the angles of the polygon, are less than twice as many right angles as there are sides of the polygon; but twice as many right angles as there are sides of the polygon are equal to the angles† • Cor. 33 I. of the polygon, together with four right angles; ∴ the plane angles forming solid angles at A, together with angles of polygon, are less than angles of polygon, together with four right angles, ∴ angles forming solid angles are together less than four right angles. Q. E. D.



The study of the last two propositions will be of value in connection with the section on Crystallography.—Ed.

CHAPTER VIII.

SPHERICAL GEOMETRY.

Introduction.—This chapter on Spherical Geometry, is intended to be strictly introductory to the cognate science of Spherical Trigonometry. To explain their relation, the following, for our present purposes, will suffice. The Science of Geometry, as given in the first six books of Euclid's Geometry, contains, along with others, a variety of propositions concerning the relations between the sides and angles of plane triangles. And these propositions may be *directly* applied to solve a variety of problems by *construction*—*e. g.*, if we are asked to construct an equilateral and equiangular pentagon on a given straight line, we can do this, with rule and compasses, by skilfully availing ourselves of certain properties of lines and angles which Euclid has proved. But if the question were asked—given that one side of a triangle is so many feet long, and that the angles adjacent to that side are respectively certain parts of a right angle, how many feet long are the remaining sides? The question is one, not of *construction*, but of *calculation*, and we cannot solve it directly, but only by the intervention of a science which shall give algebraical expressions for the relations between the sides and angles of triangles. Such a science has been invented, and is called *plane trigonometry*. It clearly *presupposes* a knowledge of the relations which Euclid has established, and assumes them as its basis. Now, suppose the triangles to be described, not on a plane, but on the surface of a sphere, spherical trigonometry is the science which gives us the means of *calculating* from given data the sides and angles of *such* triangles. This science, therefore, stands to the *spherical* triangle in the same relation that plane trigonometry stands to the *plane* triangle. And as the latter science rests on that part of the science of Geometry which treats of plane triangles as its basis, so the former science must rest on another portion of the science of Geometry, which shall treat of triangles described on the surface of a sphere as its basis.

The need of such a science as Spherical Trigonometry will be apparent to any one who reflects on the circumstance that the surface of the globe is (very nearly) spherical; consequently, all the triangles calculated in the course of a survey on a large scale are, when reduced to the surface of the earth, spherical triangles. Hence, surveying on a large scale (Geodesy) cannot be carried on without the investigations of spherical trigonometry. Again, in practical astronomy, the positions of all the heavenly bodies are referred to the surface of the great sphere—that, namely, which has the centre of the earth, supposed to be fixed, for its centre; and thus the triangles recognised in practical astronomy are spherical triangles, and the requisite calculations cannot be carried on except by means of the science of spherical trigonometry.

Having thus explained that this so needful science demands as its basis the investigation of certain properties of the spherical triangle, we will proceed to investigate those properties. As already stated, we shall confine ourselves strictly to such propositions as we shall hereafter need in treating of spherical trigonometry.

We have already, in general terms, said that a spherical triangle is one described on the surface of a sphere; we must, however, define this and other points more accurately, which we shall do as we proceed.

It is to be observed, that we suppose that we can draw any plane through any three given points; or, which is the same thing, through any straight line, and through a point not on that same straight line; also that we can cut any given solid, by a plane, in any direction whatever.

N.B.—From Euclid VI., 33, it appears, that in a given circle, any angle at the centre is proportional to the arc on which it stands. The arc is therefore said to measure the angle.

DEFINITIONS.

I.

A *solid* is a space which has three dimensions—namely, length, breadth, and thickness.

II.

A *sphere* is a solid bounded by a surface, of which every point is equally distant from a point within it called the *centre*.

III.

The *radius* of a sphere is a straight line drawn from the centre, to any point in the surface of the sphere.

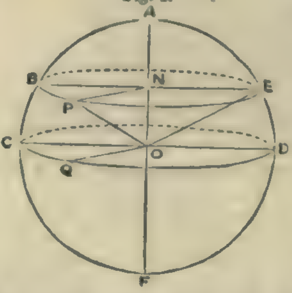
IV.

A straight line drawn through the centre, and terminated both ways by the surface of the sphere, is called the *diameter*.

PROPOSITION I.

Every section of a sphere made by a plane is a circle.

Fig. 1.



Let A B C D be the sphere; draw O A any radius whatever; let B P E N be a plane cutting the sphere's surface in the line B P E. It is supposed that the plane of the paper passes through the centre of the sphere perpendicularly to this cutting plane, which also cuts the radius O A in the point N; and suppose O A to be perpendicular to the plane; take P, any point in the line B P E, join P N, P O, O E. Then because P N is in the plane B P E, and O N is perpendicular to the plane, ∴ P N O is a right angle. For the same reason O N E is a right angle, ∴ in the triangles P N O, O N E, we have $PN^2 + NO^2 = PO^2$ and $EN^2 + NO^2 = OE^2$. Now, O P = O E, because each are radii of the sphere, ∴ $PN^2 + NO^2 = EN^2 + NO^2$, ∴ P N = E N. Similarly of any other point in the line B P E, ∴ B P E is a circle, the centre of which is N.

If the plane pass through the centre of the sphere, as plane C Q D, take Q any point in the line in which the plane cuts the surface of the sphere. Join O Q, O D. Then O Q, O D are radii of the sphere, ∴ O Q = O D. Similarly of any other point in the line C Q D, ∴ the section C Q D is a circle. Hence every section of a sphere is a circle. Q. E. D.

N.B.—The figure, as thus drawn, will, it is hoped, be quite comprehensible; it may be observed, however, that the circle A C D is the section of the sphere made by the plane of the paper. The other sections of the sphere are made by planes which intersect the plane of the paper in straight lines—*e.g.*, in B E, and in C D, and these sections are seen in perspective, as C Q D, B P E.

Def. V.—The section of a sphere made by a plane which does not pass through the centre is called a *small* circle. Thus, in Fig. 1, B P E is a small circle.

Def. VI.—The section of a sphere made by a plane which passes through the centre is called a *great* circle. Thus, in Fig. 1, C Q D is a great circle.

PROPOSITION II.—Theorem.

A great circle may be drawn through any two points on the surface of a sphere, but in general not through more than two points.

For, taking any two points on the surface of the sphere, we can draw a plane through them, and this plane can be made to pass through any third point, *viz.*, through the centre of a sphere. The section of the sphere made by this plane is a great circle, and the two points clearly lie on it.

These three points determine the plane, and ∴ we cannot be sure of its passing through any other point, whether on the surface of the sphere or not. Q. E. D.

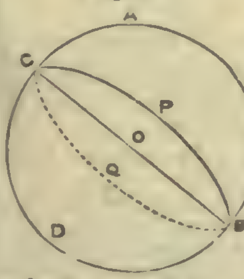
Cor.—It is plain that a small circle may be made to pass through any three points. For a plane being drawn through two points can be made to pass through a third; and if these three points are on the surface of a sphere, the plane cuts the sphere in a circle on which these three points lie.

N.B.—We shall henceforth assume that we can draw arcs of great circles in any possible direction; for instance, through any two points. For this is merely equivalent to drawing a plane through the centre of the sphere, and those two points, which of course cuts the sphere in the required great circle.

PROPOSITION III.

Two great circles bisect one another.

Fig. 2.

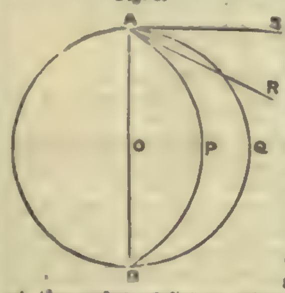


For suppose A B C D, the section made by the plane of the paper, to be one circle, and B P C, a section made by any other plane B P C Q, to be the other, then these planes intersect in the straight line B C, which passing through O, the centre of the sphere B C is a diameter of each of the circles, and ∴ bisects each of the circles, ∴ B P C = C Q B, and B A C = C D B, or the two great circles bisect each other. Q. E. D.

PROPOSITION IV.

The inclination of two great circles is the angle between the tangents drawn to those circles at their point of intersection.

Fig. 3.



Let one great circle be that made by the plane of the paper A Q B. Let A P B, the other circle, be that made by any other plane, then the diameter A O B is the line in which the planes intersect; in plane of paper draw A S perpendicular to A B; in the plane A P B draw A R perpendicular to A B. Then (*Planes, ante*, p. 590, Def. 4) R A S is the angle between the planes. But A R touches the circle A P B at point A, and A S touches the circle A Q B at point A (Euclid III., 16), ∴ the inclination of two great circles is the angle between their tangents at the point of intersection. Q. E. D.

N.B.—The angle R A S, between the tangents R A, S A, is generally supposed to be measured on the sphere, and is called the angle P A Q.

Def. VII.—If from the centre of a sphere a line be drawn perpendicular to the plane of any circle, whether great or small, and be produced both ways to meet the surface of the sphere, the points in which that line meets the surface of the sphere, are called the *poles* of the circle.

Thus, in Fig. 1, let C Q D be the plane of a great circle, O being the centre of the sphere. Through O draw O A perpendicular to the plane C Q D, and produce it to meet the surface of the sphere in F and A. Then F and A are the *poles* of the great circle C Q D.

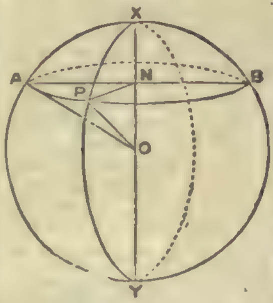
Again, if B P E be the plane of a small circle B P E, from O draw O N perpendicular to that plane, produce O N both ways to meet the surface of the sphere in A and F. These are the poles of the small circle B P E. It is usual to call A (the pole nearest to the small circle), *the* pole of the circle.

From the demonstration of Proposition I., it is plain that N is the centre of the circle B P E.

PROPOSITION V.

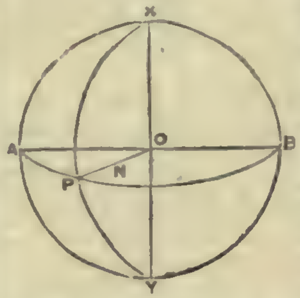
If from the pole of a circle great circles be drawn to any two points of that circle, the intercepted arcs are equal.

Fig. 4.



(1). In the case of a small circle, let A P B be the plane of the small circle, and X O Y perpendicular to that plane, and meeting it in N, then X Y are the poles of the circle, and N is its centre. Let X A Y, the section made by the plane of the paper, be one great circle, X P Y the section made by the plane passing through any other point P be the other great circle. We have to prove that the arc X P = arc X A. For, since N is the centre of the circle A P B, we have A N = P N; also, since O is the centre of the sphere O A = O P, ∴ in the triangle A O N, P O N, we have the sides A O, O N, = the sides P O, O N, each to each, and the base A N = the base P N, ∴ the angle A O N = angle P O N. But in equal circles, equal angles stand on equal circumferences, ∴ the arc A X = arc P X.

Fig. 5.



(2). In the case of a great circle, let A P B be the great circle, O its centre, and X O Y perpendicular to the plane A P B. Then, X Y are the poles of the circle. Let the section made by the plane of the paper X A Y be one of the great circles, and let X P Y be the other; we have to show that arc A X = arc P X—join O A, O P. Then, because X O is perpendicular to the plane, X O A and X O P are right angles, and ∴ are equal to each other. Hence as before, arc A X = arc P X. Q. E. D.

Cor. 1.—Hence the pole of a circle is equally distant from every point of that circle. *The distance being measured along a great circle.*

Cor. 2.—In the case of the pole of the great circle, it is plain, since A O X is a right angle, that A X is the fourth part (or *quadrant*) of the great circle A X B Y.

Cor. 3.—Also any plane passing through the poles of a great circle is clearly perpendicular to the plane of that circle; since the line joining the poles X O Y (Fig. 5) is perpendicular to the plane A P B. (See *Planes*, p. 590, Def. 2).

Cor. 3 (Fig. 5).—The inclination of the two great circles X A Y, X P Y is clearly measured by the arc A P. For P O and A O are each perpendicular to X Y, the line of intersection of the great circle, ∴ P O A is the inclination of the great circles, and P O A is measured by the arc A P.

Cor. 4.—We have already seen that the angle A X P, *i. e.*, the angle between the tangents to the circles at the point X, is the inclination between the planes, ∴ A P measures the angle A X P. (See Prop. IV.)

Def. VIII.—A spherical triangle is the portion of a surface of a sphere contained by the arcs of three great circles.

Thus, let A X B, C Z D, E Y F be three great circles which intersect in the points Z Y X, then the space

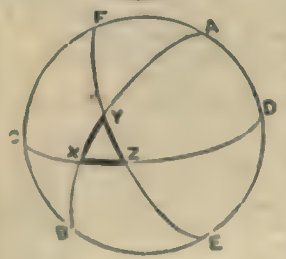


Fig. 6

Z X Y inclosed by the arcs Z Y, Y X, X Z is called a spherical triangle.

It will be observed, that the great circle in a spherical triangle is analogous to the straight line in the case of a plane triangle; but there is this difference to be observed, that two straight lines, when produced, never meet, whereas two great circles, when produced, always meet, *viz.*, in a point distanced from the other by a whole semicircle. To consider the result of this circumstance, we will suppose the section made by the plane of the paper (A B *ab*) Fig. 7, to be one great circle, and the two others to be A C*ac* and B C*bc*, O the centre of the sphere, A O*a*, B O*b*, C O*c*, are diameters. It will be seen that A B C is a spherical triangle, as in the case of figure 6. But the three circles, in addition to A B C, make seven other spherical triangles, *viz.*, *ab*C, B C*a*, *b*C A, on the one hemisphere, ABC*a*, and AB*c*, *abc*, *bc*A, B*ca*, on the hemisphere A*cba*.

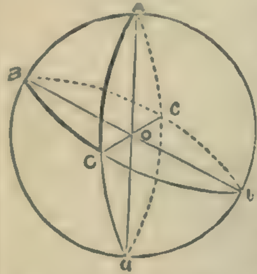

Fig. 7.

Also, it is plain that the triangles on the one hemisphere are equal to those on the other, each to each; thus, the triangle A B C is equal to the triangle *abc*. For A C*a*, and C*ac* are each halves of the same circle, and ∴ are equal to each other; take away the common part C*a*, and we have left A C = *ac*. Similarly A B = *ab*, and B C = *bc*. Again, the angle of the triangle *acb*, which is the angle between the planes, is equal to the angle A C B, which is also the angle between the planes; similarly the other angles are equal, and they are described on the surface of the same sphere; if, therefore, the triangles were superimposed, they would coincide, and are ∴ equal.

N.B.—The student will do well to consider very carefully the above observations: he must also take notice of the assumption, that triangles taken off the surface of the same sphere will coincide, provided their sides and angles are equal. This is merely assuming that the *curvature* of the same sphere is the same at all parts; which is obviously true, as the following consideration will assure us:—Suppose we have two spheres of equal radii—suppose these centres to coincide—then, since every point in each sphere is equally distant from their common centre, their surfaces coincide, and will continue to coincide however we may move either of them, provided their centres continue to coincide.

It is plain that the side A B measures the angle AOB. Hence the side of a spherical triangle is spoken of as an angle, *viz.*, the plane angle it subtends at the centre of the sphere.

PROPOSITION VI.

Any two sides of a spherical triangle are together greater than the third, and the three sides of the triangle are together less than four right angles.

For (*Planes*, see Prop. 20), if a solid angle be contained by three plane angles, any two are greater than a third; but (Fig. 7) the solid angle at O is contained by A O B, B O C, C O A, ∴ any two of these are greater than a third; and hence any two of the three sides of A B C (which sides measure these angles respectively) must be greater than the third.

Again (*Planes*, Prop. 21), the three angles, A O B, B O C, C O A, are together less than four right angles; and ∴ the three sides, A B, B C, C A, which measures these angles must be less than four right angles. Q.E.D.

Def. IX.—A *lune* is the portion of the surface of a sphere inclosed by the arcs of two great circles.

Thus (Fig. 7), A B*a* is a lune.

Def. X.—The angle of a *lune* is the angle between the two great circles which bound it.

Thus (Fig. 7), B A*a* is the angle of the lune.

PROPOSITION VII.

On equal spheres, if the angles of two lunes are equal, the lunes themselves are equal.

Let A C B D, A E B F, be two lunes described on equal and coincident spheres, having the angle C A D = angle E A F, these lines shall be equal; for suppose the one sphere to revolve till the circle A E B coincides with A C B, then because angle C A D = angle E A F, we must have A F B coinciding with A D B. The lunes, therefore, coincide and are equal.

N.B.—In the above demonstration we have assumed that the lunes have the same extremities, A B: we are obviously entitled to do this, since by shifting the spheres these extremities can be brought to coincide. Also, the proposition is plainly true when the lunes are on the *same* sphere. Also, it is manifest that the *greater* lune has the *greater* angle, and *vice versâ*.

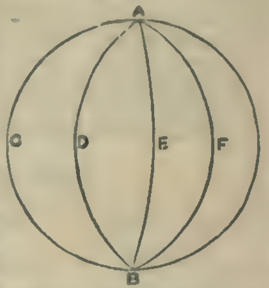

Fig. 8.

PROPOSITION VIII.

In the same or equal spheres, lunes are to each other in the ratio of their angles.

For let l and m be two lunes, the angles of which are a and b; let A be any multiple of a, and L the lune corresponding to A; then it is plain that L is the same multiple of l that A is of a. Similarly let B be any multiple of b, and let M be the corresponding lune; then it is plain that M is the same multiple of m that B is of b. We have then four magnitudes, l, m, a, b; and of the first and third we have taken any equimultiples, L and A; and of the second and fourth we have taken any equimultiples, M and B. Now, by last proposition, if $L > M$, A is $> B$; if equal, equal; if less, less ∴ (Def. V., p. 571), $l : m :: a : b$. Q. E. D.

Cor.—It is plain that the area of half a hemisphere is a lune whose angle is a right angle, ∴ if X be the area of a sphere, and if A be any lune whose angle is B,

$$A : \frac{X}{4} :: B : \text{one right angle.}$$

$$\therefore A : X :: B : \text{four right angles.}$$

Or area of lune : area of sphere : : anglé of lune : four right angles.

Def. XI.—The spherical excess of a spherical triangle is the excess of the sum of its three angles over two right angles.

It will be seen by the next proposition that the sum of the three angles of a spherical triangle are really greater than two right angles—the excess of the angles above two right angles is clearly due to the *sphericity* of the triangle; hence the term "spherical excess."

PROPOSITION IX.

To prove that the angles of a spherical triangle are together greater than two right angles, and that the area of a spherical triangle has to the area of half the sphere on which it is described the same ratio that the spherical excess has to two right angles.

For (Fig. 7) let A B C be the triangle, then the lunes corresponding to each of the angles are B*a*A corresponding to A, B*b*A corresponding to B, C*abc* corresponding to C. For the sake of brevity, call these lunes respectively L_1, L_2, L_3.

Then by Corol. to Prop. VIII.,

$$L_1 : \text{area of sphere} :: A : 4 \text{ right angles.}$$

$$\text{or, } L_1 : \text{area of hemisphere} :: A : 2 \text{ right angles.}$$

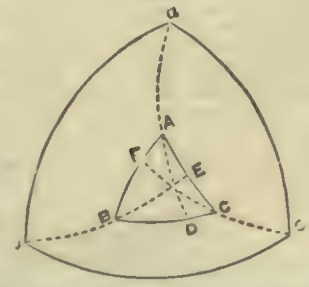
Similarly—

L_2 : area hemisphere : : B : 2 right angles.
L_3 : area hemisphere : : C : 2 right angles.

∴ $L_1 + L_2 + L_3$: area hemisphere : : $A + B + C$: two right angles. Now, the three lunes clearly make up the hemisphere B A C*ab*, together with the triangle *abc*. Hence the three lunes are in all cases greater than a hemisphere, and ∴ the three angles of the triangle are together greater than two right angles.

Again, triangle *abc* is equal to triangle A B C (Remarks on Def. VIII.), ∴ $L_1 + L_2 + L_3$ = area of hemisphere + area of triangle A B C. Also, $A + B + C$ = two right angles + spherical excess ; ∴ area hemisphere + triangle A B C : area hemisphere : : two right angles + spherical excess : two right angles, ∴ area triangle A B C : area hemisphere : : spherical excess : two right angles. Q. E. D.

Fig. 9.



DEF. XII.—The triangle formed by the great circles which join the poles at the sides of a given triangle, is called the polar or supplemental triangle.

Thus, let A B C be a given triangle ; then if *a*, *b*, *c*, be respectively the poles of the sides B C, C A and A B, *abc* is the polar triangle. And clearly, if *a*A be joined by the arc of a great circle, and this be produced to meet B C in D, then *a*D is a quadrant of a circle, and A D is perpendicular to B C, and similarly of the other poles.

The relation between the given triangle and its polar triangle is very important, as will be seen when we come to employ its properties in Spherical Trigonometry ; the properties on which its importance depends are proved in the following propositions.

PROPOSITION X.

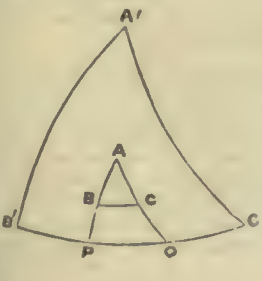
If two great circles intersect, their points of intersection will be the poles of the great circle which passes through their poles.

For (in Fig. 5), take the plane of the paper for the plane of one circle, and Y P X for any other, so that X and Y are the points of intersection of the two circles ; through O draw a plane A P B perpendicular to X Y, and ∴ perpendicular to both the planes X A B, and X P Y, and ∴ the plane A P B will contain the lines drawn perpendicular to those planes, and therefore will contain the poles of the two given circles. Hence A P B is the great circle joining the poles of the circles X A Y and X P Y ; but Y O X is perpendicular to the plane A P B, ∴ X and Y are the poles of the circle A P B ; *i. e.*, are the poles of the great circle which joins the poles of the two given circles.

PROPOSITION XI.

If A B C *be a given triangle, and* A′B′C′, *is its polar triangle, then is* A B C *the polar triangle of* A′B′C′.

Fig 10.



For since C′ is the pole of A B, and B′ is the pole of A C, ∴ (by last Prop.) the point of intersection A of A B and A C is the pole of the great circle joining B′C′, *i. e.*, A is the pole of B′C′, similarly B is the pole of C′A′, and C the pole of A′B′. Q. E. D.

PROPOSITION XII.

If A B C *be a triangle, and* A′B′C′ *its polar triangle, then the arc on the sphere, which measures the angle* A, *together with the side* B′C′, *equals the semi-circumference of a great circle.* (See Fig. 10).

For, produce A B, A C to meet B′C′ in P and Q. Then because A P and A Q are quadrants, P Q is the arc that measures the angle A (Cor. 4, Prop. V) ; now B′C′ + P Q = B′P + C′Q + Q P = B′Q + C′P. But since B′ is the pole of A C, ∴ B′Q is a quadrant. Similarly C′P is a quadrant, and the two together are a semicircle, ∴ B′C′, together with the arc on the great circle which measures A, equals the semi-circumference of a great circle.

COR. 1.—If for these arcs we substitute the angles they measure, we may state the proposition as follows :—

$$A + B'C' = 2 \text{ right angles.}$$

Similarly—

$$B + C'A' = 2 \text{ right angles,}$$
$$C + A'B' = 2 \text{ right angles.}$$

COR. 2.—And since ABC is the polar triangle of A′B′C′, we have—

$$A' + BC = 2 \text{ right angles.}$$
$$B' + CA = 2 \text{ right angles.}$$
$$C' + AB = 2 \text{ right angles.}$$

COR. 3.—Hence, the sum of the angles of any triangle, together with the sides of the polar triangle, = six right angles. But the sides of the polar triangle must have some magnitude, and must be less than four right angles (Prop. VII.) Hence the three angles of a triangle must be less than six, and greater than two right angles.

It is plain, since the three angles of a spherical triangle are greater than two right angles, and less than six right angles, that a spherical triangle may have one, two, or even three of its angles right angles.

DEF. XIII.—A right-angled spherical triangle is one which has *one* or *more* right angles.

DEF. XIV.—A quadrantal triangle is one which has at the least one side a right angle, *i. e.*, the quadrant of a great circle.

PROPOSITION XIII.

If A B C *be a right-angled triangle, having a right angle* C, *and* A′B′C′ *be its polar triangle, then* A′B′C′ *is a quadrantal triangle, having the side* A′B′ *a quadrant.*

For by the last proposition (Cor. 1)—

$$C + A'B' = \text{two right angles.}$$

Now, C is a right angle, ∴ A′B′ is a right angle, *i. e.*, is a quadrant. Q. E. D.

COR.—Hence, if all three angles, A′B′C, are right angles, the sides of the polar triangle are all right angles. For if two sides of a triangle are right angles, the third side measures the opposite angle ; ∴ if the third side be also a right angle, all the angles are right angles. Hence in the polar triangle the sides and angles are *all* right angles. And since the angles of the polar triangle are each right angles, the sides of A B C will be right angles (last Prop., Cor. 2). Hence, if all the angles of any triangle are right angles, the sides are right angles (*i. e.*, quadrants) also.

With this chapter we conclude the Elements of Geometry, both plane and spherical. In the succeeding one, the subject of Practical Geometry will be treated on, as well as Conic Sections. In the section on Astronomy, the student will require a considerable knowledge of the properties of the ellipse, parabola, &c. ; which are the most important of the conic sections, properly so called ; excluding, however, the circle, which has already been discussed in the Elements of Euclid. The subject of Trigonometry, plane and spherical, will follow Practical Geometry. An extended series of the logarithms of sines, tangents, &c., will be given at the end of this section.—ED.

CHAPTER IX.

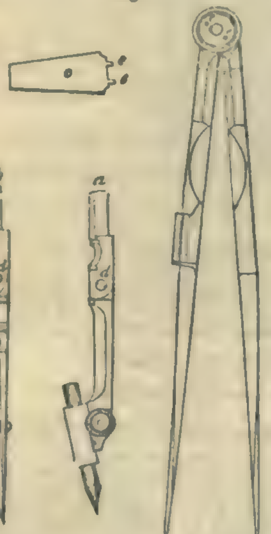
PRACTICAL GEOMETRY.

THE preceding portions of this section having given, at the commencement of the several Books of Euclid, the general definitions of *a point, a line*, &c., also the *Postulates* and *Axioms*, it is unnecessary to repeat them, it being sufficient for the student to refer to them when requisite, in order to give him a clear understanding or conception of the Problem he may at the time have under discussion. It is not here intended to give all the Problems contained in a complete treatise on Practical Geometry, but merely a selection of those which may be considered most useful in assisting the mechanical draughtsman, workman, or others who may be engaged in like pursuits.

INSTRUMENTS.—For the purpose of performing the construction of the different Geometrical figures, the only instruments absolutely required are a pair of compasses, a ruler, a lead pencil, and a drawing pen.

Compasses.—The best form of compasses, or dividers (Fig. 1), are made of metal, such as brass or silver, from five to six inches in length, having steel points, and formed with one of the points or legs movable, which at any time, as occasion may require, can be replaced by another containing a pencil leg (*a*), or a pen leg (*b*), the pen being constructed in the same manner as the drawing pen, afterwards described. The various uses to which the compasses may be applied are well known; the principal, however, being to measure or transfer distances, and when fitted with a pencil or pen, to describe circles, the one with black-lead pencil, the other with ink.* The small figure (*c*) is an instrument used for tightening the joint of the compasses when the legs work too easily, or the reverse; the two points (*e e*) at the one end fitting into two small holes (*e e*) at the head of the compasses—the other end being used for screwing up the nails (*d d*) in the pencil or pen leg, so as to make the joint work easily.

Fig. 1.



Ruler.—The ruler in general use is merely a bar of wood or metal, the edges being formed straight, and, for convenience, should be from six to twelve inches in length, about an inch in breadth, and is for the purpose of guiding the motion of the pencil or pen in a straight line or direction.

Pencil.—It may perhaps be considered unnecessary to give a description of a common drawing pencil; but as there are a few who, in commencing to draw mathematical figures, can form a proper point to their pencils, a few words may suffice to show the best method of doing it.

A pencil for drawing (Fig. 2) is generally prepared by sharpening the wood and lead, so as to form a fine point, similar to (No. 1) in the cut; but the point (No. 2), as shown in the figure, is the best form used for mechanical drawing, and is made by cutting two sides of the wood and lead flat, and leaving but a small flat edge on the other two sides, the one side showing a broad point, as at (*a*), the other a fine point, as at (*b*). In this way, the lead of the pencil may be kept close to the ruler, and at the same time draw a fine line. A very simple and beautiful little instrument, not much known, called the "pencil Cutter and Sharpener" (Fig. 3), has been invented, which forms the pencil point (No. 1), and is used by placing the pencil through the guides (*a*) into the hole or cone (*b*); and by turning it round with the hand against the knife edge (*c*), the point of the pencil is gradually formed.

Fig. 2.

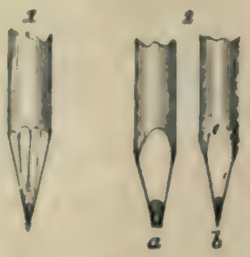


Fig. 3.

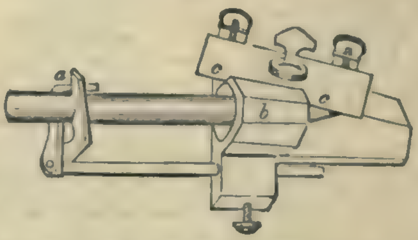
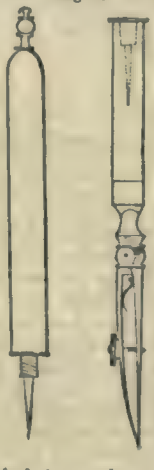


Drawing Pen.—The drawing pen (Fig. 4), like a pencil, is used for drawing straight lines, guided along the edge of the ruler; it is usually made in two parts—*viz.*, the pen and the handle. The pen part consists of two blades, with steel points, so bent that the ends or points meet, but leaving a space or cavity for the ink; and in order to draw lines of different thickness, those blades can be opened more or less by a small screw. The best pens are also made with a joint to one of the blades, to admit of the pen being more easily cleaned by separating them. The other, or upper part, forming the handle of the pen, screws into the lower portion, having attached to it a short piece of steel with a very fine point, generally called the protecting pin, and is used for setting off points in a line, or marking their intersections.

Fig. 4.

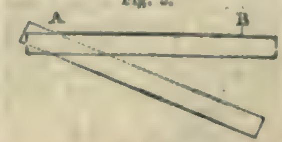


Having briefly described the few instruments requisite, it will be necessary to show their application, by performing the three following simple problems, generally given as Postulates (Euclid, Definitions, page 541), which, however, by constructing, the student will the more readily become familiar with the instruments and their use.

PROBLEM I.—*To draw a straight line from any one point* (A) *to any other point* (B).

Lay one edge of the ruler upon the point A, as shown in dotted lines in the figure, and move the ruler round until it coincides with the point B; draw the point of the pencil or pen from A to B, keeping it always close to the edge of the ruler: the trace or mark left upon the surface of the paper is the straight line required.

Fig. 5.



---

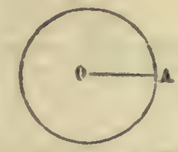
* The ink commonly used in drawing mathematical figures, &c., is that known as China Ink, which, being rubbed on a plate or palette, with a little water, runs more freely from the pen, and dries more quickly than common black writing ink; it also has the advantage of not running or blotting so much on the paper.

PROBLEM II.—*To prolong or produce the straight line* (A B) *to any length towards* (C), *in a straight line.*

Place one edge of the ruler upon the point B at the extremity of the line A B; take any point in A B, such as *a*, so far from B that the distance may be less than the length of the ruler; make the ruler coincide with that point *a*, and draw as before with the pencil or pen from B towards C, which will leave the line produced as required. This operation may be repeated as often as wished, so as to prolong a line to any extent.

Fig. 6.

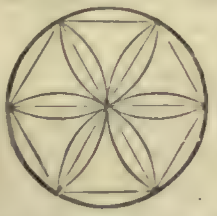
Fig. 7.



PROBLEM III.—*To describe a circle from a centre* (O), *and at any distance* (O A) *from the centre* (O).

Place the fixed leg or point of the compasses in the centre O, opening them until they take in the given distance O A or radius of the circle to be drawn; then move them round, describing the circumference of the required circle.

Fig. 8.



After performing the three preceding problems, it will be useful, in order to acquire a free use of the instruments in describing circles, to draw lines through points of intersection, join points by straight lines, and thus to produce the accompanying figure several times. The student may thereafter proceed to the construction of the following problems.

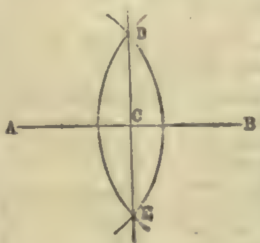
PROBLEM I.

To bisect or divide into two equal parts a given straight line (A B). (Euclid, Book I., Prop. X.)*

1ST METHOD.—*When there is not sufficient space in the drawing on either side of the given line.* By means of the compasses, place a leg at one of the extremities of the line, open them until the other leg is at any other point near the middle of the line; mark this point; transfer the leg of the compasses to the other extremity of the line, and mark the distance of the other leg from this point; if the two points so marked do not coincide, open the compasses to as near the middle of these two points as the eye will direct: proceed as before; the distance between the new points will be smaller than before, and a trial or two will enable us to bisect the line accurately.

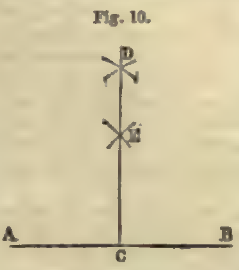
2ND METHOD.†—*When the given line* (A B) *occurs in or near the centre of the drawing, and there is sufficient room on both sides of the given line* (A B). With the centre A (Fig. 9), and any radius greater than the half of A B, describe an arc; with the centre B, and the same radius, describe another arc, cutting the former in D and E; join the points of intersection D and E, cutting the line A B in C, which will bisect A B in the point C.

Fig. 9.



3RD METHOD.—*When the given line* (A B) *occurs near the bottom of the drawing, and sufficient room is only left on one side of the given line* (A B). With centres A and B (Fig. 10), and any equal radii greater than the half of A B (this radius should be as long as can be conveniently got), describe arcs cutting each other in the point D. With the same centres, and less equal radii, also greater than the half of A B, describe arcs cutting each other in the point E; join D E, and produce the line until it cuts A B in C, which will be the point of bisection of A B.

Fig. 10.

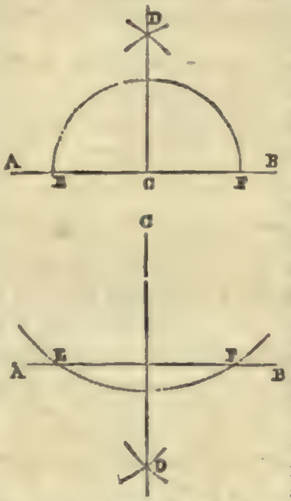


PROBLEM II.

To draw a perpendicular or a straight line at right angles to a given straight line (A B) *from a given point* (C). (Euclid, Book I., Prop. XI. and XII.)

1ST METHOD.—*When the given point* (C) *is within or without the given line* (A B) *and near the middle of it.* With the centre C (Fig. 11), and any radius, describe an arc cutting the line A B in the points E and F. With the centres E F, and the same, or any other equal radii, describe arcs cutting each other in the point D; join D C, then the line D C is perpendicular to the line A B as required.

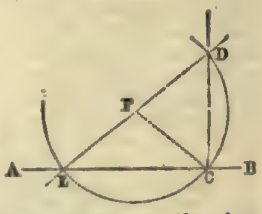
Fig. 11.



2ND METHOD.—*When the given point* (C) *is within and at or near the extremity of the given line* (A B). Take any point F (Fig. 12) above the line A B, and with the radius F C describe the arc E C D, cutting A B in the point E; join E F, and produce it until it cuts the arc E C D in the point D, and join D C, which will be perpendicular to A B, as required.

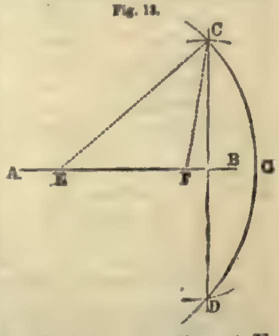
3RD METHOD.—*When the given point* (C) *is without and opposite the extremity of the given line* (A B). In the line A B (Fig 13) take any two convenient points E, F. With the centre E, and radius E C, describe the arc C G D, and with the centre F, and radius F C, describe an arc cutting the former arc C G D in the point C and D; join C D; the line C D will be perpendicular to the given line A B, as required.

Fig. 12.



A very simple method of setting off a perpendicular on the ground may be performed with a tape line in the following manner:—Suppose it were required to set out a straight line of road (C D) (Fig. 12) at right angles, or perpendicular to another straight line of road (A B) from any point (C) in A B. Put in a pin at the point C, and also one at E, along one side of the line of road A B, and three feet distant from C; put the end of the tape line at E,

Fig. 13.



---

* References are made to the propositions in Euclid, where several of the Problems are demonstrated, in order that the student, should he wish to investigate the Problems further, may do so by examining the methods of construction there adopted.

† This is the method most frequently used to bisect a line; but in practice it is not necessary to draw the whole arcs, but merely the intersections, and by means of the ruler placed on those points, to mark the centre point C. The line D C or D E, in this and the following Problem, when drawn, will also be found to be perpendicular to A B.

pass it round the pin at C, carrying it up in the direction of the line of new road to D. Bring the line back to the pin at E, and holding the end of the tape line fast at E, stretch the line tight. When stretched, this will give a triangle, having sides three (E C), four (C D), and five (E D) feet respectively in length, of which D C will be perpendicular to E C, and form one side of the new road required.

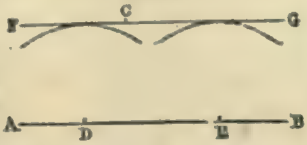
This method of setting off a perpendicular is taken from that beautiful theorem in Euclid (Book I., Prop. XLVII.), where in this case, E D, the hypothenuse of the triangle, is equal to 5 feet, and the two sides E C and C D, 3 and 4 feet respectively; therefore $5^2 = 3^2 + 4^2$, or $25 = 9 + 16$. The sum of the three sides being 12, or the whole length of line used; but any numbers may be used (consistent with the length of the tape line), provided they fulfil the required value. It may be easily remembered that any multiple of the numbers used, *viz.*, 3, 4, 5, will suffice.

PROBLEM III.

To draw a straight line parallel to a given straight line (A B), *and through any given point* (C). (Euclid, Book I., Prop. XXXI.)

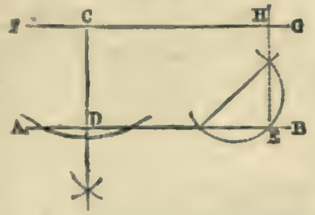
1st Method.—Take any two points, D and E (Fig. 14), in the given line A B, the further apart from each other the better; with the centres D and E and radii equal to the distance between the point C and the line A B* describe two arcs, and draw a straight line to touch or be a tangent to both arcs, then the line G F is parallel to A B.

Fig. 14.



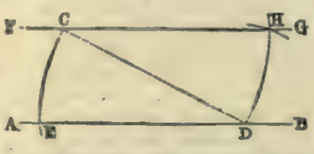
2nd Method.—From the point C (Fig. 15) draw the line C D perpendicular to A B; at another point anywhere in the line A B, but as far from D as convenient, draw E H perpendicular to A B. Make E H equal to C D, and draw through the points C and H the straight line F G, which will be parallel to A B.

Fig. 15.



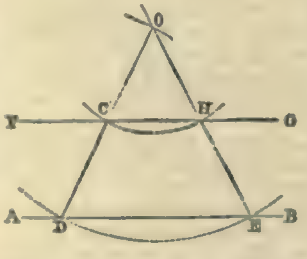
3rd Method.—Take any point D (Fig. 16), the further from C the better, in the line A B; join D C, and with the centre D, and radius D C (or any other convenient radius which will cut D C), describe an arc cutting A B in E; also with the centre C, and the same radius, describe an arc D H; again with the centre D, and a radius equal to the distance between C and E, describe an arc cutting the latter arc in H; draw the line F G passing through the points C and H; the line F G will be parallel to A B.

Fig. 16.



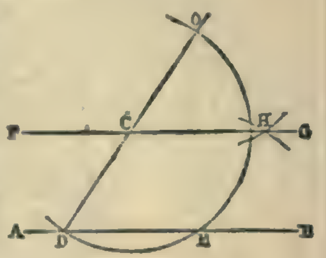
4th Method.—Take any point D (Fig. 17) in the line A B; join D C and produce it, making C O equal to C D; with the centre O and radii O C and O D, describe two arcs, the latter cutting A B in E; join O E, cutting the lesser arc in the point H; draw the line F G passing through the points C and H, then F G will be parallel to A B.

Fig. 17.



5th Method.—Take any point D (Fig. 18) in the line A B; join D C and produce it; with the centre C, and radius C D, describe a circle, cutting A B in E, and, D C produced, in O; with the centres E and O, and the same radius, describe arcs intersecting in the point H; draw F G passing through the points C and H; then F G will be parallel to A B.

Fig. 18.

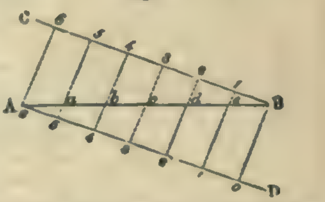


PROBLEM IV.

To divide a given straight line (A B) *into any given number* (*say* 6) *of equal parts.*

Through A (Fig. 19) draw a line A D at any angle with A B, and through B draw B C parallel to A D; from A set off six equal parts on the line A D (*those equal parts should be as nearly the length of the required equal parts of* A B *as can be estimated*), and from B on the line B C set off the same number (six) equal parts of the same length as before; join B and *o*, 1 and 1, 2 and 2, 3 and 3, 4 and 4, 5 and 5, A and 6; then the points where those lines cut A B, *viz.*, in *a*, *b*, *c*, *d*, *e*, will divide the line A B into the required number (six) of equal parts.

Fig. 19.

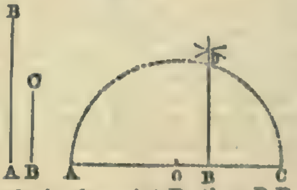


PROBLEM V.

To find a mean or mean proportional between two given lines (A B *and* B C).

Draw a straight line A B C (Fig. 20) equal in length to AB and BC together; bisect AC in O, and with the centre O and radius O A, or O C, describe a semicircle; from the point B = B C, the small line measured from C on A O C, draw a line perpendicular to A C, and meeting the semicircle in the point D, then B D is a mean or mean proportional between A B and B C.

Fig. 20.

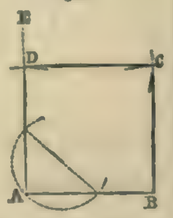


PROBLEM VI.

To describe a square on a given straight line (A B). (Euclid, Book I., Prop. XLVI.)

From the point A (Fig. 21) draw A E perpendicular to A B (Problem II.), and from A E cut off A D equal to A B; draw D C and C B parallel to A B and A D respectively, intersecting at the point C; or, with B and D as centres, and radii equal to A B, describe arcs intersecting at the point C, and join D C and B C, then A B C D is the square required.†

Fig. 21.



PROBLEM VII.

To describe a square which shall be equal to any number of given squares (1, 2, 3, 4, 5).

Draw any two lines, A B and A C (Fig. 22), at right angles to each other; in A B make A D equal to the side of the square 1, and in A C make A E equal to the side of the square 2, and join D E; then in A B make A F equal to D E, and in A C make A G equal to the side of the square 3, and join F G; again, in A B make A H equal to F G, and in A C, A K equal to the side of the square 4, and join H K; lastly, in A B make A L equal to H K, and in A C make A M equal to the side of the square 5, and join L M; then the square L M N O, described on the line L M, is equal to the sum of the squares 1, 2, 3, 4, 5.

---

* The distance between C and the line A B is easily got by placing one point of the compasses at C, and opening them until the other point just touches. F G may be drawn parallel to A B at any distance apart, by merely using that distance as the radii of the arcs, as in Fig. 15.

† Of course, any rectangle whose length and breadth are given, can be constructed in a similar manner, by making the perpendicular equal to the breadth, and either drawing parallels or using the length of the sides as radii.

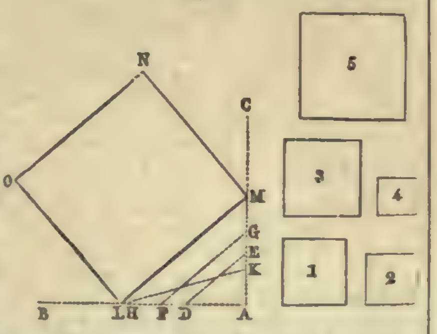


Fig. 22.

By proceeding in a similar manner till all the sides of any number of given squares are employed, a square may be constructed equal to the sum of the given number of squares; this, as well as the next problem, depending throughout their whole construction on Euclid, Book I., Prop. XLVII.

PROBLEM VIII.

To describe a square which shall be equal to the difference of any two given squares (F *and* G).

Draw any two lines, A B and A C (Fig. 23), at right angles to each other; in A C make A D equal to the side of the less of the two given squares, F; with the centre D, and a radius equal to a side of the other given square G, describe an arc cutting A B in E; the square A E H K, described on the line A E, is the square equal to the difference of the two squares F and G.

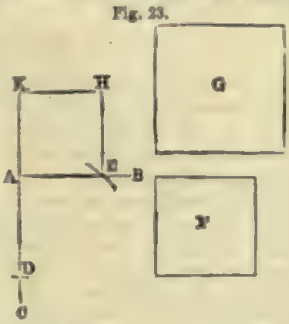

Fig. 23.

PROBLEM IX.

To describe a square which shall be equal to a given parallelogram (A B C D).

Draw any line G K, which shall be a mean proportional between the two sides, A B and B C of the given parallelogram (*Problem* V.), and upon the line G K describe the square H G K L, which will be equal to the given parallelogram, A B C D. (Fig. 24).

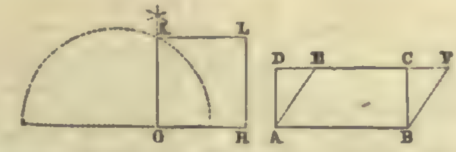

Fig. 24.

When the given parallelogram is not a rectangle, as A E F B, *then draw a rectangle* A B C D, *standing on the same base, and between the same parallels* (Euclid, Book I., Prop. XXXV.), *equal to it, and proceed as before.*

PROBLEM X.

To draw through a given point (E) *a straight line, which shall tend to the intersection of two given straight lines* (A B, C D), *but whose point of intersection* (O) *falls beyond the limits of the drawing* (L M N).

1st Method.—Through the given point E (Fig. 25), draw any line E C, meeting A B in A, and C D in C, draw any other line H K parallel to E C, meeting A B and C D in G and K; join C G, and through K draw K F parallel to it, meeting A B in F; join E G, and through F draw F G parallel to it, meeting K G produced in H; join E H, which, if produced, would pass through the point of intersection O.

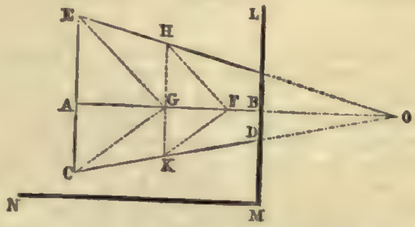

Fig. 25.

2nd Method.—Draw any two parallels E C and G K (Fig. 26), as before; join A K and C G, intersecting in F, and through F draw P Q parallel to E C or G K. Join E K, cutting P Q in R, and through the point R draw C H, meeting the line G K produced in H; join E H, which, if produced, would pass through the point of intersection O.

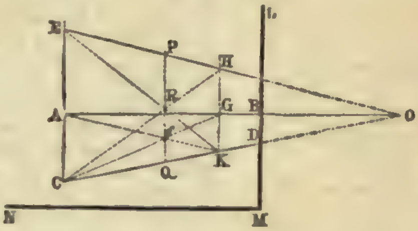

Fig. 26.

PROBLEM XI.

At a given point (E) *in a given straight line* (E D), *to make an angle equal to a given angle* (A B C). (Euclid, Book I., Prop. XXIII.)

With the centre B (Fig. 27) and any convenient radius, describe an arc, cutting A B in H, and B C in G; with the centre E and the same radius, describe an arc cutting E D in the point L; with the centre L and a radius equal to the distance H G, describe another arc, intersecting in the point K; join E K, and produce it if necessary; then the angle D E F will be equal to the angle A B C, as required.

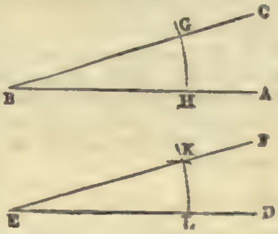

Fig. 27.

PROBLEM XII.

To bisect any given angle (A B C). (Euclid, Book I., Prop. IX.)

With the centre B (Fig. 28) and any convenient radius, describe an arc cutting B A in D, and B C in E, with D and E as centres, and any equal radii, describe arcs intersecting in the point F; join B F; then the angle A B C will be bisected by B F, or divided into two equal angles, A B F, and C B F.

By again bisecting the angles A B F, C B F, the angle A B C will be divided into four equal angles, and so on; by proceeding in a similar manner, the angle A B C may be divided into any *even* number of equal angles, continuing in geometrical progression—*viz.*, 2, 4, 8, 16, 32, 64, &c.

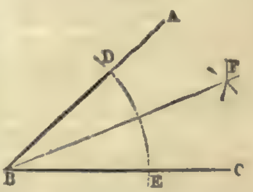

Fig. 28.

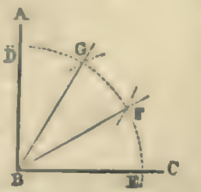
PROBLEM XIII.

To trisect or divide into three equal angles a given right angle (A B C).

Fig. 29.

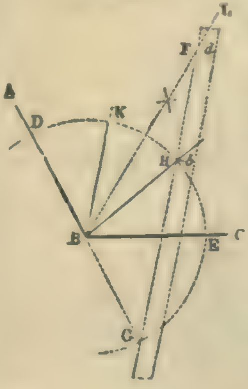


With the centre B (Fig. 29) and any radius, describe an arc, cutting B A in D, and B C in E, and from the points D and E as centres, and the same radius as before, describe [illegible] cutting the former arc in F and G; join B and the points of intersection F and G; then the angle A B C is divided into three equal angles, A B G, G B F, F B C.

PROBLEM XIV.

To trisect or divide into three equal angles any given angle (A B C).

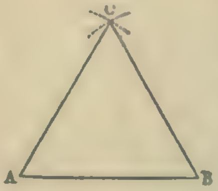
Fig. 30.



With the centre B (Fig. 30) and any radius, describe a circle cutting B A in D, and B C in E; bisect the angle A B C by the line B L (Problem XII.), and produce A B till it meets the circle in G; on the edge of the ruler mark off a distance (*bd*) equal to the length of the radius B D or B E, and lay the ruler at the point G, moving it until the point *b* cuts the circle, and the point *d* intersects the line B L, in H and F respectively; join B H, and set off H K equal to E H, leaving K D also equal to E H, and join B K; then the angle A B C will be divided into three equal angles, A B K, K B H, and H B C.

PROBLEM XV.

Fig. 31.



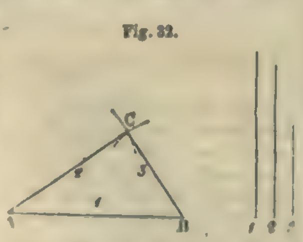
To describe an equilateral triangle upon a given straight line (AB). (Euclid, Book I., Prop. I.)

With the centres A and B (Fig. 31) and radii equal to A B, describe arcs intersecting in the point C; join A C and B C; the triangle A B C will be equilateral.

PROBLEM XVI.

To construct a triangle, whose sides shall be respectively equal to three given straight lines (1, 2, 3), *any two of which are greater than the third.* (Euclid, Book I., Prop. XXII.)

Fig. 32.



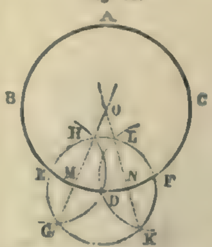
Draw any straight line, A B, (Fig. 32) equal to the given line 1, with the centre A and a radius equal to the given line 2 describe an arc, and with the centre B, and a radius equal to the given line 3, describe another arc, cutting the former at the point C; join A C and B C; then A B C will be the triangle required.

PROBLEM XVII.

*To find the centre and radius of a given circle.** (Euclid, Book III., Prop. I.)

1st Method.—In the circumference of the given circle A B C (Fig. 33), take any point D, and from it as a centre, with any radius, describe a circle cutting the circumference of the given circle in the points E and F, with which as centres, and the same radius, describe arcs intersecting the circle E F in the points G H and K L. Draw lines passing through the points H and G, L and K, and produce them until they intersect each other in the point O, which is the centre of the circle, and O M or O N the radius.

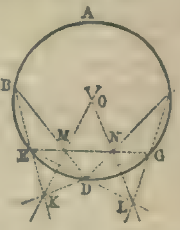
Fig. 33.



By this method the arcs D E *and* D F *are bisected, and the problem may be performed by merely drawing any two chords, such as* D E *and* D F, *bisecting those chords by perpendiculars, which being produced, until they intersect each other, will give the centre.*

2nd Method.—Take any five points, B, E, D, G, C (Fig. 34), in the circumference of the given circle A B C, equidistant from each other; draw lines passing through B E and G D, meeting in the point K; also through C G and E D, meeting in the point L; join E G, and draw B D and C D, cutting the line E G in M and N respectively; and through the points of intersection K M, and L N, draw lines, and produce them until they intersect each other in the point O, which is the centre of the given circle A B C.

Fig. 34.

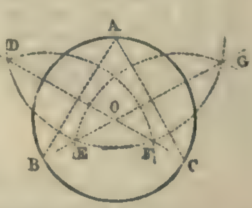


PROBLEM XVIII.

To describe a circle that shall pass through any three given points (A B C), *which are not in a straight line.*

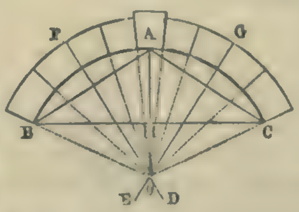
From the point A (Fig. 35), as a centre, with any convenient radius greater than half the distance A B or A C, describe an arc; with B and C as centres, and the same radii, describe arcs cutting the former in the points D, F and E G; draw lines passing through those points intersecting each other in the point O, and with the centre O, and a radius equal to the distance O A, O B, or O C, describe a circle which will necessarily pass through the three given points A, B, and C.

Fig. 35.



This problem will be found most applicable in the case of a circular arch, whose span (B C) and rise (A H) (Fig. 36) are given, and it is required to describe it; join A B and A C, bisect them by the perpendiculars D F and E G; then, as before, the point of intersection O is the centre with which to describe the circle.†

Fig. 36.



The joints of the stones or *voussoirs* forming the arch are drawn from the centre, and form continuations of the radii.

PROBLEM XIX.

To find the point in a given straight line (A B), *drawn from the one extremity of a given arc* (A E C), *through which the other extremity* (C) *of the given arc, if continued, would pass, and without using the centre.*

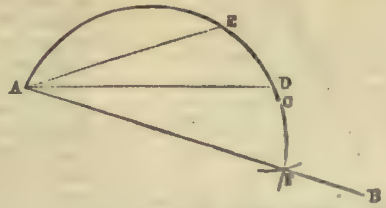
From A (Fig. 37) draw any chord A D, and also any other chord A E, making the angle D A E equal to the angle B A D; with the centre D and radius D E describe an arc cutting A B in F; then F is the point in A B, through which the arc A E C, if continued, would pass.

---

* This Problem is performed in Euclid by drawing any chord, bisecting it by a perpendicular meeting the given circle at its two extremities, which gives the diameter of the circle, by bisecting which, both the centre and radius of the circle are found.

† See *Euclid*, Book III., Prop. XXV.

Fig. 37.



When the centre is either not known, or at too great a distance to be conveniently used (as very frequently occurs in practice), this problem will be found exceedingly useful.

PROBLEM XX.

To draw a tangent to a given circle (A B C) *through a given point* D *in the circumference.* (Euclid, Book III., Prop. XVII.)

1st Method.—If the centre O of the given circle A B C (Fig. 38) be not given, find it by Problem XVII.; join O D, and through the given point D draw E F perpendicular to O D; then E F is the tangent required.

Fig. 38.

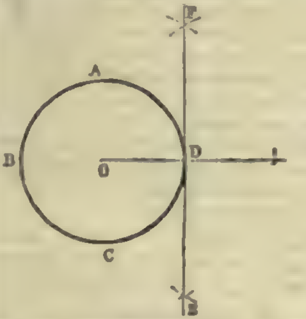


Fig. 39.

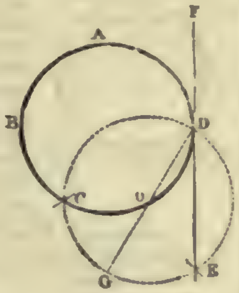
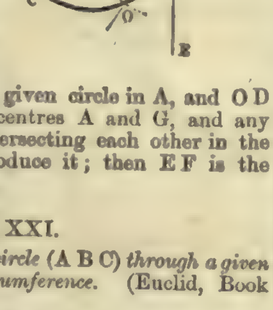


2nd Method.—Take any other point O (Fig. 39) in the circumference of the given circle A B C; join D O and produce it; with the centre O, and radius O D describe a circle cutting the given circle in C, and D O produced in G; make the arc G E equal to the arc G C; join E D and produce it; then E F is the tangent required.

3rd Method.—Take any other point O (Fig. 40) in the circumference of the given circle A B C; join O D and produce it; with the centre D, and radius D O, describe a circle cutting the given circle in A, and O D produced in G; with the centres A and G, and any equal radii, describe arcs intersecting each other in the point F; join F D and produce it; then E F is the tangent required.

Fig. 40.



PROBLEM XXI.

To draw a tangent to a given circle (A B C) *through a given point* (D) *without the circumference.* (Euclid, Book III., Prop. XVII.)

1st Method.—Find the centre O (Fig. 41) of the given circle A B C; join O D, and bisect it in G; with the centre G, and radius G O or G D, describe a semicircle, cutting the given circle A B C in the point C, which is the point of contact; join D C and produce it; then E D is the tangent required, touching the circle at the point C, and drawn from the point D.

Fig. 41.

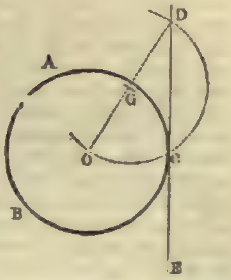


Fig. 42.

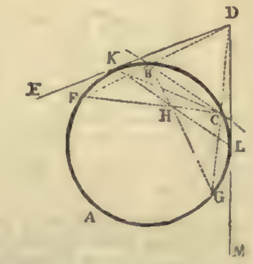
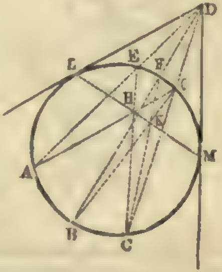


2nd Method.—With the given point D (Fig. 42) as a centre, and any radius, describe an arc cutting the given circle A B C in B and C; join D B, D C, and produce them till they meet the circumference of the given circle A B C in F and G; join B G and C F, cutting each other in the point H; join B C, and through H draw a line parallel to B C, and meeting the circle in the points K L; draw from the point D lines D E and D M, passing through K and L, which will be tangents to the circle A B C.

3rd Method.—From the given point D (Fig. 43) draw any three lines cutting the given circle in E, A in F, B and in G, C respectively; join G B, F C, intersecting in K, and G A, E C, intersecting in H; draw through H and K a line meeting the circle in the points L, M which will be the points of contact; and lines drawn from D through those points L, M will be tangents to the circle A B C.

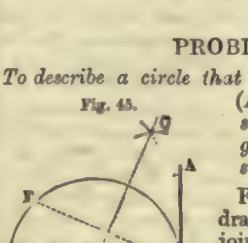
Fig. 43.



PROBLEM XXII.

To describe a circle that shall touch two given straight lines (A B *and* C D) *not in the same straight line, and touching at a given point* (E) *in one of them* (A B).

Fig. 44.

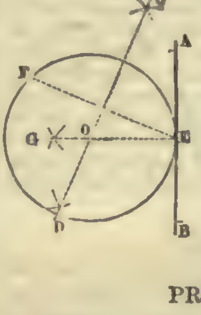


Produce the given lines, AB and C D (Fig. 44), till they meet in the point G; make G F equal to G E: from E and F draw E O and F O perpendicular to A B and C D, respectively intersecting in the point O; and with the centre O, and radius O E or O F, describe the circle HEF, which will touch the given lines A B, C D, and also A B in the point E, as required.

PROBLEM XXIII.

To describe a circle that shall touch a given straight line (A B) *in a given point* (E), *and shall also pass through another given point* (F) *not in the same straight line* (A B).

Fig. 45.

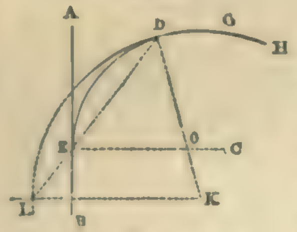


From the given point E (Fig. 45) draw E G perpendicular to A B; join E F, and bisect it by a perpendicular C D, cutting E G in the point O, with which as a centre, and the radius O E, describe the circle E D F, which will touch the line A B in the given point E, and also pass through the given point F.

PROBLEM XXIV.

To describe a part of a circle that shall touch a given *straight line* (A B) *in a given point* (E), *and shall also touch a given arc* (D G H).

Fig. 46.

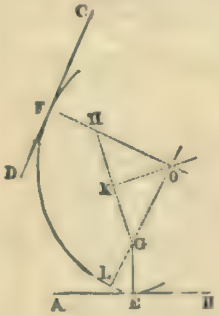


Draw E C (Fig. 46) perpendicular to A B; and through the centre K of the given arc D G H, draw K L parallel to E C, and meeting the arc D G H continued in the point L; join L E, and produce it to meet the given arc in the point D, and join D K, cutting E C in O; then with the centre O, and radius O E, describe a part of a circle which will touch the given line A B in the given point E, and also the given arc D G H in the point D.

PROBLEM XXV.

To describe two arcs that shall meet each other in the line of their centres, and shall touch two given straight lines (A B, C D) *at the given points* (E, F) *in those lines, the radius* (E G) *of the lesser arc being also given.*

Fig. 47.

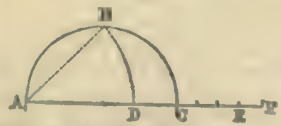


From the point E (Fig. 47) draw E G perpendicular to A B, and equal to the given radius, and from the point F draw F H perpendicular to C D, and make it equal to E G; join G H; bisect G H by a perpendicular K O, cutting F H produced, in the point O; join O G, and produce it, then with O as a centre, and radius O F, describe an arc meeting O G produced in L. With the centre G, and radius G E or G L, describe an arc meeting the former arc in L; then the arcs F L and E L are those required, meeting each other at the point L in the line L O, passing through both their centres G and O, and also touching A B and C D in E and F.

PROBLEM XXVI.

To find a straight line nearly equal to the length of a given arc (A B C).

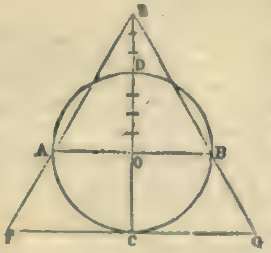
Fig. 48.



Bisect the given arc in B (Fig. 48), and draw the lines A B, A C; with the centre A, and radius A B, describe an arc cutting A C in D; make D E in A C produced, equal to A D, divide C E into three equal parts, and make E F equal to one of the parts; then A F will be nearly equal to the arc A B C.

PROBLEM XXVII.

Fig. 49.



To draw a straight line nearly equal to the semi-circumference of a given circle (A D B C).

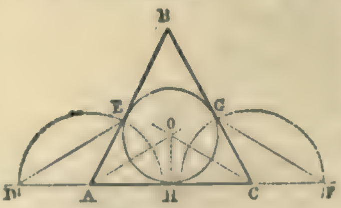
Draw the diameters A B and C D (Fig. 49) at right angles to each other; produce C D until D E is equal to three-fourths of D O; through C draw F G parallel to A B; join E A, E B, and produce them until they meet F G in F and G; then F G will be nearly equal to the semi-circumference of the circle A D B C.

PROBLEM XXVIII.

To inscribe a circle in a given triangle (A B C) *that shall touch all its sides.* (Euclid, Book IV., Prop. IV.)

Produce A C (Fig. 50) both ways; with the centre A, and any radius, describe an arc cutting A C produced in D, and A B in E; also with the centre C, and the same radius, describe an arc cutting AC produced in F, and B C in G; join D E and F G, and draw through A and C lines parallel to DE and F G respectively, and cutting each other in the point O; then O is the centre of the required circle (*the lines* A O *and* O C *will bisect the angles* B A C *and* A C B, *which might be done by Problem* XII.) From O draw O H perpendicular to A C; then with the centre O, and radius O H, describe a circle which will touch all the sides of the given triangle A B C.

Fig. 50.



PROBLEM XXIX.

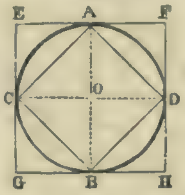
To describe a circle about a given triangle (A B C). (Euclid, Book IV., Prop. V.)

This Problem is simply to describe a circle passing through three given points, A B C, as given before in Problem XVIII.

PROBLEM XXX.

To draw a square within or about a given circle (A C B D). (Euclid, Book IV., Props. VI. and VII.)

Fig. 51.

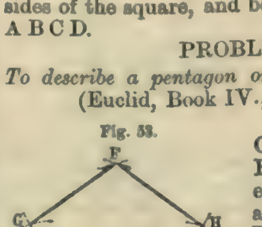


Draw through the centre O (Fig. 51) any two diameters, A B and C D, at right angles to each other, meeting the circle in the points A C B D. To *inscribe* a square in the circle, join those four points; then A C B D is the square required; and to *describe* a square about the circle, draw tangents or lines parallel to the diameters at those four points, then EFHG is the square required.

PROBLEM XXXI.

To circumscribe and inscribe circles to a given square (A B C D). (Euclid, Book IV., Props. VIII. and IX.)

Fig. 52.

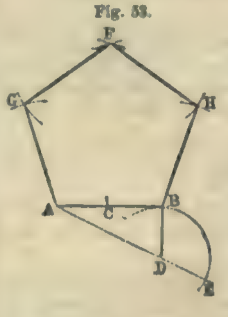


Draw the diagonals, A C, B D (Fig. 52), intersecting in the point O, the centre of the required circles. With the centre O, and radius O A, describe a circle which will pass through A, B, C and D, and be *circumscribed* about the given square A B C D. From O, draw O E perpendicular to D C; and again with the centre O, and radius O E, describe a circle which will touch all the four sides of the square, and be *inscribed* in the given square A B C D.

PROBLEM XXXII.

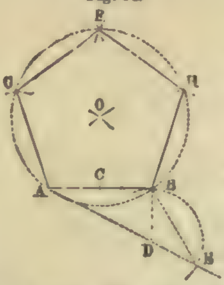
To describe a pentagon on a given straight line (A B) (Euclid, Book IV., Props. XI. and XII.)

Fig. 53.



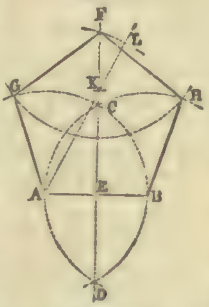
1st Method.—Bisect A B in C (Fig. 53), and from B draw B D perpendicular to A B, and equal to A C or B C; join A D and produce it; with the centre D and radius D B describe a circle cutting A D produced, in E; with the centres A and B and radii, each equal to A E, describe arcs intersecting in F; lastly, with the centres A and F, and radii, each equal to A B, describe arcs intersecting in G, and with B and F as centres, and the same radii, describe arcs intersecting in H; join A G, F G, F H, and B H; then A B H F G is the pentagon required.

Fig. 54.



2nd Method.—Bisect A B in C (Fig. 54), and from B draw BD perpendicular to AB, and equal to A C or B C; join A D and produce it; with the centre D, and radius D B, describe a circle cutting A D produced, in E; join B E, and with the centres A and B and radii, each equal to BE, describe arcs intersecting in O, with which as a centre and radius O A or O B, describe a circle. With the centres A and B and radii, each equal to AB, describe arcs cutting the circle in G and H; lastly, with the centre G or H, and the same radius, describe an arc cutting the circle in F, and join A G, G F, F H, H B; then A G F H B is the pentagon required.

Fig. 55.

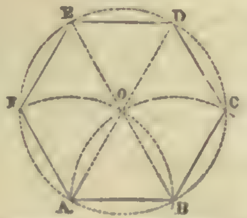


3rd Method.—With the centres A and B (Fig. 55), and radii, each equal to AB, describe circles intersecting in C and D; join C D, cutting A B in E, and produce it. Make E K equal to A B; join A K, and produce it, till K L is equal to A E or E B; with the centre A, and radius A L, describe an arc cutting D C produced in F; and with the centre F and radius A B describe a circle cutting the circles D A C and D B C in H and G respectively; join A G, F G, F H, and B H; then A B H F G is the pentagon required.

PROBLEM XXXIII.

To describe a regular hexagon upon a given straight line. (Euclid, Book IV., Prop. XV.)

Fig. 56.



With the centres A and B (Fig. 56), and radii, each equal to A B, describe circles intersecting in O; with the centre O, and the same radius, describe another circle, cutting the two former in F and C respectively; join A O and B O, and produce them till they meet the latter circle in D and E respectively; join BC, CD, D E, E F, and F A; then A B C D E F is the hexagon required. From this it will be seen that the side of a hexagon is equal to the radius of the circumscribed circle; and by merely finding the centre O as above, and setting off the length of the given line *six* times round the circumference, the hexagon will be constructed.

PROBLEM XXXIV.

To describe a regular octagon on a given straight line (AB).

With the centres A and B (Fig. 57), and radii equal to A B, describe circles intersecting in K; with the centre K, and the same radius, describe a circle cutting the two former in L and M; with the centres L and M, and still the same radius, describe arcs cutting the last circle in N and O; join A N and B O, by lines cutting the two first circles in P and Q, and produce them; join A Q and B P, and produce them till P G and Q D are each equal to A B; and lastly, with the centres G and D, and the same radii, equal to A B, describe circles cutting the two first circles in H and C, and the lines A N and B O produced, in F and E. Join B C, C D, D E, E F, F G, G H and H A; then A B C D E F G H is the octagon required.

Fig. 57.

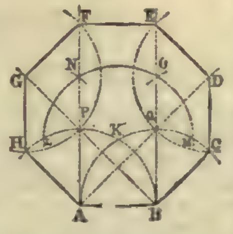


Fig. 58.

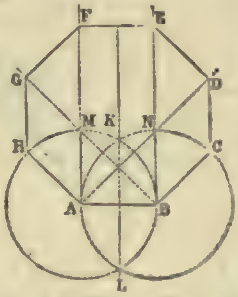
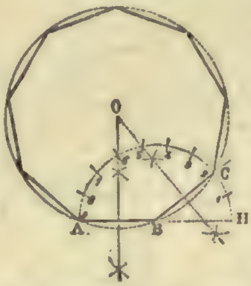


2nd Method.—With the centres A and B (Fig. 58), and radii, each equal to A B, describe circles cutting each other in K and L; join K L, and through A and B draw A F and B E parallel to K L, cutting the circles in M and N; join A N and B M, and parallel to them through A and B draw A H and B C, meeting the circles in H and C; through H and C draw H G and C D parallel to K L, and meeting B M and A N produced in G and D; and lastly, through G and D draw G F and D E parallel to A D and B G, cutting A M and B N produced in F and E; join FE; then ABCDEFGH is the octagon required.

PROBLEM XXXV.

To describe a regular polygon (containing any number of given sides) upon a given straight line (A B).

Fig. 59.



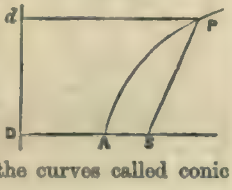
With the centre B (Fig. 59), and radius A B, describe a semicircle, meeting A B produced in H; divide the semicircle into as many equal parts as in the proposed polygon; join B and the second point of division C; bisect each of the sides A B and B C by perpendiculars intersecting in O; then with the centre O, and radius O A, O B, or O C, describe a circle, which will pass through the points A, B, and C; this circle will be that described about the required polygon; and therefore, by setting off A B as many times as required round the circle thus formed, the polygon will be described. The example given in the figure is a nonagon, or nine-sided figure.

CHAPTER X.

ON THE CONSTRUCTION OF THE CONIC SECTIONS.

THE preceding propositions depend entirely on the properties of straight lines and the circle, and therefore admit of construction by rule and compasses. Now, beside the circle there are several curves which are used more or less, by draughtsmen; these are for the most part drawn, when required, by determining accurately several points in them, which are then neatly joined by the hand. Of these curves the *ellipse* is the one oftenest needed, and is used, in fact, almost as much as the circle, in consequence of the perspective representation of a circle being an ellipse. Besides the *ellipse*, the *hyperbola* and *parabola* are often needed in the delineation of shadows. These three curves are generally called conic sections, for this reason—if a right cone is cut by a plane, the curve which bounds the section is one of these three, except in the special cases when the elliptic section degenerates into a circle, and the hyperbolic into two straight lines. The object of the few following pages is to prove such properties of these curves as shall enable us to give rules for their construction. The complete investigation of their properties, which forms a distinct and very interesting branch of mathematics, is not here intended.

Fig. 60.

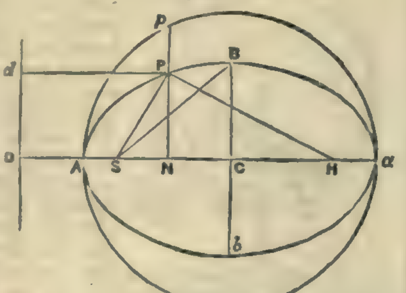


DEFINITION 1.—Let dD (Fig. 60) be a given fixed straight line, called the directrix; S a given fixed point, called the focus; P a movable point. Let Pd be perpendicular to the given straight line, then if P move in such a manner that S P bears a constant ratio to Pd, it traces out one of the curves called conic sections.

DEFINITION 2.—Suppose $SP : Pd :: e : 1$, then if $e \angle 1$, the curve is an *ellipse;* if $e = 1$, the curve is a *parabola;* if $e \not> 1$, the curve is a *hyperbola.* (e = the eccentricity of the denoted curve).

THE ELLIPSE.

Fig. 61.



Let Dd, S and P (Fig. 61) be the same as in the foregoing definitions; through S draw D Aa perpendicular to Dd. Then if A and a are so taken that $SA : AD :: e : 1$, and $Sa : aD :: e : 1$, then A and a are points in the ellipse; also the line A a is the *transverse* diameter or *major* axis; bisect A a in C, then C is the *centre* of the ellipse; through C draw B C b perpendicular to A a, then B b is called to *conjugate* to the transverse diameter, or the *minor* axis; take H, so that $a\text{H} = \text{AS}$, or so that $\text{CS} = \text{CH}$, then H and S are called the *foci* (singular *focus*).

(1.) *To show that in the ellipse* $\text{CS} = e, \text{AS}$.

We have already seen that $\text{AS} = e. \text{AD}$, also that $\text{S}a = e. a\text{D}$ $\therefore a\text{S} - \text{SA} = e\,(a\text{D} - \text{DA})$, and $a\text{H} = \text{AS}$. $\therefore \text{SH} = e. \text{A}a$, or $\text{SC} = e. \text{AC}$. Q. E. D.

N.B.—e is called the eccentricity of the ellipse.

(2.) *To show that* $\text{SB} = \text{AC}$.

Manifestly $\text{SB} = e. \text{DC} = e\,\text{AD} + e\,\text{AC} = \text{AS} + \text{SC} = \text{AC}$. Q. E. D.

COR.—Hence, $\text{BC}^2 = \text{SB}^2 - \text{SC}^2 = \text{AC}^2 - \text{SC}^2 = \text{AC}^2 (1 - e^2)$.

(3.) *To show that* $\text{SP} = \text{AC} - e. \text{CN}$.

Manifestly,

$$\begin{aligned}\text{SP} &= e\,\text{DN} = e\,(\text{D}c - \text{CN}) = e\,(\text{DA} + \text{AC}) - e\,\text{CN}\\ &= e\,\text{DA} + e\,\text{AC} - e\,\text{CN} = \text{AS} + \text{SC} - e\,\text{CN}\\ &= \text{AC} - e\,\text{CN}.\end{aligned}$$

(4.) *To show that* $\dfrac{\text{PN}^2}{\text{CB}^2} + \dfrac{\text{CN}^2}{\text{CA}^2} = 1$.

For $\text{SP}^2 = \text{SN}^2 + \text{PN}^2$ (Eucl. I., 47). But $\text{SP} = \text{AC} - e\,\text{CN}$ and $\text{SN} = \text{SC} - \text{CN}$ $\therefore (\text{AC} - e\,\text{CN})^2 = (\text{SC} - \text{CN})^2 + \text{PN}^2$ and $\text{SC} = e\,\text{AC}$.

$$\therefore \text{AC}^2 - 2\,e\,\text{AC}, \text{CN} + e^2\,\text{CN}^2 = e^2\,\text{AC}^2 - 2\,e\,\text{AC}\,\text{CN} + \text{CN}^2 + \text{PN}^2.$$

$$\therefore \text{AC}^2 (1 - e^2) = \text{CN}^2 (1 - e^2) + \text{PN}^2.$$

$$\therefore 1 = \frac{\text{CN}^2 (1 - e^2)}{\text{AC}^2 (1 - e^2)} + \frac{\text{PN}^2}{\text{AC}^2 (1 - e^2)} \qquad \text{Now } \text{AC}^2 (1 - e) = \text{CB}^2.$$

$$\therefore 1 = \frac{\text{CN}^2}{\text{AC}^2} + \frac{\text{PN}^2}{\text{BC}^2}$$

$$\therefore \frac{\text{PN}^2}{\text{BC}^2} + \frac{\text{CN}^2}{\text{AC}^2} = 1. \qquad \text{Q. E. D.}$$

COR.—With centre C and radius C A, describe a circle Apa; produce N P to meet the circumference in p; join Cp, which is plainly equal to A C.

Now $\quad p\text{N}^2 + \text{CN}^2 = \text{C}p^2 = \text{CA}^2$.

$$\therefore \frac{\text{PN}^2}{\text{CA}^2} + \frac{\text{CN}^2}{\text{CA}^2} = 1.$$

$$\therefore \frac{\text{PN}^2}{\text{CB}^2} = \frac{p\text{N}^2}{\text{CA}^2}$$

Or, $\quad \text{PN} : p\text{N} :: \text{CB} : \text{CA}$.

This result, and the previous one, we shall have occasion to use in the article on Mensuration in a future chapter.

(5.) *To show that* $\text{HP} = \text{AC} + e\,\text{CN}$.

For $\text{HP}^2 = \text{PN}^2 + \text{NH}^2 = \text{PN}^2 + (\text{CN} + \text{CS})^2 = \text{PN}^2 + (\text{CN} + e\,\text{CA})^2$.

Now from art. 4. $\text{PN}^2 = \text{CB}^2 - \dfrac{\text{CB}^2}{\text{CA}^2}\text{CN}^2 = (1 - e)^2\,\text{CA}^2 - (1 - e^2)\,\text{CN}^2$.

$$\therefore \text{HP}^2 = \text{CA}^2 - e^2\,\text{CA}^2 - \text{CN}^2 + e^2\,\text{CN}^2 + \text{CN}^2 + 2\,e\,\text{CA}, \text{CN} + e^2\,\text{CA}^2.$$

$$= \text{CA}^2 + 2\,e\,\text{CA}, \text{CN} + e^2\,\text{CA}^2 = (\text{CA} + e\,\text{CN})^2.$$

$$\therefore \text{HP} = \text{CA} + e\,\text{CN}.$$

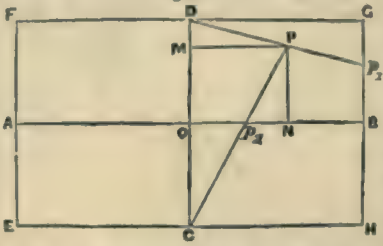
COR.—Hence, $\text{SP} + \text{HP} = \text{CA} - e\,\text{CN} + \text{CA} + e\,\text{CN} = 2\,\text{CA} = \text{A}a$.

Or, $\text{SP} + \text{PH}$ = the major axis of the Ellipse.

On this property of the Ellipse the first and third practical methods of construction depend.

(6.) *If* EFGH (Fig. 62) *be a rectangular parallelogram, and* D C *and* A B *are the lines joining the bisections of the opposite sides, divide* G B *into* n, *equal parts, and also* O B *into* N, *equal parts. Let* Gp_1 *contain* p *of the parts into which* G P *is divided, and let* Op_2 *contain* p *of the equal parts into which* O B *is divided, join* Dp_1 *and* Cp_2 *and produce it to meet* Dp_1 *in* P; *then* P *is a point in the Ellipse, whose major and minor axes are* A B *and* O D.

Fig. 62.



For, drawn P N parallel to D O and $\therefore$ perpendicular to AB.

Now, $Op_2 = \frac{p}{n} OB$. and $Gp_1 = \frac{p}{n} OD$.

Also, $\frac{OD - PN}{ON} = \frac{OD - p_1B}{OB} = \frac{Gp}{OB} = \frac{p}{n} \cdot \frac{OD}{OB}$.

Again, draw P M perpendicular D O. Then

$$\frac{Op_2}{OC} = \frac{MP}{MC}, \text{ or } \frac{ON}{OC + OM} = \frac{p}{n} \cdot \frac{OB}{OC}.$$

$$\text{Now } OC = OD \therefore \frac{OD + PN}{ON} = \frac{n}{p} \cdot \frac{OD}{OB}.$$

But we have already seen that $\frac{OD - PN}{ON} = \frac{p}{n} \cdot \frac{OD}{OB}$.

$$\therefore \frac{OD^2 - PN^2}{ON^2} = \frac{OD^2}{OB^2}.$$

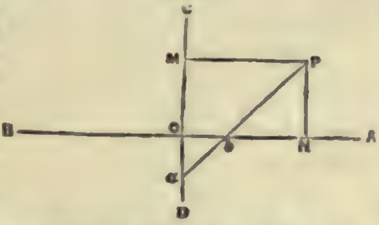
$$\therefore \frac{PN^2}{OD^2} + \frac{ON^2}{OB^2} = 1.$$

Hence by article (4), P is a point in an ellipse, whose major and minor axes are O B and O D respectively.

On this principle the second practical method is founded.

(7.) *If* A B, C D (Fig 63) *are two lines at right angles to each other, and bisecting each other in the point* O, *then if* P*ab be a straight line, so placed that* P*b* = O C *and* P*a* = O A, *then the point* P *is in an ellipse, whose axes are* A B *and* C D.

Fig. 63.



For draw P N, P M at right angles to O C and O A. Now by similar triangles,

$$\frac{Ob}{ab} = \frac{PM}{Pa} = \frac{ON}{OA}.$$

$$\text{and } \frac{Oa}{ab} = \frac{PN}{Pb} = \frac{PN}{OC}.$$

$\therefore \frac{PN^2}{OC^2} + \frac{ON^2}{OA^2} = \frac{Ob^2 + Oa^2}{ab^2} = \frac{ab^2}{ab^2} = 1$. Since bOa is a right angle.

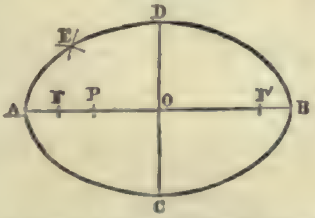
Hence (art. 4) P is a point in the specified ellipse. Q. E. D.

This is the principle of the trammel described in the fourth practical method.

To describe an Ellipse, the transverse (A B) *and conjugate* (C D) *diameters being given.*

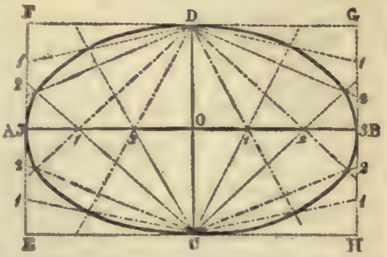
1st Method.—Draw A B and C D, bisecting each other at right angles, in the centre O (Fig. 64); with the centre D or C and radius O A or O B, describe arcs cutting A B in F and F′, which points will be the foci of the ellipse; take any other point P in the transverse diameter A B, and with the centres F, F′ and radii equal to A P and P B, respectively, describe arcs intersecting in the point E, which will be a point in the curve. By taking several points in the transverse diameter, and proceeding in a similar manner, as many points in the curve may be found as may be required, through which the ellipse may be drawn.

Fig. 64.



2nd Method.—Through the extremities of the given diameters draw the rectangle E F G H (Fig. 65); divide A E, A F and B H, B G into any number of equal parts (say 3); also divide A O and O B into the same number of equal parts; join D and the points of division in A F and B G, also C and those in A E, and B H. Again, from D draw lines through the points of division in A O and O B, intersecting the lines drawn from C to the points in A E and B H; and in the same manner from C draw lines through the points of division in A O and O B, intersecting the lines drawn from D to the points in A F and B G; the intersections thus derived are points in the curve through which the required ellipse may be drawn.

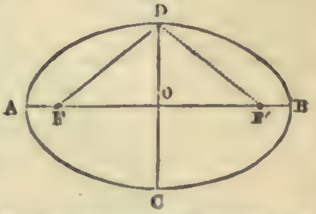
Fig. 65.



3rd Method.—An ellipse may easily be drawn by means of a thread, in the following manner:—

Find the foci F and F′ (Fig. 66) as in the first method; take a piece of thread equal in length to the distance between the foci added to the transverse diameter, and fasten the two ends; having fixed two pins in the foci, pass the thread round them and stretch it, place a pencil in the angle made by the thread when stretched, and commencing at one end (D) of the conjugate diameter, the thread being in the position F D F (as shown in dotted lines), move the pencil-point round, keeping the thread always stretched until the point again meets at D; the ellipse will be drawn.

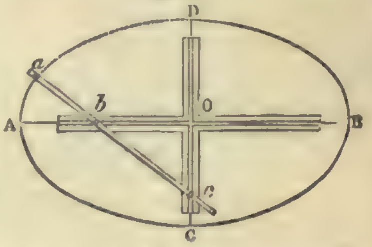
Fig. 66.



4th Method.—An instrument called a *trammel* is sometimes used for describing an ellipse, and is generally formed of two pieces of wood fixed at right angles to each other, and having a groove running through the centre of each, the groove being made a little wider at the bottom than at the top, in order to keep the guides *b*, *c*, (Fig. 67), attached to the bar, *abc*, in the groove; the bar, *abc*, should have a pencil fixed at the end *a*, the two guides, *b* and *c*, being movable or sliding along the bar, but when set ready for use, secured by small screws in the proper positions. The method of using the trammel is as follows:—

1st. Set the grooved pieces of wood on the given diameters A B and C D of the ellipse (as in the figure); the centre, where the two pieces cross, being on the centre O of the ellipse.

Fig. 67.



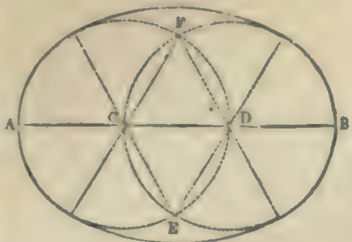
2nd. Make the distance from the pencil at *a* to the first sliding-guide at *b* equal to half the conjugate diameter, (or *ab* equal to O D or O C); and from the same point *a* to the second sliding-guide at *c* equal to half the transverse diameter (or *ac* equal to O A or O B).

3rd. Move the end *a* round, commencing at the point D, allowing the guides to move freely in the grooves, and the pencil will be found to describe the ellipse required.

The oval, although not an ellipse, so nearly resembles it, that very frequently, from the simplicity of drawing an *oval*, it is used in place of an *ellipse*. It is formed of parts of circles by the following methods:—

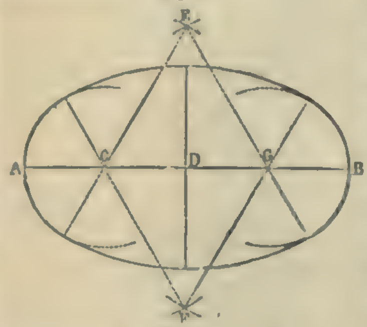
1st Method.—Divide any line A B (Fig. 68) representing the transverse diameter, into three equal parts by the points C D. With the centres C and D and the equal radii C A and D B, describe two circles. At the points E and F, where they intersect, as centres, and the equal radii A D or B C, describe parts of other two circles joining the circumferences of the two first circles (*the exact points of junction of the two circles may be got by joining the centres of both circles, as shown by the dotted lines*), which will complete the oval required.

Fig. 68.



2nd Method.—It is often required to draw a *flat or long-shaped oval*, in which case divide the line A B (Fig. 69) into four equal parts by the points C, D, G, and with the centres C and G and radii equal to C A and G B, describe two circles; also with the same centres and radii equal to any two parts of the line A B, such as A D, describe arcs intersecting at E and F, with which, as centres and radii equal to three parts, of A B, such as A G, describe portions of other two circles joining the circumferences of the first circles, which will complete the oval required.

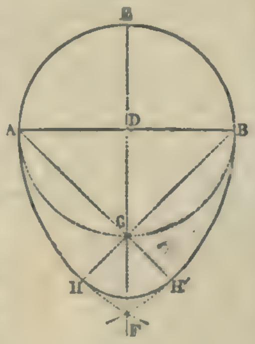
Fig. 69.



3rd Method.—*To draw an egg-shaped oval.*

Bisect the diameter A B in the point D (Fig. 70), with which, as a centre, and D A or D B as a radius, describe a circle cutting the diameter E F in the point G: with the centres A and B and radii equal to A B describe two arcs, A H and B H′; join A G and B G, and produce them until they cut the arcs A H and B H′ in the points H and H′, and with the centre G and radius G H, describe a part of a circle touching the two latter drawn arcs, which will complete the oval.

Fig. 70.

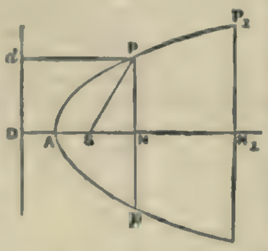


THE PARABOLA.

(1.) *To show that* $PN^2 = 4AS, AN$.

Let D*d* (Fig. 71) be the directrix, S the focus; draw D A N perpendicular to D*d* through S; this line is called the *axis* of the parabola. Draw P N perpendicular to D N, and P*d* perpendicular to P N. Now S P = P*d*. Hence if A S = A D, A is a point in the parabola, and is called its vertex.

Fig. 71.



Now $PS = Pd$ (by Def. 2) $= DN = DA + AN = AS + AN$.

Also $PS^2 = PN^2 + SN^2 = PN^2 + (AN - AS)^2$ $\therefore$ $(AS + AN)^2 = PN^2 + (AN - AS)^2$.

$$\therefore PN^2 = 4AS, AN.$$

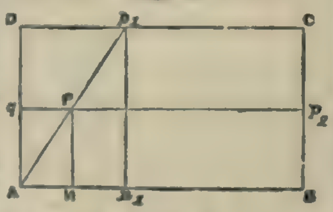
Cor. (1.) Hence A S. is a third proportional to A N, and the half of P N.

Cor. (2.) Also if P_1 be any other point, and $P_1 N_1$ be parallel to P N, we have $P_1N_1^2 : PN^2 :: 4AS.AN_1 : 4AS.AN :: AN_1 : AN$.

N.B.—If $P_1 N_1$ bound the curve it is sometimes called the base, and AN_1 the height of the curve. Also it is plain that if P N be produced, so that $pN = NP$, then $pN^2 = 4AS.AN$, and therefore p is a point in the parabola; which is therefore *symmetrical* about AN_1; the line Pp is called a double ordinate.

(2.) If A B C D (Fig. 72) be any rectangle, and if D C and C B are each divided into n equal parts, and let $Dp_1 = p$ of the equal parts into which C D is divided, and $Bp_2 = p$ of the parts into which C B is divided; join Ap_1 meeting p_2q (parallel to A B) in P; then P is a point in the parabola which has for its base C B and height B A.

Fig. 72.



For, draw P N perpendicular to A B, and $p_1 n_1$ parallel to P N.

$$\text{Now, } Bp_2 = \frac{p_1}{n_1}.CB.,\ An_1 = \frac{p_1}{n_1}.\ AB \text{ and } PN = Bp_2.$$

$$\text{Also, } \frac{PN}{AN} = \frac{p_1n_1}{An_1} = \frac{CBn_1}{ABp_1}$$

$$\text{And } PN = \frac{p_1}{n_1}\ CB.$$

$$\because \frac{PN^2}{AN} = \frac{CB^2}{AB}$$

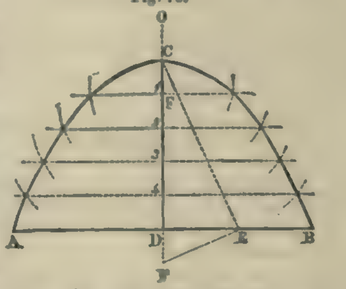
$\therefore PN^2 : CB^2 :: AN : AB$.

$\therefore$ P is a point in the specified parabola by corollary to last article. The second of the following practical methods is founded on the above principles. The first and third depend entirely on the definition of the parabola.

To describe a parabola, any absciss (that is, a portion of, as C1 C2, &c.) *of the axis and the corresponding ordinate being given; or, the half width of the base* (A D *or* D B), *and the height of the curve* (C D) *being given.*

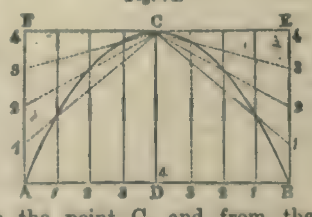
1st Method.—Bisect D B (Fig. 73) in the point E; join C E, and from E draw E F perpendicular to C E, and meeting C D produced in F; make C O in D C produced and C F_1 each equal to D F, F_1 will be the focus of the required parabola. Take any number of points, 1, 2, 3, 4 (&c.), in C D; through them draw double ordinates, or lines perpendicular to the axis C D; then with the centre F_1, and radii O F_1, O1, O2, O3, O4 (O &c.), describe arcs cutting the ordinates; the curve drawn through the points of intersection will be the parabola required.

Fig. 73.



2nd Method.—A B (Fig. 74) being the width at the base, and C D the height of the curve, as before, construct the parallelogram A B E F, divide D A, D B and A F, B E respectively into the same number of equal parts in the points 1, 2, 3, 4; from the points of division in A F and B E draw lines to the point C, and from the points of division in D A and D B draw lines perpen-

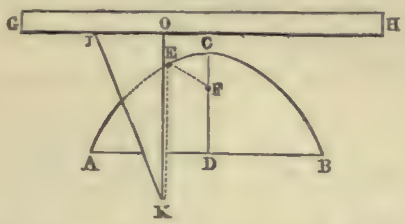
Fig. 74.



dicular to A B, or parallel to C D, cutting the former lines; then the curve drawn through the points of intersection will be the parabola required.

3rd Method.—Place a ruler G H (Fig. 75) at any convenient distance from C, parallel to the base A B, and take a piece of wood (called a square or set square), made in the form of a right-angled triangle I O K, placing the base I O against the ruler, and the other edge O K to coincide with the line C D; having found the focus F (as in the 1st method), fasten one end of a string at F, place a pencil at the point C, passing the string round it, and bringing the string back to K, fasten it to the end or point of the triangle; move the triangle or square along the ruler, keeping the pencil always against the edge of the square (as at E), and with the string stretched the pencil will describe one-half of the curve. By reversing the square and proceeding in a similar manner, the other half may be drawn, and the parabola required completed.

Fig. 75.



THE HYPERBOLA.

If the reasoning employed in the case of the ellipse be carefully gone over, attending only to the difference that will result from the circumstance that $e > 1$, the student will readily deduce that the following expressions will be found to hold good of the hyperbola, which are entirely analogous to the corresponding expressions in the case of the ellipse.

(1.) $SC = e\,AC$.

(2.) BC must be so taken that $BC^2 = CS^2 - CA^2 = (e^2 - 1)\,CA^2$.

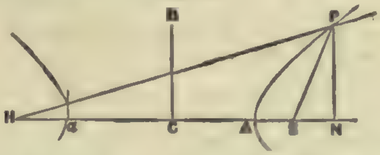
(3.) $SP = e.\,CN - AC$.

(4.) $\dfrac{PN^2}{CB^2} - \dfrac{CN^2}{CA^2} = -1$.

(5.) $HP = e.\,CN + AC$.

(6.) $HP - SP = 2\,AC$.

Fig. 76.



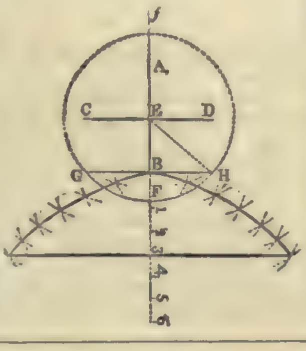
It is on this (6th) property that the following practical construction is founded.

The terms major axis, transverse axis, &c., in the hyperbola, are entirely analogous to the same terms in the ellipse.

To describe a hyperbola, the transverse (A B) *and conjugate* (C D) *axes being given.*

Through B (Fig. 77), at one end of the transverse axis A B, draw G H parallel to the conjugate axis C D, and make G H equal to C D; with the centre E and radius, equal to E H, describe a circle cutting A B, produced both ways, in the points F and f, which will be the foci of opposite hyperbolas; take any number of points, 1, 2, 3, 4 (&c.), in A B produced, and with the centres F and f, and radii B1, B2, B3, B4, (B &c.), and A1, A2, A3, A4 (A &c.), describe arcs cutting each other; the curve drawn through the points of intersection will be the hyperbola required.

Fig. 77.



The following consideration materially simplifies the construction of a hyperbola.

Through A (Fig. 78) draw A D parallel and equal to B C, join C D and produce it indefinitely, take P any point in the curve, draw pPN, meeting CD produced in p. Then

$$\frac{DA}{CA} = \frac{pN}{CN}$$

$$\therefore \frac{pN^2}{CB^2} - \frac{CN^2}{CA^2} = 0$$

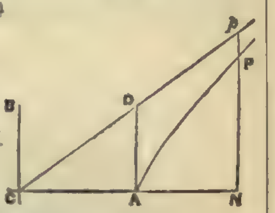
$$\text{But (4)} \quad \frac{PN^2}{CB^2} - \frac{CN^2}{CA^2} = -1$$

$$\therefore \text{subtracting } \frac{pN^2 - PN^2}{CB^2} = 1$$

$$\therefore (pN - PN)(pN + PN) = CB^2$$

$$\therefore Pp = \frac{CB^2}{pN + PN}.$$

Fig. 78.



Now it is plain that PN and pN increase as P is farther from A, or N from A, and therefore, the farther P is from the vertex the nearer it approaches C D produced. C D is called an asymptote—after a short distance the curve *sensibly* coincides with the asymptote. Hence, if in the practical construction above given E H be produced, it will serve as a *guide* to the curve, which can be drawn very accurately after a very few points have been determined by the construction.

THE CYCLOID.

Besides the conic sections, which we have briefly discussed above, there are several curves possessing curious or useful properties. Amongst the chief of these is the cycloid. The construction of this curve is sometimes useful to the artist. The following will suffice to explain the nature of the curve, and the method of its construction.

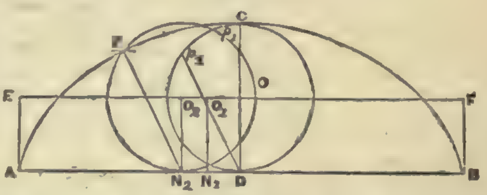
The cycloid is a curve formed by a point in the circumference of a circle (called the generating circle), revolving on a straight or level line; it may be best described as the curve traced out by a point in the wheel of a carriage when in motion along a level road. When the generating circle revolves round another circle, the curve described by a point in the circle is then called an epicycloid, and is constructed in a similar manner to the cycloid.

To describe a cycloid, the diameter or width at the base (AB), *and height* (C D), *of the curve being given.*

The most common method of describing the cycloid is by placing a ruler along the line A B, and taking a circle, such as a shilling, &c., according to the size or height of the curve required, and having fixed a point in that circle, to move it slowly along the ruler, marking different points in the curve, or by keeping a pencil fixed at the point chosen, and thus describing the curve. This, however, is liable to error, as the circle used very often slips, and cannot then revolve accurately; by construction, however, the curve may be correctly formed thus:—

Let A C B (Fig. 79) represent the curve in question, A B its base, C D its height. Bisect C D in O, and through O draw E F parallel to A B; with centre O and radius O C describe a circle, and divide the circumference into any number of equal parts, as Cp_1, Cp_2, . . . join

Fig. 79.



Dp_1 Dp_2 . . . Again, divide A D into the same number of equal parts, D N_1 D N_2 . . . . and draw O_1 N_1 O_2 N_2 . . . . parallel to C D; with centre O_2 and radius C D describe a circle, and with centre N_2 and radius Dp_2 describe an arc cutting the circle in the point P. This is a point in the curve, similarly with the centre O_1 and radius C D. Another circle may be described and intersected by the arc of a circle described with centre N_1 and radius Dp_1, and thus another point be determined; and so on for any number of points, which, being joined carefully, will give the curve in question.

We thus conclude our treatise on Practical Geometry. It has been our endeavour to confine it in extent to that which it is absolutely necessary the scientific draughtsman should be familiar with; and in the foregoing pages will be found all that is required for practical purposes—no really essential propositions being omitted.

CHAPTER XI.

PLANE TRIGONOMETRY.

1. *On representing Lines and Angles by Numbers.*

If we have a line of any length, we can represent it numerically by the number of times it contains a given line, which we take to represent unity. Thus, if we take a line a foot long to be the unit of length, a line seven feet long can be represented by 7. Of course, the same holds good of any other line. And so when we speak of a line 8, 5, or whatever the number may be, we mean that the line in question contains 8 or 5 of the given unit, as 8 feet, or 5 feet. And of course, if we can represent lines by numbers, we can generalise the numbers by letters, and thus we can represent lines by algebraical symbols; so that $a\,b\,c$, $x\,y\,z$, &c., may be understood to represent lines. In the same manner as before, if we speak of a line a, we mean a line containing as many units of length (*e.g.*, feet) as a contains units of number.

On the same principle we may express angles by numbers or by letters. This is done by dividing the right angle into 90 equal parts, each of which is called a degree, and dividing the degree into 60 equal parts, each called a minute, and the minute into 60 equal parts, each called a second. An angle is then expressed as being so many degrees, with odd minutes and seconds, *e.g.*, 36 degrees, 57 minutes, 31 seconds (which is usually written $36° \, 57' \, 31''$), in the same manner as a line is expressed by so many yards, with odd feet and inches.

Of course, as we can thus represent angles by numbers, we may also represent them by letters, and may have angles A B C; where the angle A (for instance) means that the angle contains as many degrees and parts of a degree as A contains units and parts of a unit. It is usual to denote angles either by Roman capital letters, A B C; or else by Greek small letters, $\alpha, \beta, \gamma \ldots \theta, \phi, \psi \ldots$ while generally the small Roman $a\,b\,c$ denote lines. This is, of course, only a conventional arrangement.

In the same manner as we may measure lines either by feet or yards, or miles, so we might take, as the unit of angular measure, any other part of the right angle than the $\frac{1}{90}$th; and, in fact, at the end of last century, when the decimal notation was introduced into France, it was proposed by certain French mathematicians, to make the degree the $\frac{1}{100}$th part of the right angle. The proposition was at no time extensively accepted, and is now quite abandoned.

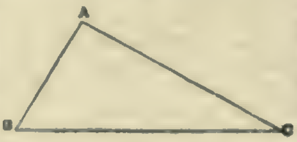
2. *Definition of the Science of Trigonometry.*

We are thus enabled to express lines and angles by numbers; and this is the first step towards making calculations in which lines and angles are the data. However, before these calculations can be performed, it is necessary that the relations which exist between straight lines and angles should be investigated. It is the object of the science of Trigonometry to make these investigations.

The object of the science will, perhaps, be more clearly stated, if we limit the definition so as to make it correspond more closely to its derivational meaning, by saying that *the science of Trigonometry has for its object the investigation of the relations which exist between the sides and angles of triangles and the algebraical expression of those relations.*

The immediate application of the science is to the calculation of certain parts of a triangle from certain given parts; *e. g.*, having given the sides B A, A C, and the angle B A C of the triangle A B C, we can calculate the magnitude of the side B C.

Fig. 1.



The science has, however, very many other uses besides the one from which its name is taken—viz., the measurement of triangles.

3. *The Circular Measure of an Angle.*

The measures above given, enable us to compare arithmetically one straight line with another, and one angle with another. But it is to be observed, that an angle and a line are heterogeneous magnitudes; and therefore, if we would perform algebraical operations into which lines and angles enter, we must devise some plan of measuring angles that shall express them by means of lines, or of the ratios of lines.

In fact, when we speak of an angle (of 57° suppose) it tells us what the angle is, but does not at once give us the means of comparing that angle with given lines.

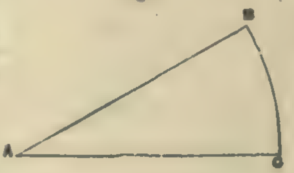
The measure of the angle adopted for the purpose of such calculations, is called the circular measure.

It is founded on the two well-known geometrical propositions.

(*a*) That in circles of the same radius, the angle is proportional to the arch which subtends it.

(*b*) And that for the same angle, in circles of different radii, the arc varies as the radius.

Fig. 2.



If a = the arc B C,
θ = the angle B A C, subtended by the arc B C,
r = the radius A C.

we may express these propositions by the two variations

$$a \backsim \theta \text{ when } r \text{ is constant.}$$
$$a \backsim r \text{ when } \theta \text{ is constant.}$$
$$\therefore a \backsim r\theta \text{ when both vary.}$$
$$\therefore \theta \backsim \frac{a}{r}$$

or the angle is measured by the ratio of the arc to the radius.

If we take the unit of angle to be the angle which is subtended by an arc of the same length as the radius, then

$$\theta = \frac{a}{r}.$$

In this case, the angle being measured by the ratio of two lines, it can enter a calculation in which we are dealing with lines.

N.B.—We can easily find the number of degrees in the angle which is the unit of circular measure.

Let x = the number of degrees required. Then x is subtended by an arc of the length of the radius = r.

Now an angle of 180° is subtended by a semicircle; *i. e.*, by an arc = πr, where $\pi = 3{\cdot}14159$.

$$\therefore \frac{x^\circ}{180^\circ} = \frac{r}{\pi r} = \frac{1}{\pi}$$

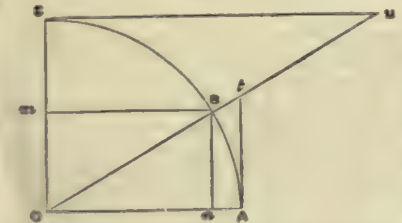
$$\therefore x = \frac{180^\circ}{3{\cdot}14159} = 57^\circ{\cdot}29577.$$

4. *The Definitions of the Trigonometrical Lines and Ratios.*

It is, however, generally more convenient, and for our present purposes necessary, to determine an angle not by an arc, or by the ratio of an arc to its radius, but by certain straight lines, or by the ratio of certain straight lines to each other. These lines, or, as they are now more commonly regarded, these ratios, are called respectively the sine, tangent, secant, cosine, cotangent, or cosecant of the angle. We proceed to define these terms.

Let A O B be an angle O A. Draw O C perpendicular to O A, and with the centre O and any radius O A describe an arc of a circle, meeting O C in C.

Fig. 3.



Draw B*n*, B*m*, perpendicular to O A, to O C; at A and C draw A*t*, C*u*, perpendicular to O A, O C. Then B*n* is defined to be the sine of the angle A O B, to the radius O A.

A*t* is defined as the tangent of A O B.
O*t* . . . . secant of A O B.
A*n* . . versed sine of A O B.
Hence, also B*m* (or O*n*) is the sine of B O C.
C*u* . . tangent of B O C.
O*u* . . secant of B O C.

Now B O C is 90° – A.

And B*m*, C*u*, O*u*, are defined as being the cosine, cotangent, cosecant respectively of A O B.

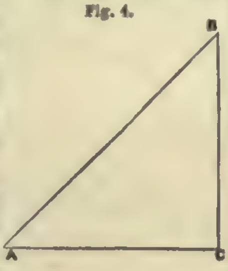
Hence—

$$\left.\begin{array}{r} Bn = \text{sine } A \\ Bm \text{ or } On = \text{cosine } A \\ At = \text{tan. } A \\ Cu = \text{cotan. } A \\ Ot = \text{sec. } A \\ Ou = \text{cosec. } A \end{array}\right\} \text{to the radius } OA.$$

To this method there is the obvious objection that the sines, &c., of a given angle have different values, according as they are referred to different radii; accordingly, instead of defining the sines, &c., as lines, it is, as above stated, now more usual to define them as ratios; by which means all consideration of the radius to which the sines are referred is avoided. According to this method the definitions are given as follow :—

C A B any right-angled triangle having the right angle at C.

Fig. 4.



Then The sine of A is $\frac{BC}{AB}$

The tangent of A is $\frac{BC}{AC}$

The secant of A is $\frac{AB}{AC}$

Hence— The sine of B is $\frac{AC}{AB}$

The tangent of B is $\frac{AC}{BC}$

The secant of B is $\frac{AB}{BC}$

But because A = 90 — B
The sine of B is the cosine A.
The tangent of B, cotangent of A.
The secant of A is the cosecant of A.

Hence— Sine $A = \frac{BC}{AB}$ Cosine $A = \frac{AC}{AB}$

Tan. $A = \frac{BC}{AC}$ Cotan. $A = \frac{AC}{BC}$

Sec. $A = \frac{AB}{AC}$ Cose. $A = \frac{AB}{BC}$

N.B.—The angle which with another makes up 90° is called the complement of that angle. Hence B is the complement of A; and the cosine, cotangent, and cosecant of an angle are evidently the sine, tangent, and secant of its complement.

It is plain (Euc. VI. 4) that the values of these ratios depend solely on the angle, and are quite independent of the magnitude of the sides of the triangles. If, then, we can by any means calculate the value of these ratios, which correspond to any angle, these values can be arranged in a table; and it is plain that, having such tables, if we have given any one of the ratios defined above, we know the angle; and *vice versâ*, if we have the angle given, we know the ratio.

Such tables have been calculated on principles to be hereafter explained;—for our present purpose it is sufficient for us distinctly to understand, that if we have given to us the numerical value of any one of the ratios, we know the angle that corresponds to it, and *vice versâ.*

5. *On the relations existing between the Trigonometric Ratios of the same Angle.*

Let A B C be a right-angled triangle,
A any given angle.
C the right angle.

Then $AC^2 + BC^2 = AB^2$ (Eucl. 47, Book I.)

$$\therefore \frac{AC^2}{AB} + \frac{BC}{AB} = 1.$$

$$\therefore \text{cos. }^2A + \text{sin. }^2A = 1 \ldots\ldots (1).$$

Again $$\text{tan. } A = \frac{BC}{AC}$$

$$\text{cotan. } A = \frac{AC}{BC}.$$

$$\therefore \text{tan. } A,\ \text{cotan. } B\ A = 1. \ldots\ldots (2).$$

Again, $$\text{tan. } A = \frac{BC}{AC} = \frac{\frac{BC}{AB}}{\frac{AC}{AB}}$$

$$\therefore \text{tan. } A = \frac{\text{sin. } A}{\text{cos. } A} \ldots\ \ldots (3).$$

Again, $$\text{secant } A = \frac{AB}{AC} = \frac{1}{\frac{AC}{AB}}$$

$$\therefore \text{sec. } A = \frac{1}{\text{cos. } A} \ldots\ldots (4).$$

In the same manner it may be easily proved that

$$\text{Cotan. } A = \frac{\text{cos. } A}{\text{sin. } A} \ldots\ldots (5).$$

$$\text{Cosec. } A = \frac{1}{\text{sin. } A} \ldots\ldots (6).$$

$$\frac{\text{Sec. } A}{\text{Cosec. } A} = \text{tan. } A. \ldots\ldots (7).$$

It is of very great importance that the student be familiar with the relations we have just established. He will therefore do well to perform the following exercises :—

Show that

(1). $\text{sin. } A = \sqrt{1 - \text{cos.}^2 A}$.

(2). $\text{tan. } A = \sqrt{\frac{1}{\text{cos. }^2A} - 1}$.

(3). $\text{tan. } A \text{ cosec. } A = \text{sec. } A$.

(4). $\text{tan. } A + \text{cotan. } A = \frac{1}{\text{sin. } A.\ \text{cos. } A}$.

(5). $\text{cosec. } A - \text{sin. } A = \text{cos. } A \text{ cotan. } A$.

(6). $\frac{1 + \text{cos. } A}{\text{sin. }^2A} = \frac{1}{1 - \text{cos. } A}$

(7). $\frac{1}{\sin.^2 A} = 1 + \text{cotan.}^2 A.$

(8). Express each of the trigonometrical ratios of an angle A in terms of the sine of A.

There are two or three angles, the numerical values of the trigonometrical ratios of which can be easily determined. These angles are 45°, 60°, and 30°.

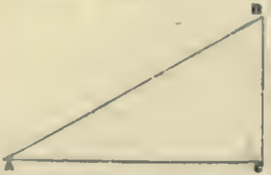
6. *To find the Trigonometrical Ratios of an Angle of 45°.*

A B C, a right-angled triangle. C the right angle.
If $A = 45°$, then $A = B$, and $AC = BC$.
Now, $AC^2 + BC^2 = AB^2$. (Eucl. I. 47).

$\therefore\ 2AC^2 = AB^2,$

or $2BC^2 = AB^2.$

Fig. 5.



$\therefore\ \sin. 45° = \frac{BC}{AB} = \frac{1}{\sqrt{2}}$

$\tan. 45° = \frac{BC}{AC} = 1.$

$\sec. 45° = \frac{AB}{AC} = \sqrt{2},$

and $\text{cosin.}\ 45° = \sin. (90 - 45) = \sin. 45°.$

$\therefore\ \cos. 45° = \frac{1}{\sqrt{2}}$

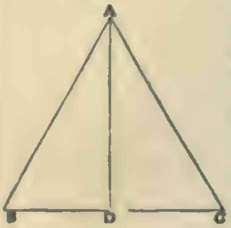
Similarly, $\cot. 45° = 1.$

$\text{cosec.}\ 45° = \sqrt{2}.$

7. *To find the Trigonometrical Ratios of an Angle of 60°.*

A B C, an equilateral triangle. The angle A B C is one of 60°. Draw A D perpendicular to B C. Now $BD = \frac{1}{2}.\ BC = \frac{1}{2}.\ AB$ and $AD^2 = AB^2 - BD^2 = \frac{3}{4}.\ AB^2.$

Fig. 6.



$\therefore AD = \frac{\sqrt{3}}{2}\cdot AB.$

$\therefore \sin. 60° = \frac{AD}{AB} = \frac{\sqrt{3}}{2}.$

$\tan. 60° = \frac{AD}{BD} = \frac{\frac{\sqrt{3}}{2}\cdot AB}{\frac{1}{2}\ AB} = \sqrt{3}.$

$\sec. 60° = \frac{BD}{AB} = 2.$

$\cos. 60° = \frac{BD}{AB} = \frac{1}{2}.$

$\text{cotan.}\ 60° = \frac{BD}{AD} = \frac{1}{\sqrt{3}}.$

$\text{cosec.}\ 60° = \frac{AB}{AD} = \frac{2}{\sqrt{3}}.$

Since $30° = 90° - 60°$
we shall have $\sin. 30° = \cos. 60° = \frac{1}{2}.$

And similarly $\tan. 30° = \frac{1}{\sqrt{3}}$ $\sec. 30° = \frac{2}{\sqrt{3}}.$

$\cos. 30° = \frac{\sqrt{3}}{2}.$ $\text{Cotan.}\ 30° = \sqrt{3}.$

$\text{Cosec.}\ 60° = \frac{1}{2}.$

8. *Generalisation and Extension of the Principles and Definitions previously laid down.*

The definitions above given hold good for angles that are less than ninety degrees; the definition, both of an angle and of the ratios which determine it, admit of and require extension; the nature of which extension and the principle on which it is made we will now proceed to explain.

9. *The use of the Negative Sign to denote position.*

Fig. 7.

Let A B be a line, the length of which is a. Let B C be a line, the length of which is b. Then it is plain that A C is $a - b$. This distance, A C, is arrived at by measuring a distance (a) to the right from A, and then measuring another distance (b) to the left from B, the $+a$ and the $-b$ being measured in opposite directions.

It appears, therefore, that when a stands for a line measured from a given point in one direction, $-a$ will stand for a line of the same length measured in the opposite direction. In other words, the magnitude of the line is determined by the number of units in a, while the direction is determined by its sign.

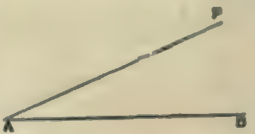
Fig. 8.

It is generally understood that $+a$ signifies a line measured to the right of a given point, as A B, and therefore that $-a$ signifies a line measure to the left of the fixed point, as AB′.

10. *Extension of the Definition of an Angle.*

We now proceed to extend the definition of an angle. An angle, as defined by Euclid—*i. e.*, as the inclination of one line to another—must be less than two right angles. But if we regard an angle as the space swept out by a right line revolving in one plane, about a fixed point in a given straight line, we clearly remove the limit imposed by Euclid's definition on the magnitude of the angle.

Fig. 9.

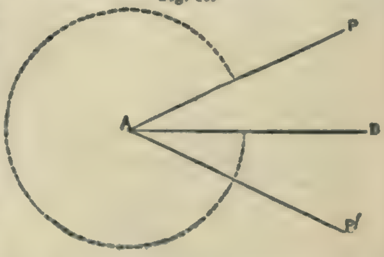


Thus if A be the fixed point in the fixed line A B, A P the movable line, let the angle B A P, according to Euclid's definition, be A.

Now it is plain that in one revolution AP passes through an angle equal to four right angles, or 360°. Moreover, A P will always come to its present position after one, two, or any number of revolutions; and therefore, according to our extended definition, B A P may be either A or 360° + A, or 2 × 360° + A, or, generally, $360°n + A$, where n is any integer.

11. *Negative Angles.*

Fig. 10.



In the same manner as we have shown that $+a$ and $-a$ mean equal lines measured in a contrary direction, so + A and — A will mean angles measured in contrary directions. Thus, AB and AP have the same meaning as before. Let A P′ be so placed that $P'AB = PAB$; then if $PAB = A$, $P'AB = -A$.

It is plain that if A P′ comes into the position A P, it must revolve through an angular space of $-360° + A$, as denoted by the portion of a dotted circle in figure, or through a certain number of total revolutions besides $-360° + A$. Hence B A P may also be represented by $-360° + A$, $-360° \times 2 + A$, or generally by $-360° \times n + A$, where n is any positive integer.

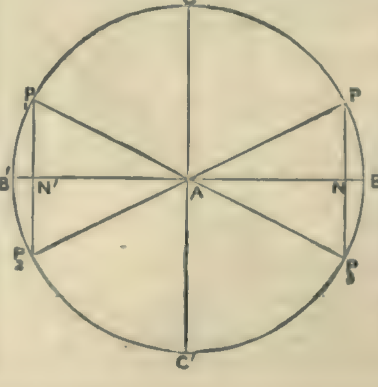
Hence we conclude that if A be any geometrical angle, its most general trigonometrical form will be

$$n \times 360° + A,$$

where n is any positive or negative integer whatever.

12. *Extension of Definitions of Trigonometrical Ratios.*

Fig. 11.



We now proceed to consider the trigonometrical ratios of angles greater than a right angle. We shall, in the first instance, confine our attention to the sines and cosines of angles, less than four right angles.

We have already explained that

$$\text{Sin. } B\,A\,P = \frac{P\,N}{A\,P}$$

$$\text{Cos. } B\,A\,P = \frac{A\,N}{A\,P}$$

Now as A N is measured along A B to the right, A N is positive. And if we reckon lines measured upward, from A towards C positive, it is plain that P N, being measured parallel to that direction, is positive.

The signs of the sine and cosine of an angle less than ninety degrees are then, by this way of reckoning the signs of the measurements, positive, as they should be.

Now if we consider an angle B A P_1, it is clear that P_1 N′ stands in the same relation to B A P_1 that P N does to B A P.

Hence we define

$$\text{Sin. } B\,A\,P_1 = \frac{P_1 N'}{A\,P_1}$$

$$\text{Cos. } B\,A\,P_1 = \frac{A\,N'}{A\,P_1}$$

It is plain that P_1 N′ is positive, and A N′ is negative. Hence

The sine of an angle ⁊ 90° ∠ 180° is positive, and the cosine of an angle ⁊ 90° ∠ 180° is negative.

In like manner, if B A P_2 be the angle subtended by the circumference B P_1 P_2,

$$\text{Sin. } B\,A\,P_2 = \frac{P_2 N'}{A\,P_2}$$

$$\text{Cos. } B\,A\,P_2 = \frac{A\,N'}{A\,P_2}$$

Now P_2 N′ is negative, and A N′ is negative. Hence the sine of an angle ⁊ 180° ∠ 270° is negative, and the cosine of an angle ⁊ 180° ∠ 270° is negative. In like manner if P_3 A B signify the angle subtended by the circumference B P_1 P_2 P_3,

i. e., ⁊ 270° but ∠ 360°.

$$\text{Sin. } B\,A\,P_3 = \frac{P_3 N}{A\,P_3}$$

$$\text{Cos. } B\,A\,P_3 = \frac{A\,N}{A\,P_3},$$

And P_3 N is negative, and A N is positive. Hence, sine of an angle ⁊ 270° ∠ 360° is negative: and the cosine of an angle ⁊ 270° ∠ 360° is positive. These four angles which we have considered are said to be in the first, second, third, and fourth quadrants respectively.

By means of the above, if we have given the signs both of sine and cosine of an angle, we can tell in what quadrant it must lie.

Thus if sine $\theta = +m$ and cos. $\theta = -n$, θ must lie in the second quadrant; *i.e.*, must be greater than 90° and less than 180°.

13. *To express the Trigonometrical Ratios of any angle in terms of those of an angle less than* 90°.

Again, the trigonometrical ratios of any angle can be expressed by means of the ratios of an angle less than 90°.

For if, in the same figure, B A P, B′A P_1, B′A P_2, B A P_3, are equal to one another, and therefore the lines P N, P_1 N′, P_2 N′, P_3 N, are equal in magnitude; as also are A N and A N.

If then we take account both of sign and magnitude,

$$\text{Sin. } B\,A\,P_1 = \frac{P_1 N'}{A\,P_1} = \frac{P\,N}{A\,P} = \text{sin. } B\,A\,P.$$

$$\therefore \ \text{sin. } (180° - A) = \text{sin. } A.$$

$$\text{Sin. } B\,A\,P_2 = \frac{P_2 N'}{A\,P_2} = \frac{-P\,N}{A\,P} = -\text{sin. } B\,A\,P.$$

$$\therefore \text{ sin. } (180° + A) = -\text{sin. } A.$$

$$\text{Sin. } B\,A\,P_3 = \frac{P_3 N}{A\,P_3} = \frac{-P\,N}{A\,P} = -\text{sin. } B\,A\,P.$$

$$\text{Sin. } (360° - A) = -\text{sin. } A.$$

In the same manner it is easy to show that

$$\text{Cos. } (180° - A) = -\text{cos. } A.$$

$$\text{Cos. } (180° + A) = -\text{cos. } A.$$

$$\text{Cos. } (360° - A) = \text{cos. } A.$$

For example, we have seen that cos. $60° = \frac{1}{2}$.

Cos. $120° = \text{cos. } (180° - 60°) = -\text{ cos. } 60° = -\frac{1}{2}$.

Similarly—

Sin. $315° = \text{sin. } (360° - 45°) = -\text{ sin. } 45° = -\frac{1}{2}$.

If we consider the case of the tangent of an angle, ∠A being an angle, $<90°$.

$$\text{Tan. } (180° - A) = \frac{\text{sin. } (180° - A)}{\text{cos. } (180° - A)} = \frac{+\text{sin. } A}{-\text{cos. } A} = -\text{tan. } A.$$

$$\text{Tan. } (180° + A) = \frac{\text{sin. } (180° + A)}{\text{cos. } (180° + A)} = \frac{-\text{sin. } A}{-\text{cos. } A} = \text{tan. } A.$$

$$\text{Tan. } (360° - A) = \frac{\text{sin. } (360° - A)}{\text{cos. } (360° - A)} = \frac{-\text{sin. } A}{\text{cos. } A} = -\text{tan. } A.$$

In the same manner we may express the other trigonometrical ratios of angles greater than 90° by means of those angles less than 90.

It is to be observed, that if we suppose A P to make one complete revolution from A P, it returns to its present position. So that A N and N P are the same both in magnitude and direction for the angle 360° + A as for A.

The same is true of any number of complete revolutions.

Hence, if f denote any trigonometrical ratio whatever,

$$f\,(n\,360° + A) = f\,(A),$$

where n is any positive integer whatever. Thus,

$$\text{Sin. } (n\,360° + A) = \text{sin. } (A)$$

$$\text{Cos. } (n\,360° + A) = \text{cos. } (A)$$

And so on.

There are a great variety of relation similar to those above deduced. The following are worth notice:—

We have before stated that if B A P = A, then P_3 A B = − A.

$$\therefore \text{sin. } (-A) = \text{sin. } B\,A\,P_3 = \frac{NP_3}{AP_3}$$

$$= -\frac{PN}{AP} = -\text{ sin. } A.$$

$$\therefore \text{ sin. } (-A) = -\text{ sin. } A.$$

Similarly,

$$\text{Cos. } (-A) = \text{cos. } A,$$

$$\text{and } \therefore \text{ tan. } (-A) = \text{tan. } A.$$

$$\text{and } \quad \text{cot. } (-A) = -\text{ cot. } A.$$

This result can be arrived at by reference to formulas previously proved.

We have seen that under all circumstances

$$f\,(n.360° + A) = f\,(A).$$

$$\therefore \text{ sin. } (360° - A) = \text{sin. } (-A).$$

But we have also seen that

$$\text{sin. } (360° - A) = -\text{ sin. } A;$$

$$\therefore \text{sin. } (-A) = -\text{ sin. } A$$

14. *On the Magnitudes of the Trigonometrical Functions of Angles*, 0°, 90°, 180°, 270°.

The definition of sine B A P tells us that

$$\text{sin. } A = \frac{PN}{AP}.$$

Now if A P coincide with A B, A = 0 and P N = 0, ∴ sin. 0° = 0.

If A P revolve round A, P N increases until A P coincides with A C, when A = 90°, and P N = A P.

$$\therefore \text{ sin. } 90° = 1.$$

After which, as A P revolves towards A B′, P N decreases until at A B coincides with A B^1, when P N = 0, A = 180°, and therefore

$$\text{Sin. } 180° = 0.$$

As A P revolves from A B′ towards A C, P N increases negatively until A P coincides with A C, when A = 270° and P N = − A P.

$$\therefore \text{ sin. } 270° = -1.$$

As A P revolves from A C′ towards its original position A B, P N decreases negatively, until when A P coincides with A B, we have A = 360°, and P N vanishes.

$$\therefore \text{ sin. } 360° = 0.$$

In like manner, if we take the cosine we have

$$\text{Cos. } A = \frac{AN}{AP}.$$

Now when A = 0 A N = A P ∴ cos. 0° = 1.
A = 90° A N = 0 ∴ cos. 90° = 0.
A = 180° A N = − A P cos. 180° = − 1.
A = 270° A N = 0 cos. 270° = 0.
A = 360 A N = A P cos. 360° = 1.

Now $\tan. A = \dfrac{\sin. A}{\cos. A}$

$$\therefore \tan. 0^\circ = \frac{\sin. 0^\circ}{\cos. 0^\circ} = \frac{0}{1} = 0$$

$$\tan. 90^\circ = \frac{\sin. 90^\circ}{\cos. 90^\circ} = \frac{1}{0} = \infty$$

$$\tan. 180^\circ = \frac{\sin. 180^\circ}{\cos. 180^\circ} = \frac{0}{1} = 0$$

$$\tan. 270^\circ = \frac{\sin. 270^\circ}{\cos. 270^\circ} = \frac{1}{0} = \infty$$

$$\tan. 360^\circ = \frac{\sin. 360^\circ}{\cos. 360^\circ} = \frac{0}{1} = 0$$

If we apply similar reasoning to the various trigonometric functions to that employed in discussing the variations of the sine of A, we obtain results which may be arranged in a tabular form, as follows :—

QUADRANT.

Line.	0°	< 90° > 0	90°	< 180° > 90°	180°	< 270° > 180°	270°	< 360° > 270°	360°
Sine	0	+	1	+	0	—	—1	—	0
Cosine	1	+	0	—	—1	—	0	+	1
Tangent	0	+	∞	—	0	+	∞	—	0
Cotangent . . .	∞	+	0	—	∞	+	0	—	∞
Secant	1	+	∞	—	—1	—	∞	+	1
Cosecant	∞	+	1	+	∞	—	—1	—	∞

The student will do well to verify carefully all the results given in this table ; he will also observe that the trigonometrical ratios illustrate the principle that if a function of a variable changes its sign, it must pass through the values of either zero (.0) or infinity (∞).

As the values of the ratios are continuous, the ratios increase gradually to their greatest value, and then decrease to their least. Thus, to take the case of the sine of an angle, which we call θ.

Sine θ increases from 0, when $\theta = 0^\circ$ up to 1, when $\theta = 90^\circ$. It then decreases to 0, when $\theta = 180^\circ$; after which it still further decreases till it equals -1, when $\theta = 270^\circ$, and finally increases up to 0, when $\theta = 360^\circ$.

15. *To determine all the angles which have the same sine, or cosine.*

There is another class of questions presented to us by this extension of our definition of an angle, *viz.*, having given a trigonometrical ratio of an angle, to find all the angles corresponding to it.

For example, $\tan. \theta = p$.

Now, if we did not reckon any angles but those less than 180°, as is the case in geometry, we could only have one value of θ corresponding to a given value of $\tan. \theta$. Suppose this value $= a$.

Then, if we take the trigonometrical or generalised conception of an angle, we shall have another $= 180^\circ + a$.

And since no trigonometrical ratio changes either its value or its sign when its angle is increased by any multiple of 360°, it is plain that in addition to a we shall have a series of values, $360 + a$, $2 \times 360^\circ + a$, $3 \times 360^\circ + a + \ldots.$, $n\,360^\circ + a$; and in addition to the value $180^\circ + a$, we shall have a series of values, $360^\circ + 180^\circ + a$, $2 \times 360^\circ + 180^\circ + a$, $3 \times 360^\circ + 180^\circ + a$, $\ldots.\ n\,360^\circ + 180^\circ + a$. Both these series may be included in one formula,

$$\theta = m\,180^\circ + a,$$

where m is any integer number whatever.

In the same manner, if

$$\text{Cos. } \theta = q,$$

and a be the value of θ less than 180°, which has for its cosine q, then all the values of θ which have a cosine q are included in the formula,

$$\theta = m.\ 360^\circ \pm a,$$

where m is any integer.

And similarly if

$$\text{Sin. } \theta = q,$$

the value of θ is included in the formulas—

$$\theta = 2m\ 180^\circ + a,$$

$$\text{and } \theta = (2m + 1)\ 180^\circ - a,$$

m being any integer whatever.

These may be included in one formula, as follows :—

$$\theta = k.180^\circ + (-1)^k a,$$

where k is any integer whatever ; for when k is even, $(-1)^k$ is positive ; and when k is uneven, $(-1)^k$ is negative.

As practice in the preceding articles, the student may verify the following results :

1. $\text{Sin. } 180^\circ = 0.$
2. $\text{Sin. } 135 = \dfrac{1}{\sqrt{2}}$
3. $\text{Cos. } 135^\circ = \dfrac{1}{\sqrt{2}} = \cos.\ 225^\circ.$
4. $\text{Cos. } 315^\circ = \dfrac{1}{\sqrt{2}} = \sin.\ 405^\circ.$
5. $\text{Sin. } 120^\circ = \dfrac{1}{2} = -\sin.\ 300^\circ.$
6. $\text{Cos. } 300^\circ = \dfrac{\sqrt{3}}{2} = -\cos.\ 150^\circ.$
7. $\text{Sin. } 150^\circ = \dfrac{\sqrt{3}}{2}.$
8. $\text{Cos. } 300^\circ = \dfrac{1}{2}.$

Given that sine $\theta = \dfrac{1}{2}$, show that the following are the values of θ which satisfy that equation, 30°, 150°, 390°, 510°, 750°, 870°, &c.

Given that cos. $\theta = \dfrac{1}{\sqrt{2}}$, show that the following are the values of θ which satisfy this equation, 45°, 315°, 405°, 675°, 765°, &c.

Given that tan. $\theta = 1$, show that the values of θ are 45°, 225°, 405°, 585°, 765°, &c.

THE RELATIONS BETWEEN THE TRIGONOMETRICAL FUNCTIONS OF DIFFERENT ANGLES.

The formulas we have already proved hold good of the ratios of the same angle ; we now proceed to investigate the formulas which express the relations between two or more different angles. There is a very great variety of formulas of this kind, and they admit of an almost infinite number of combinations and modifications. They are, however, all derived mediately or immediately from the following four :—

$\text{Sin. } (A + B) = \sin. A, \cos. B + \sin. B, \cos. A. \ldots.$ (8).
$\text{Sin. } (A - B) = \sin. A, \cos. B - \sin. B, \cos. A. \ldots.$ (9).
$\text{Cos. } (A + B) = \cos. A, \cos. B - \sin. A, \sin. B. \ldots.$ (10).
$\text{Cos. } (A - B) = \cos. A, \cos. B + \sin. A, \sin. B. \ldots.$ (11).

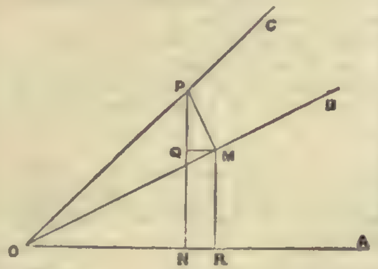
These four formulas can be easily remembered—and it is of great importance that they should be remembered

—by observing that the sine of the sum of two angles is the sum of the product of the sine of the first angle and the cosine of the second, and of the product of the sine of the second angle and the cosine of the first; while the sine of the difference of the angles is the former product minus the latter. The cosine of the sum of two angles is the product of the cosines of those angles minus the product of their sines; and the cosine of the difference of two angles is the sum of the product of the cosines and of the product of the sines.

16. *To prove the Formula*

Sin. (A + B) = sin. A cos. B + sin. B cos. A.

Fig. 12.



Let AOB be the angle A, BOC the angle B; ∴ A O C is the angle A+B. In O C take any point P, and from P let fall PN, PM, perpendiculars on O A and O B, and from M let fall M Q and M R, perpendiculars on PN and O R.

Then—

$$\text{sin. }(A+B)=\frac{PN}{QP}=\frac{QN+PQ}{OP}=\frac{QN}{OP}+\frac{PQ}{OP}$$

$$=\frac{MR}{OP}+\frac{PQ}{OP}=\frac{MR}{OM}\cdot\frac{OM}{OP}+\frac{PQ}{PM}\cdot\frac{PM}{OP}$$

Now $\frac{MR}{ON}=$ sin. A and $\frac{OM}{OP}=$ cos. B

And since PMO is a right angle, QPM = QMO = MOR,

$$\therefore\ \frac{PQ}{PM}=\frac{OR}{OM}=\text{cos. }A=\frac{PM}{OP}=\text{sin. }B\ ;$$

∴ sin. (A + B) = sin. A. cos. B + sin. B, cos. A.

17. *To prove the Formula*

Cos. (A + B) = cos. A. cos. B − sin. A, sin. B.

For as before,

$$\text{Cos. }(A+B)=\frac{ON}{OP}=\frac{OR-QM}{OP}=\frac{OR}{OP}-\frac{QM}{OP}$$

$$=\frac{OR}{OM}\cdot\frac{OM}{OP}-\frac{QM}{PM}\cdot\frac{PM}{OP}$$

Now $\frac{OR}{OM}=$ cos. A. $\frac{OM}{OP}=$ cos. B,

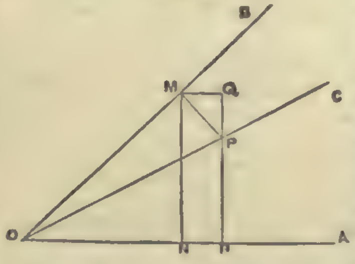
And $\frac{QM}{PM}=\frac{MR}{OM}=$ sin. A. $\frac{PM}{OP}=$ sin. B;

∴ cos. (A + B) = cos. A. cos. B − sin. A. sin. B.

18. *To prove the Formula*

Sin. (A − B) = sin. A. cos. B − sin. B. cos. A.

Fig. 13.



Let A O B = A. B O C = B. Take in O C any point P; from P draw P M and P R perpendicular to O B and O A. Draw M N and M Q perpendicular to O A and M N. Then A O C = A − B.

$$\therefore\ \text{sin. }(A-B)=\frac{PR}{OP}=\frac{QN-QP}{OP}=\frac{MR}{OP}-\frac{QP}{OP}$$

$$=\frac{MR}{OM}\cdot\frac{OM}{OP}-\frac{QP}{PM}\cdot\frac{PM}{OP}.$$

Now $\frac{MR}{OM}=$ sin. A. $\frac{OM}{OP}=$ cos. B.

Again ∠ M P Q = Q M B = B O A = A.

$$\therefore\ \frac{PQ}{MP}=\frac{QR}{OM}=\text{cos. }A.\ \frac{PM}{OP}=\text{sine }B.$$

∴ sin. (A − B) = sin. A. cos. B − sin. B. cos A.

19. *To prove the Formula*

Cos. (A − B) = cos. A. cos. B + sin. A. sin. B.

$$\text{cos. }(A-B)=\frac{ON}{OP}=\frac{OR}{OP}+\frac{MQ}{OP}=\frac{OR}{OM}\cdot\frac{OM}{OP}+\frac{MQ}{MP}\cdot\frac{MP}{OP}$$

But $\frac{OR}{OM}=$ cos. A. $\frac{OM}{OP}=$ cos. B. $\frac{MQ}{MP}=$ sin. A and $\frac{MP}{OP}=$ sin. B.

∴ cos. (A − B) = cos. A. cos. B + sin. A. sin. B.

20. *To extend the above proofs in special cases.*

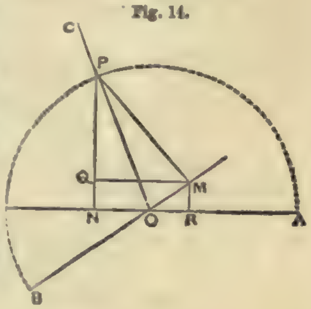
The proofs above given are clearly limited to the cases in which A, B, and A + B or A − B, are each less than 90°. They admit of extension to any case whatever. Thus—

If A is $> 180^\circ < 270^\circ$, B $> 90^\circ < 180^\circ$, and A − B $> 90^\circ < 180^\circ$.

To show that

Sin. (A − B) = sin. A cos. B − sin. B cos. A.

Fig. 14.



In this case the figure will be the following:—

A O B is the angle A, measured as indicated by the dotted circle. B O C is the angle B. ∴ C O A is the angle A − B.

From any point P in O C draw P N, P M perpendicular to O A and O B produced, and from M draw M Q, M R perpendicular P N and O A.

Then

$$\text{Sin. }(A-B)=\frac{PN}{PO}=\frac{PQ}{PO}+\frac{QN}{PO}=\frac{PQ}{PO}$$

$$+\frac{MR}{PO}=\frac{PQ}{PM}\cdot\frac{PM}{PO}+\frac{MR}{MO}\cdot\frac{POM}{PO}$$

Now $\frac{PQ}{PM}$ cos. M P Q = cos. A O M = cos. (A − 180°)

= cos. (180° − A) = − cos. A.

$\frac{PM}{PO}=$ sin. P O M = sin. (180° − B) = sin. B.

Similarly $\frac{MR}{MO}=$ sin. M O A = − sin. A

$\frac{OM}{PM}=$ cos. P O M = − cos. B;

∴ Sin. (A − B) = sin. A. cos. B − sin. B. cos. A.

In the same case,

$$\text{cos. }(A-B)=-\frac{ON}{OP}=-\frac{NR-OR}{OP}$$

$$=-\frac{QM}{OP}+\frac{OR}{OP}=-\frac{MQ}{MP}\cdot\frac{MP}{OP}+\frac{OR}{OM}\cdot\frac{OM}{OP}.$$

Now $\frac{MQ}{MP}=$ sin. MPQ = sin. MOA = − sin. A,

$\frac{MP}{OP}=$ sin. POM = sin. POB = sin. B.

$\frac{OR}{OM}=$ cos. MOA = − cos. A.

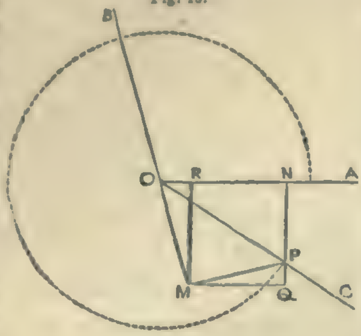
$\frac{OM}{OP}=$ cos. POM = − cos. B.

∴ cos. (A − B) = cos. A cos. B + sin. A sin. B.

Again, to show that sin. (A + B) = sin. A cos. B + sin. B cos. A.

When A + B > 270° ∠ 360°   A > 90° ∠ 180°
B > 180° ∠ 270°.

Fig. 15.



Let A O B be the angle A; B O C be the angle B. Then A O C is the angle A + B, B O C, and therefore A O C, being measured as indicated by the dotted circles. In C take any point P and draw P N, P M perpendiculars to O A and O B produced, and from M draw M R and M Q perpendiculars to O A and N P produced.

Then

$$\text{Sine }(A+B)=-\frac{PN}{OP}=\frac{PQ-QN}{OP}$$

$$=\frac{PQ}{OP}-\frac{RM}{OP}=\frac{PQ}{MP}\cdot\frac{MP}{OP}+\frac{RM}{OM}\cdot\frac{OM}{OP}$$

$$\text{Now }\frac{PQ}{OM}=\cos.\ MPQ=\cos POA=-\cos A.$$

$$\frac{MP}{OP}=\sin.\ POM=-\sin.\ B.$$

$$\frac{RM}{OM}=\sin.\ AOM=\sin.\ A.$$

$$\frac{OM}{OP}=\cos.\ POM=-\cos.\ B.$$

$$\therefore \sin.\ (A+B)=\sin.\ A.\cos.\ B+\sin.\ B.\cos.\ A.$$

The student may verify for practice the formulas in the following cases :—

Sin. (A + B) A ⁊ 90° ∠ 180° A + B ⁊ 180° B ⁊ 90°
Cos. (A − B) A ⁊ 90° ∠ 180° A + B ∠ 90° B ⁊ 90°
Cos. (A + B) A ⁊ 180° ∠ 270° A + B ⁊ 360° ∠ 450°
B ⁊ 90° ∠ 180°

21. *The principle on which the proof may be considered as established generally.*

The above examples will be sufficient to satisfy the reader that the four formulas above given hold good for all angles whatever. It is worth while to observe, however, that, independently of these examples, this follows from the circumstance that the extension given above to the definitions of angular magnitude, and of the trigonometric ratios, are made in strict accordance with the extension given to the meaning of the negative sign in algebra. Thus, $a-b$ primarily signifies that the number b is to be subtracted from the number a; if therefore b be greater than a, $a-b$ is impossible, unless we generalise the definition of the negative sign. If we do this so as to render $a-b$ susceptible of meaning for all values of a and b, then whatever theorem we prove to be true of $a-b$, and its combinations with the restriction, will be equally true of $a-b$, and its combinations without the restriction.

In like manner, if we prove a trigonometrical formula to hold good for all geometrical angles, these will equally hold good of the angles when defined according to the trigonometrical conception of an angle explained above. The principle which we have to guide us in all these generalisations, is called "The Principle of the Permanence of Equivalent Forms," and is that which lies at the root of all extensions of merely Arithmetical Algebra, as explained in the treatise on Logarithms and Series. (See Chapter VI., p. 512, in this section). The reader who wishes to see a full account of the application of this principle to Trigonometry, will do well to consult Dr. Peacock's *Algebra*, vol. ii., p. 144, &c., 2nd edition.

22. *Relation between the Four Fundamental Formulas.*

It is to be observed that the last three of the four formulas given above can be derived from the first of them.

Thus, $\sin.\ (A+B)=\sin.\ A\cos.\ B+\sin.\ B\cos.\ A.$
For B write $-B$. Now $\sin.\ (-B)=-\sin.\ B.$
And $\cos.\ (-B)=-\cos.\ B.$

$$\therefore \sin.\ (A-B)=\sin.\ A\cos.\ B-\sin.\ B\cos.\ A.$$

Again

$$\begin{aligned}\cos.\ (A+B)&=\sin.\ (90^\circ-A-B)\\&=\sin.\ (90^\circ-A)\cos.\ B-\sin.\ B\cos.\ (90^\circ-A)\\&=\cos.\ A\cos.\ B-\sin.\ A\sin.\ B.\end{aligned}$$

Again

$$\begin{aligned}(\text{Cos. }(A-B)&=\sin.\ (\overline{90^\circ-A}+B)\\&=\sin.\ (90^\circ-A)\cos.\ B+\cos.\ (90^\circ-A)\\&=\cos.\ A\cos.\ B+\sin.\ A\sin.\ B.\end{aligned}$$

23. *Formulas derived from the Fundamental ones.*

From these four the following formulas of frequent occurrence can easily be derived :—

$$\text{Sin. }A\cos.\ B+\sin.\ B\cos.\ A=\sin.\ (A+B)$$

$$\text{Sin. }A\cos.\ B-\sin.\ B\cos.\ A=\sin.\ (A-B).$$

∴ adding $2\sin.\ A\cos.\ B=\sin.\ (A+B)+\sin.\ (A-B)$; and subtracting $2\cos.\ A\sin.\ B=\sin.\ (A+B)-\sin.\ (A-B)$.

Similarly,

$$2\sin.\ A\sin.\ B=\cos.\ (A-B)-\cos.\ (A+B)\ldots.\quad(12)$$

$$2\cos.\ A\cos.\ B=\cos.\ (A-B)+\cos.\ (A+B)\ldots.\quad(13)$$

The same formulas are of frequent occurrence in a different form. Evidently

$$\theta=\frac{\theta+\phi}{2}+\frac{\theta-\phi}{2}$$

$$\phi=\frac{\theta+\phi}{2}-\frac{\theta-\phi}{2}$$

$$\therefore \sin.\ \theta=\sin.\frac{\theta+\phi}{2}\cos.\frac{\theta-\phi}{2}+\sin.\frac{\theta-\phi}{2}\cos.\frac{\theta+\phi}{2}$$

$$\sin.\ \phi=\sin.\frac{\theta+\phi}{2}\cos.\frac{\theta-\phi}{2}-\sin.\frac{\theta-\phi}{2}\cos.\frac{\theta+\phi}{2}$$

$$\therefore \sin.\ \theta+\sin.\ \phi=2\sin.\frac{\theta+\phi}{2}\cdot\cos.\frac{\theta-\phi}{2}\quad\ldots.(14).$$

$$\sin.\ \theta-\sin.\ \phi=2\cos.\frac{\theta+\phi}{2}\cdot\sin.\frac{\theta-\phi}{2}\quad\ldots.(15).$$

Similarly,

$$\text{Cos. }\theta+\cos.\ \phi=2\cos.\frac{\theta+\phi}{2}\cdot\cos.\frac{\theta-\phi}{2}\quad\ldots.(16).$$

$$\text{Cos. }\phi-\cos.\ \theta=2\sin.\frac{\theta+\phi}{2}\cdot\cos.\frac{\theta-\phi}{2}\quad\ldots.(17).$$

24. *Formula for the Tangent of the Sum of Two Angles.*

Again, we can easily derive from the formulas for the sines and cosines of A + B and A — B, expressions for the tangents of A + B and A − B. Thus,

$$\text{Tan. }(A+B)=\frac{\sin.\ (A+B)}{\cos.\ (A+B)}$$

$$=\frac{\sin.\ A\cos.\ B+\sin.\ B\cos.\ A}{\cos.\ A\cos.\ B-\sin.\ A\sin.\ B}$$

Divide both numerator of this fraction by cos. A cos. B.

$$\therefore \tan.\ (A+B)=\frac{\dfrac{\sin.\ A\cos.\ B}{\cos.\ A\cos.\ B}+\dfrac{\sin.\ B\cos.\ A}{\cos.\ B\cos.\ A}}{\dfrac{\cos.\ A\cos.\ B}{\cos.\ A\cos.\ B}-\dfrac{\sin.\ A\sin.\ B}{\cos.\ A\cos.\ B}}$$

$$=\frac{\dfrac{\sin.\ A}{\cos.\ A}+\dfrac{\sin.\ B}{\cos.\ B}}{1-\dfrac{\sin.\ A\sin.\ B}{\cos.\ A\cos.\ B}}=\frac{\tan.\ A+\tan.\ B}{1-\tan.\ A\tan.\ B}\quad\ldots.(18).$$

Similarly,

$$\text{Tan. }(A-B)=\frac{\tan.\ A-\tan.\ B}{1-\tan.\ A\tan.\ D}\quad\ldots.(19).$$

25. *Expressions in which the Sum of Three Angles occur.*

We can easily derive from the above, expressions for the sines, cosines, &c., of the sum of three or more angles. Thus,

$\text{Sin. }(A+B+C)=\sin.\ (A+B)\cos.\ C+\cos.\ (A+B)\sin.\ C=(\sin.\ A\cos.\ B+\sin.\ B\cos.\ A)\cos.\ C+(\cos.\ A\cos.\ B-\sin.\ A\sin.\ B),\sin.\ C=\sin.\ A\cos.\ B\cos.\ C+\sin.\ B\cos.\ C\cos.\ A+\sin.\ C\cos.\ A\cos.\ B-\sin.\ A\sin.\ B\sin.\ C.$

In the same manner,

Cos. (A + B + C) = cos. A cos. B cos. C — cos. A sin. B. sin. C — cos. B sin. C sin. A — cos. C sin. A sin. B.

And hence,

$$\text{Tan. }(A+B+C) = \frac{\text{tan. }A + \text{tan. }B + \text{tan }C - \text{tan. }A\text{ tan. }B\text{ tan. }C}{1 - \text{tan. }B\text{ tan. }C - \text{tan. }C\text{ tan. }A - \text{tan. }A\text{ tan. }B.}$$

26. *Certain other Formulas.*

Again, since—

$$\text{Sin. }\theta + \text{sin. }\phi = 2\text{ sin.}\frac{\theta+\phi}{2}\cdot\text{ cos. }\frac{\theta-\phi}{2}.$$

$$\text{Sin. }\theta - \text{sin. }\phi = 2\text{ cos.}\frac{\theta+\phi}{2}\cdot\text{sin.}\frac{\theta-\phi}{2}.$$

$$\therefore\ \frac{\text{Sin. }\theta + \text{sin. }\phi}{\text{Sin. }\theta + \text{sin. }\phi} = \frac{\text{sin. }\frac{\theta+\phi}{2}}{\text{cos. }\frac{\theta+\phi}{2}}\cdot\frac{\text{cos. }\frac{\theta-\phi}{2}.}{\text{sin. }\frac{\theta-\phi}{2}.}$$

$$= \text{tan. }\frac{\theta+\phi}{2}\cdot\text{ cotan. }\frac{\theta-\phi}{2}\ldots\ldots(20).$$

In like manner,

$$\frac{\text{Cos. }\phi - \text{cos. }\theta}{\text{Cos. }\phi + \text{cos. }\theta} = \text{tan. }\frac{\theta+\phi}{2}\text{tan.}\frac{\theta-\phi}{2}\ldots\ldots(21).$$

There are many similar combinations of the trigonometric ratios besides those above given. These are of very frequent occurrence, and the student who has thoroughly mastered the above will be at no loss in investigating other combinations that may occur in his subsequent reading.

27. *The Sines, Cosines, &c., of Multiples of given Angles.*

We have already seen that

Sin. (A + B) = sin. A, cos. B + sin. B, cos. A.

This being true of all values of A and B is true when A = B, and ∴ when A + B = 2A.

$$\therefore\ \text{Sin. }2A = 2\text{ sin. }A,\text{ cos. }A\ \ldots\ (22).$$

Similarly, since

$$\text{Cos. }(A+B) = \text{cos. }A,\text{ cos. }B - \text{sin. }A,\text{ sin. }B.$$

$$\therefore\ \text{Cos. }2A = \text{cos.}^2A - \text{sin.}^2A.\ \ldots\ldots\ (23).$$

$$\text{Now, }1 = \text{cos.}^2A + \text{sin.}^2A.$$

Add this equation to (23), and we obtain

$$\text{Cos. }2A = 2\text{ cos.}^2A - 1.$$

$$\text{And Cos. }2A = 1 - 2\text{ sin.}^2A.$$

Similarly,

$$\text{Tan. }2A = \frac{2\text{ tan. }A}{1-\text{tan.}^2A}\ldots\ldots\ (24)$$

Again,

$$\begin{aligned}\text{Sin. }3A &= \text{sin. }(2A + A).\\ &= \text{sin. }2A,\text{ cos. }A + \text{cos. }2A,\text{ sin. }A\\ &= 2\text{ sin }A,\text{ cos. }A,\text{cos.}A + (\text{Cos.}^2A - \text{sin.}^2A)\text{sin. }A.\\ &+ 3\text{ sin. }A,\text{ cos}^2A - \text{sin.}^3A.\\ &= 3\text{ sin. }A - 4\text{ sin. }^3A.\ \ldots\ldots\ (25).\end{aligned}$$

Similarly,

$$\text{Cos. }3A = 3\text{ Cos. }A + 4\text{ cos.}^3A.\ \ldots\ldots\ (26),$$

and

$$\text{Tan. }3A = \frac{3\text{ tan. }A - \text{tan.}^3A}{1-3\text{ tan.}^2A}\ldots\ldots\ (27).$$

28. *Determination of Sine, &c., of an Angle in terms of the Sine, &c., of the Sub-multiples of that Angle.*

From these expressions we may derive others expressing the sines, &c., of an angle in terms of the sines, &c. of the submultiples of that angle. Thus, writing $\frac{\theta}{2}$ for A, we have

$$\text{From (22)}\quad \text{Sin. }\theta = 2\text{ sin.}\frac{\theta}{2}\text{ cos. }\frac{\theta}{2}.$$

$$\text{From (23)}\quad \text{Cos. }\theta = \text{cos.}^2\frac{\theta}{2} - \text{sin.}^2\frac{\theta}{2}$$

$$= 1 - 2\text{ sin.}^2\frac{\theta}{2}$$

$$= 2\text{ cos.}^2\frac{\theta}{2} - 1.$$

$$\text{From (24)}\quad \text{Tan. }\theta = \frac{2\text{ tan.}\frac{\theta}{2}}{1-\text{tan.}^2\frac{\theta}{2}}.$$

And writing ϕ for $\frac{A}{3}$ we have

$$\text{From (25)}\quad \text{Sin. }\phi = 3\text{ sin. }\frac{\phi}{3} - 4\text{ sin.}^3\frac{\phi}{3}.$$

$$\text{From (26)}\ \text{Cos. }\phi = -3\text{ cos. }\frac{\phi}{3} + 4\text{ cos.}^3\frac{\phi}{3}$$

$$\text{From (27)}\quad \text{Tan. }\phi = \frac{3\text{ tan. }\frac{\phi}{3} - \text{tan.}^3\frac{\phi}{3}}{1-3\text{ tan.}^2\frac{\phi}{3}}$$

29. *On the "Ambiguities" resulting from the use of the above Formulas.*

These formulas enable us to solve the following question :—Having given the sine, &c., of an angle, we can find from it the sine, &c., of double that angle ; and conversely having given the sine, &c., of an angle, we can find the sine, &c., of half that angle.

(*a*). Thus, having given sin. A = p, to find cos. 2 A, we have

$$\text{Cos. }2A = 1 - 2\text{ sin.}^2A = 1 - 2p^2$$

and so, having given sin. A = p to find sin. 2 A.

Since sin. A = p cos. A = $\sqrt{1-p^2}$

$\therefore$ sin. 2 A = $\pm 2p\sqrt{1-p^2}$.

It will be seen, from the above formulas, that for one given value (p) of sin. A, there is one value of cos. 2 A, while there are two of sine 2 A equal in magnitude, but of different signs. This is sometimes spoken of as an ambiguity. It will be observed, however, that the ambiguity in the determination of sin. 2 A arises necessarily from the data, since it appears by considering the values of A which satisfy the equation.

$$\text{Sin. }A = p,$$

that there will be one value of cos. 2 A and two values of sin. 2 A resulting from the data. Thus, if A^1 be one angle which satisties the equation, then all the values of A are included in the two formulas.

$$A = 2m\,180^\circ + A^1$$
$$\text{and }A = (2m+1)\,180^\circ + A^1$$

m being any integer whatever ;

$$\therefore\ \text{cos. }2A = \text{cos. }(2m\,360^1 + 2A') = \text{cos. }2A^1,$$
$$\text{or} = \text{cos. }(2m+1)\,360^\circ - 2A^1) = \text{cos. }2A^1$$

Under all circumstances, therefore,

$$\text{Cos. }2A = \text{cos. }2A^1,$$

and therefore has but one value. Whereas

$$\text{Sin. }2A = \text{sin. }(2m\,360^1 + 2A^1) = \text{sin. }2A^1.$$
$$\text{or} = \text{sin. }\{(\overline{2m+1})\,360^\circ - 2A^1)\} = -\text{sin. }2A^1.$$

$\therefore$ sin. 2 A has the two values + sin. 2 A^1 and −1 sin. 2 A^1.

If, however, we know A, or even the limits between which A lies, as well as that sin. A = p, then all indeterminateness vanishes from the expression for sin. 2 A. Thus, if A be less than 90°, then 2 A is $\angle$ 180° and sin° 2 A must be positive. And, again, if A $\not>$ 90° $\angle$ 180°, then 2 A $\not>$ 180° $\angle$ 360°, and the sin. 2 A is negative in the former case ; therefore,

$$\text{Sin. }2A = 2p\sqrt{1-p^2}.$$

In the latter,

$$\text{Sin. }2A = -2p\sqrt{-1p^2}.$$

(*b*). Again, we have

$$\text{Cos. } \theta = 1 - 2 \text{ sin. } \frac{{}^2\theta}{2} = 2 \text{ cos. } \frac{{}^2\theta}{2} - 1.$$

$$\therefore \text{sin. } \frac{\theta}{2} = \sqrt{\frac{1 - \text{cos. } \theta}{2}}$$

$$\text{Cos. } \frac{\theta}{2} = \sqrt{\frac{1 + \text{cos. } \theta}{2}}$$

Hence it appears that for a given value of cos. θ there will be two values of sin. $\frac{\theta}{2}$, likewise two values of cos. $\frac{\theta}{2}$ equal in magnitude, but with different signs. This is, as before, necessarily the case, if we only know the value of cos. θ. For if we have a given value p of cos. θ, so that

$$\text{Cos. } \theta = p,$$

and if θ^1 be a value of θ which satisfies this equation, then all the values of θ, which satisfy this equation, are expressed by,

$$\theta = m\,(360^\circ \pm \theta^1).$$

$$\therefore \text{sin. } \frac{\theta}{2} = \text{sin. } (m\ 180^\circ \pm \frac{\theta^1}{2})$$

$$\text{which} = \pm \text{ sin. } \frac{\theta^1}{2} \text{ if } m \text{ be even,}$$

$$\text{or, } \mp \text{ sin. } \frac{\theta^1}{2} \text{ if } m \text{ be odd,}$$

under any circumstances; therefore there must be two values of sin. $\frac{\theta}{2}$ equal in magnitude, but with different signs; the same result as that we obtained from the equations for sin. $\frac{\theta}{2}$ and cos. $\frac{\theta}{2}$

(*c*). Again, we have given sin. θ to find sin. $\frac{\theta}{2}$ and cos. $\frac{\theta}{2}$

We have—

$$\text{sin. }^2 \frac{\theta}{2} + \text{cos. }^2 \frac{\theta}{2} = 1$$

$$2 \text{ sin. } \frac{\theta}{2} \text{ cos. } \frac{\theta}{2} = \text{sin. } \theta$$

Adding these equations we obtain,

$$\text{sin. }^2 \frac{\theta}{2} + 2 \text{ sin. } \frac{\theta}{2} \text{ cos. } \frac{\theta}{2} + \text{cos. }^2 \frac{\theta}{2} = 1 + \text{sin. } \theta$$

And, subtracting the second from the first,

$$\text{sin. }^2 \frac{\theta}{2} - 2 \text{ sin. } \frac{\theta}{2} \text{ cos. } \frac{\theta}{2} + \text{cos. }^2 \frac{\theta}{2} = 1 - \text{sin. } \theta$$

Extracting the square root of each of these equations, and we have—

$$\text{sin. } \frac{\theta}{2} + \text{cos. } \frac{\theta}{2} = \sqrt{1 + \text{sin.}}$$

$$\text{sin. } \frac{\theta}{2} - \text{cos. } \frac{\theta}{2} = \sqrt{1 - \text{sin. } \theta}$$

$\therefore$ Adding—

$$2 \text{ sin. } \frac{\theta}{2} = \sqrt{1 + \text{sin. } \theta} + \sqrt{1 - \text{sin. } \theta}$$

and subtracting—

$$2 \text{ cos. } \frac{\theta}{2} = \sqrt{1 + \text{sin. } \theta} - \sqrt{1 - \text{sin. } \theta}$$

$$\therefore \text{sin. } \frac{\theta}{2} = \tfrac{1}{2} \left\{ \sqrt{1 + \text{sin. } \theta} + \sqrt{1 - \text{sin. } \theta} \right\}$$

$$\text{and cos. } \frac{\theta}{2} = \tfrac{1}{2} \left\{ \sqrt{1 + \text{sin. } \theta} - \sqrt{1 - \text{sin. } \theta} \right\}$$

And since each square root has two sines, it follows that if we have given merely the value of sin. θ, *i. e.*, sin. $\theta = p$. we have *four* different values of sin. $\frac{\theta}{2}$ viz. $\tfrac{1}{2}(\sqrt{1+p.} + \sqrt{1-p.})$, $\tfrac{1}{2}(\sqrt{1+p.} - \sqrt{1-p.})$ $\tfrac{1}{2}(-\sqrt{1+p.} + \sqrt{1-p.})$, and $\tfrac{1}{2}(-\sqrt{1+p.} - \sqrt{1-p.})$

We may prove, as before, that this amount of indeterminateness is involved in the data: for if

$$\text{sin. } \theta = p,$$

and if θ' be a value of θ. which satisfies this equation, then all the values of θ which satisfy the equation, are given by the formulas.

$$\theta = 2\,m.\ 180^\circ + \theta$$
$$\text{and } \theta = (2\,m. + 1)\ 180^\circ - \theta'$$

where m is any whole number whatever.

$\therefore$ sin. $\frac{\theta}{2}$ may be either one of the two forms, as follows:—

Sin. $(m.180^\circ + \frac{\theta^\circ}{2})$ or sin. $(m.\ 180^\circ + 90 - \frac{\theta'}{2})$ or according as m is odd or even, *i. e.*, according as m is $2\,n$ or $2\,n + 1$.

One of the four—

$$\text{Sin. } (2\,n.\ 180^\circ + \frac{\theta'}{2}) \text{ sin. } (\overline{2\,n + 1.}\ 180^\circ + \frac{\theta'}{2})$$

$$\text{Sin. } (2\,n.\ 180^\circ + 90 - \frac{\theta'}{2}) \text{ or sin. } \overline{(2\,n + 1.}\ 180^\circ$$
$$+\ 90^\circ - \frac{\theta'}{2})$$

And these are respectively equal to

$$\text{Sin. } \frac{\theta'}{2},\ -\text{sin. } \frac{\theta'}{2},\ \text{cos. } \frac{\theta'}{2}, \text{ and } -\text{cos. } \frac{\theta'}{2}.$$

i. e., it may have one of the four different values—

$$\text{Sin. } \frac{\theta}{2},\ -\text{sin. } \frac{\theta'}{2}, \text{cos. } \frac{\theta'}{2},\ -\text{cos. } \frac{\theta'}{2}.$$

If, however, we know the limits within which the value of θ lies, this indeterminateness vanishes. Thus, if $\theta \urcorner 90^\circ \angle 180^\circ$, then $\frac{\theta}{2} \urcorner 45^\circ \angle 90^\circ$, and therefore sin. $\frac{\theta}{2}$ must be $\urcorner \frac{1}{\sqrt{2}} \angle 1$. and be positive. Hence, in this case,

$$\text{Sin. } \frac{\theta}{2} = \frac{1}{2} \{+\sqrt{1 + \text{sin. } \theta} + \sqrt{1 - \text{sin. } \theta}\}.$$

$$\text{For when } \theta = 90 \text{ this gives sin. } \frac{\theta}{2} = \frac{1}{\sqrt{2}}$$

$$\theta = 180 - \text{sin. } \frac{\theta}{2} = 1.$$

and between these limits the value of the formula continually increases.

If, however, $\theta \urcorner 270^\circ \angle 360^\circ$, we have

$$\text{Sin. } \frac{\theta}{2} = \frac{1}{2} \{-\sqrt{1 + \text{sin. } \theta} + \sqrt{1 - \text{sin. } \theta}\}.$$

The student will do well to verify this for himself.

The same kind of reasoning applies to the formula for cos. $\frac{\theta}{2}$.

(*d*). Again the formula

$$\text{Tan. } \theta = \frac{2 \text{ tan. } \frac{\theta}{2}}{1 - \text{tan}^2 \frac{\theta}{2}}$$

enables us to determine tan. $\frac{\theta}{2}$ when tan. θ is given. For we can easily put the equation into the form

$$\text{Tan. }^2 \frac{\theta}{2} + \frac{2}{\text{tan. } \theta}.\ \text{tan. } \frac{\theta}{2} = 1.$$

$$\therefore \text{ tan. } \frac{\theta}{2} + \frac{1}{\text{tan. } \theta} = \pm \frac{\sqrt{1 + \text{tan.}^2}}{\text{tan. } \theta}.\ \text{tan. } \frac{\theta}{2}$$

$$= \frac{1 \pm \sqrt{1 + \text{tan.}^2 \theta}}{\text{tan. } \theta}$$

It will be observed that for one value of tan. θ we have two values of tan. $\frac{\theta}{2}$. The ambiguity is involved in the data in this case as in others. For if

$$\tan.\ \theta = p.$$

then θ' being one value of θ, all the values of θ are included in the formula

$$\theta = m.\ 180^\circ + \theta'.$$

$\therefore$ according as m is odd or even, *i. e.*, according as m is equal to $2n$ or $2n+1$,

$$\frac{\theta}{2} = n\,180^\circ + \frac{\theta'}{2}$$

$$\text{or} \frac{\theta}{2} = n.\ 180^\circ + 90^\circ + \frac{\theta'}{2}$$

That is,

$$\text{Tan.}\ \frac{\theta}{2} = \tan.\ n\,180^\circ + \frac{\theta'}{2}$$

$$\text{or,} \qquad \tan.\ (n\,180^\circ + 90^\circ + \frac{\theta'}{2})$$

according as m is odd or even; and therefore

$$\tan.\ \frac{\theta'}{2} = \tan.\ \frac{\theta'}{2} \text{ or } \tan.\ (90^\circ + \frac{\theta'}{2})$$

$$= \tan.\ \frac{\theta'}{2} \text{ or} - \text{cotan.}\ \frac{\theta'}{2}$$

Two different values, as also appeared from the formula.

30. *On the Numerical Value of the Sines, Cosines, &c., of the Angles* 15°, 30°, 45°, 60°, 75°.

We have already investigated the value of the trigonometrical ratios of 45°, 30°, and 60°. By the aid of the above formulas we can investigate the values of many others. For example, of 15° and of 18°.

Sin. 15° = sin. (45° − 30°) = sin. 45° cos. 30° − sin. 30°, cos. 45°.

$$= \frac{1}{\sqrt{2}} \cdot \frac{\sqrt{3}}{2} - \frac{1}{2} \cdot \frac{1}{\sqrt{2}}$$

$$= \frac{\sqrt{3}-1}{2\sqrt{2}} \text{ which also equals cos. } 75^\circ,$$

since 75° = 90° − 15°.

Cos. 15° = cos. (45° − 30°) = cos. 45° cos. 30° + sin. 45° sin. 30°

$$= \frac{1}{\sqrt{2}} \cdot \frac{\sqrt{3}}{2} + \frac{1}{\sqrt{2}} \cdot \frac{1}{2} = \frac{\sqrt{3}+1}{2\sqrt{2}} = \sin.\ 75^\circ$$

Hence—

$$\text{Tan.}\ 15^\circ = \frac{\sqrt{3}-1}{\sqrt{3}+1} = \text{cotan.}\ 75^\circ$$

$$\text{Cotan.}\ 15^\circ = \frac{\sqrt{3}+1}{\sqrt{3}-1}. = \tan.\ 75^\circ$$

$$\text{Sec.}\ 15^\circ = \frac{2\sqrt{2}}{\sqrt{3}+1}. = \text{cosec.}\ 75^\circ$$

$$\text{Cosec.}\ 15^\circ = \frac{\sqrt{3}+1}{2\sqrt{2}}. = \text{sec.}\ 75^\circ$$

The student will observe that this investigation of the ratios of an angle of 15°, together with those previously investigated, gives the ratios of the series of angles 15°, 30°, 45°, 60°, 75°, 90°.

31. *To investigate the Trigonometrical Ratios of an Angle of* 18°, 36°, 54°, 72°.

Since $\qquad 54^\circ = 90^\circ - 36^\circ,$

if we write θ for 18°, we have

$$3\theta = 90^\circ - 2\theta,$$

and therefore

$$\text{Cos.}\ 3\theta = \sin.\ 2\theta.$$

$$\therefore\ 4\,\text{Cos.}^3\theta - 3\cos.\ \theta = 2\sin.\ \theta,\ \cos.\ \theta.$$

$$\therefore\ 4\,\text{Cos.}^2\theta - 3\cos.\ \theta = 2\sin.\ \theta.$$

$$\therefore 1 - 4\sin.^2\theta = 2\sin.\ \theta.$$

$$4\,\text{Sin.}^2\theta + 2\sin.\ \theta = 1.$$

$$\therefore 4\,\text{Sin.}^2\theta + 2\sin.\ \theta + \frac{1}{4} = \frac{5}{4}.$$

$$\therefore 2\,\text{Sin.}\ \theta = \frac{-1 \pm \sqrt{5}}{2}.$$

$$\text{Sin.}\ \theta = \frac{-1 \pm \sqrt{5}}{4}.$$

This is a case of ambiguity similar to those above explained, and if we only had the equation

$$4\,\text{Sin.}^2\theta + 2\sin.\ \theta = 1,$$

we should have the two values of sin. θ just given, viz.,

$$\frac{-1+\sqrt{5}}{4} \text{ and } \frac{-1-\sqrt{5}}{4}.$$

But as we not only have the equation, but also know that $\theta = 18^\circ$, this enables us to choose the only admissible value.

$$\text{Sin.}\ 18^\circ = \frac{-1+\sqrt{5}}{4}.$$

For the other value of sin. θ being negative cannot be the sine of 18°. Hence,

$$\text{Cos.}^2 18^\circ = 1 - \sin.^2 18^\circ =$$

$$1 - \frac{3-1\sqrt{5}}{8} = \frac{5+\sqrt{5}}{8}$$

$$\therefore \cos.\ 18^\circ = \frac{\sqrt{10+2\sqrt{5}}}{4}.$$

$$\text{Hence, } \sin.\ 36^\circ = \sin.\ 2 \times 18^\circ = \frac{(\sqrt{5}-1)\sqrt{2\sqrt{5}+10}}{8}$$

$$\text{and } \cos.\ 36^\circ = \frac{\sqrt{5}+1}{4}.$$

and sin. 36° = cos. 54°, and sin. 18° = cos. 72°.

Hence we evidently can obtain the trig. ratios of the angles 18°, 36°, 54°, 72°.

Again

$$\text{Sin.}\ 3^\circ = (18^\circ - 15^\circ.)$$

$$= \sin.\ 18^\circ \cos.\ 15^\circ - \cos.\ 18^\circ \sin.\ 15^\circ.$$

$$= \frac{\sqrt{5}-1}{4} \times \frac{\sqrt{3}+1}{2\sqrt{2}} - \frac{\sqrt{10+2\sqrt{5}}}{4}\,\frac{\sqrt{3}-1}{2\sqrt{2}}$$

$$= \frac{(\sqrt{15}-1)(\sqrt{3}+1) - (\sqrt{3}-1)\sqrt{10+2\sqrt{5}}}{8\sqrt{2}}.$$

Hence we may clearly obtain numerical values for the trigonometrical ratios of the series of degrees, 3°, 6°, 9°, 12°, 15°, &c.

N.B.—In reading the preceding pages the student will have observed, that in many instances, when a method of reasoning has been applied to one case, it has been merely indicated that the same method is applicable to a similar case. In all these instances he will do well to *write out at full length* the reasoning in these similar cases. By this means he will ensure a thorough comprehension of this part of the subject, and become familiar with the various combinations that trigonometric ratios can form. In regard to this very subject, Dr. Peacock observes:—"It should be the first lesson of a student, in every branch of science, not to form his own estimate of the importance of elementary views and propositions, which are very frequently repulsive or uninteresting, and such as cannot be thoroughly mastered and remembered without a great sacrifice of time and labour." To assist in obtaining this familiarity he may perform the following exercises:—

(1). $\frac{1}{2} + \cos.\ 2\,A = 2\sin.\ (60^\circ - A)\sin.\ (60^\circ + A.)$
(Remember that cos. 120° = $-\frac{1}{2}$.)

(2). $4\cos.\ m\,\theta\cos.\ n\,\theta\cos.\ r\,\theta = \cos.\ (m+n+r)\,\theta + \cos.\ (m+n-r)\,\theta + \cos.\ (m-n+r)\,\theta + \cos.\ (m-n+r)\,\theta$
(Remember that cos. (A + B) + cos. (A − B) = 2 cos. A cos. B

(3). $4\sin.^2\theta\cos.\ \theta = \cos.\ \theta\cos.\ 3\,\theta.$

(4). $\text{Tan.}\ A + \tan.\ B = \frac{\sin.\ (A+B)}{\cos.\ A\cos.\ B}$

$$\left(\text{Remember that tan. A} = \frac{\text{sin. A}}{\text{cos. A}}\right).$$

(5). $\text{Tan. }^2\text{A} - \text{tan. }^2\text{B} = \dfrac{\text{sin. (A + B) sin. (A − B)}}{\text{cos. }^2\text{A cos. }^2\text{B.}}$

(Remember that $\text{tan. }^2\text{A} - \text{tan. }^2\text{B} = (\text{tan. A} + \text{tan. B})(\text{tan. A} - \text{tan. B.})$)

(6). If $\dfrac{m \text{ sin. } \beta}{n \text{ sin. } a} = \dfrac{\text{cos. } (\text{B} + x)}{\text{cos. } (a - x)}$ then

$$\text{Tan. } x = \frac{n \text{ cotan. } \beta - m \text{ cotan. } a}{n + m.}$$

(7). If $\theta + \phi + \psi = 90^\circ$ show that

(a) $\text{Tan. } \phi \text{ tan. } \psi + \text{tan. } \psi \text{ tan. } \theta + \text{tan. } \theta \text{ tan. } \phi = 1.$

(b) $\text{Tan. } \theta + \text{tan. } \phi + \text{tan. } \psi = \text{tan. } \theta + \text{tan. } \phi \text{ tan. } \psi + \text{sec. } \theta \text{ sec. } \phi \text{ sec. } \psi$

(Remember that $\text{sin. } (\theta + \phi + \psi) = 1.$
and $\text{cos. } (\theta + \phi + \psi) = 0.$

(8). If $\dfrac{m \text{ tan. } (a - x)}{\text{cos. }^2 x} = \dfrac{n \text{ tan. } x}{\text{cos. }^2 (a - x)}$

Then, $\dfrac{\text{sin. } (2a - 2x)}{\text{sin. } 2x} = \dfrac{n}{m}.$

$$\text{and tan. } (a - 2x) = \frac{n - m}{n + m} \text{ tan. } a.$$

(9). If $\text{tan. A} + 3 \text{ cos. A} = 4$, show that A has two series of values, one of which is 45°, 225°, 405°, 585°, √. . . (i. e., tan. A = 1).

(10). If $\text{cos. } n\text{A} + \text{cos. } (n - 2) \text{ A} = \text{cos. A}$, show that A must have the values

$$\frac{30^\circ}{n - 1} \cdot \frac{330^\circ}{n - 1} \cdot \frac{390^\circ}{n - 1} \cdot \frac{690^\circ}{n - 1} \cdot \frac{750^\circ}{n - 1} \cdots$$

(11). If $\text{sin. } (x + a) + \text{cos. } (x + a) = \text{sin. } (x - a) + \text{cos. } (x - a)$, then x must be 45°, 225°, 405°. . . . .

(12). If $\text{sin. A} + \text{sin. } (\theta - \text{A}) + \text{sin. } (2\theta + \text{A}) = \text{sin. } (\theta + \text{A}) + \text{sin. } (2\theta - \text{A.})$

(13). If $2 \text{ sin. } (\theta - \phi) = 1$, and $\text{sin. } (\theta - \phi) = \text{cos. } (\theta + \phi)$, then we shall have $\theta = 45^\circ$, $\phi = 15^\circ$.

(14). If $\text{Tan. } \theta = \text{tan.}^3 \dfrac{\phi}{2}$ and $\text{cos. }^2\phi = \dfrac{m^2 - 1}{3}.$

$$\text{Then } \frac{m^2 - 1}{3} = \left(\frac{\text{cos. } \frac{2}{3}\theta - \text{sin. } \frac{2}{3}\theta}{\text{cos. } \frac{2}{3}\theta + \text{sin. } \frac{2}{3}\theta}\right)^2.$$

(15). If $\text{sin.}^2 2\theta - \text{sin.}^2\theta = \frac{1}{4}.$

Show that $\text{sin. } \theta = \pm \dfrac{1 + \sqrt{5}}{4}$, and show that the values of θ are given by the series,

$$\begin{array}{llll} 18^\circ & 162^\circ & 378^\circ & 528^\circ \ldots\ldots \\ 54^\circ & 126^\circ & 416^\circ & 486^\circ \ldots\ldots \\ 198^\circ & 342^\circ & 558^\circ & 702^\circ \ldots\ldots \\ 234^\circ & 306^\circ & 594^\circ & 666^\circ \ldots\ldots \end{array}$$

(16). Show that the series of angles in No. 9 can be expressed by the formula $m.\ 180^\circ + 45^\circ$.

In No. 10, by the formula, $\dfrac{m.\ 360^\circ \pm 30^\circ}{n - 1}.$

In No. 11, by the formula, $m.\ 180^\circ + 45^\circ$.
In No. 15, by the formulas, $m.\ 180^\circ \pm 18^\circ$.
$m.\ 180^\circ \pm 54^\circ$.

31. *On Inverse Trigonometrical Ratios Explanatory.*

The following notation, which is part of a general system of notation originally proposed by Sir J. Herschel, is very generally adopted, and is very convenient:—

If $\text{tan. } \theta = p$.

Then $\theta = \text{tan. }^{-1} p$.

i e., $\text{tan. }^{-1} p$. means the angle whose tangent is p. In like manner $\text{sin. }^{-1} p$ means the angle whose sine is p, and $\text{cos. }^{-1} p$ the angle whose cosine is p.

The system of notation originally proposed was the following :—If $\text{sin. } \theta = p$ and θ an angle, the arc subtending which, divided by radius, is equal to p; then, sin. θ is the sin. of p, and therefore $\text{sin. } \theta, = \text{sin. } (\text{sin. } \theta)$, and Sir J. Herschel proposed to write

$$\text{Sin. } (\text{sin. } \theta) = (\text{sin. }^2\theta),$$

reserving the notation $(\text{sin. A})^2$ for the squares of the sin. of θ. Upon this principle,

$$\text{Sin. } (\text{sin. } (\text{sin.. } (\ldots \text{ sin. } \theta))) = \text{sin}^n \theta,$$

and evidently

$$\text{sin.}^n (\text{sin.}^m \theta) = \text{sin.}^{n+m} \theta$$

or the notation follows the law of indices,* and the interpretation that $\text{sin.}^{-1} p$ must obtain, is that it is the angle whose sine is p.

In like manner

$$\text{log. (log. (log. } a) \text{ is written log. }^3 a$$

and $\text{log. }^{-1} a$, signifies the number whose logarithm is a.

Of this system the only part that has obtained any extensive currency is that given above in the case of the inverse trigonometric ratios.

32. *Formulas connecting inverse Trigonometric Ratios.*

There are some formulas in which these inverse ratios occur that are worthy of notice.

$$(a).\ \text{Tan.}^{-1} m + \text{tan.}^{-1} n = \text{tan.}^{-1} \frac{m + n}{1 - mn}.$$

For if $\text{tan. } \theta = m$ and $\text{tan. } \phi = n$

$$\text{tan. } (\theta + \phi) = \frac{\text{tan. } \theta + \text{tan. } \phi}{1 - \text{tan. } \theta \text{ tan. } \phi} = \frac{m + n}{1 - mn}.$$

$$\text{Now } \theta = \text{tan.}^{-1} m \text{ and } \phi = \text{tan.}^{-1} n.$$

$$\therefore \theta + \phi = \text{tan.}^{-1} m + \text{tan.}^{-1} n$$

$$\text{But } \theta + \phi = \text{tan.}^{-1} \frac{m + n}{1 - mn}.$$

$$\therefore \text{tan.}^{-1} m + \text{tan.}^{-1} n = \text{tan.}^{-1} \frac{m + n}{1 - mn}. \ldots (28).$$

Hence,

$$2 \text{ tan.}^{-1} m = \text{tan.}^{-1} \frac{2m}{1 - m^2}.$$

and

$$\text{Tan.}^{-1} m - \text{tan.}^{-1} n = \text{tan.}^{-1} \frac{m - n}{1 - mn.}$$

Again,

$$\text{sin.}^{-1} m + \text{sin.}^{-1} n = \text{sin.}^{-1} \{m \sqrt{1 - n^2} + n \sqrt{1 - m^2}\}.$$

For let $\text{sin.}^{-1} m = \theta$, $\text{sin.}^{-1} n = \phi$.

$$\therefore m = \text{sin. } \theta \ n = \text{sin. } \phi.\ \sqrt{1 - m^2}$$
$$= \text{cos. } \theta \ \sqrt{1 - n^2} = \text{cos. } \phi.$$

$$\text{Now sin. } (\theta + \phi) = \text{sin. } \theta.\ \text{cos. } \phi + \text{cos. } \theta.\ \text{sin. } \phi$$
$$= m \sqrt{1 - n^2} + n \sqrt{1 - m^2}$$

$$\theta + \phi = \text{sin. }^{-1} \{m \sqrt{1 - n^2} + n \sqrt{1 - m^2}\}$$

Or,

$$\text{Sin. }^{-1} m + \text{sin. }^{-1} n = \text{sin. }^{-1} \{m \sqrt{1 - n^2} + n \sqrt{1 - m^2}\} \ldots . (29).$$

Similarly,

$$\text{Cos. }^{-1} m - \text{cos. }^{-1} n = \text{cos. }^{-1} \{mn - \sqrt{1 - m^2} \sqrt{1 - n^2}\}.$$
$$\text{Cos. }^{-1} m + \text{sin. }^{-1} n = \text{sin. }^{-1} \{mn + \sqrt{1 - n^2} \sqrt{1 - m^2}\}.$$

33. *Examples.*

Show that

$$\text{Tan.}^{-1} \tfrac{1}{2} + \text{tan.}^{-1} \tfrac{1}{3} = 45^\circ$$

$$\text{For tan.}^{-1} \frac{1}{2} + \text{tan.}^{-1} \frac{1}{3} = \text{tan.}^{-1} \frac{\frac{1}{2} + \frac{1}{3}}{1 - \frac{1}{2} \cdot \frac{1}{3}}$$

$$= \text{tan.}^{-1} \frac{3 + 2}{6 - 1} = \text{tan.}^{-1} 1. = 45^\circ$$

It is to be observed that when we say $\text{tan.}^{-1} = 45^\circ$ we mean that this is *one* value. All the values of $\text{tan.}^{-1} 1$. are, of course, given by the formula $m 180^\circ + 45^\circ$.

Show that

(1). $\text{Sin.}^{-1} \dfrac{2}{\sqrt{5}} + \text{tan.}^{-1} \dfrac{1}{3} = 45^\circ.$

(2). $\text{Sin.}^{-1} m = \text{tan.}^{-1} \dfrac{m}{\sqrt{1 - m^2}}$

(3). $\text{Cos.}^{-1} m + \text{tan.}^{-1} m = \text{tan.}^{-1} \dfrac{\sqrt{1 - m^2} + m^2}{m - m \sqrt{1 \ m^2}}$

---

* See *ante*, p. 465.

(4). $4 \tan.^{-1} \frac{1}{5} = \tan.^{-1} \frac{120}{119}$.

(5). $4 \tan.^{-1} \frac{1}{5} - \tan.^{-1} \frac{1}{239} = 45^\circ$

(6). $\tan.^{-1} m + \tan.^{-1} n = \sin.^{-1} \left\{ \frac{m+n}{\sqrt{(1+m^2)(1+n^2)}} \right\}$

(7). If $\theta = \tan.^{-1} \frac{1}{\sqrt{3}}$ $\phi = \tan.^{-1} \frac{1}{\sqrt{15}}$; then

$$\sin. (\theta + \phi) = \sin. 60^\circ \cos. 30^\circ$$

ON THE USE OF THE SUBSIDIARY ANGLES.

34. *Explanatory.*

In making trigonometrical calculations it is nearly always necessary to conduct them by means of logarithms. For the purpose of preparing a formula for logarithmic calculation, it is often necessary or convenient to express the sum or difference of two or more magnitudes by means of a product: this can generally be performed by introducing the sine, tangent, or some other ratio of an angle chosen for that purpose, which is called a subsidiary angle. One or two examples will explain the means employed for this purpose.

35. *Examples.*

(*a*) Thus, let $x^2 = a^2 + b^2$ to find x

we have $x^2 = a^2 \left(1 + \frac{b^2}{a^2}\right)$

$$\text{Assume } \frac{b}{a} = \tan. \theta$$

$$x^2 = a^2 (1 + \tan.^2 \theta) = \frac{a}{\cos.^2 \theta}.$$

$$\therefore x = \frac{a}{\cos. \theta}.$$

so that if a and b are any two numbers whatever, we are entitled to assume that $\frac{a}{b} = \tan. \theta$, since $\tan. \theta$ may have any value whatever from o to ∞, whether the value be positive or negative. But if we assume $\frac{a}{b} = \sin. \theta$, we must be sure that $a \angle b$, for otherwise $\frac{a}{b} > 1$, or $\sin. \theta > 1$, which is impossible.

(*b*) The following case is one that frequently occurs—

$$x = a \sin. A + b \cos. A.$$

$$\text{Assume } \frac{b}{a} = \tan. \theta$$

$$\text{then } x = a \left(\sin. A + \frac{b}{a} \cos. A\right)$$

$$= a (\sin. A + \tan. \theta \cos. A)$$

$$= a \frac{\sin. A \cos. \theta + \sin. \theta \cos. A}{\cos. \theta}$$

$$= a . \frac{\sin. (A + \theta)}{\cos. \theta}$$

(*c*) Again, if we have

$$x = \frac{a^2 - b^2}{a^2 + b^2}$$

$$\text{Assume } \frac{b}{a} = \tan. \theta$$

$$\therefore x = \frac{1 - \frac{b^2}{a^2}}{1 + \frac{b^2}{a^2}}$$

$$= \frac{1 - \tan.^2 \theta}{1 + \tan.^2 \theta}$$

$$= \frac{\cos.^2 \theta - \sin.^2 \theta}{\cos.^2 \theta + \sin.^2 \theta}$$

$$= \cos.^2 \theta - \sin.^2 \theta = \cos. 2\theta.$$

N.B.—It will frequently happen in calculations that we have previously used certain logarithms, and when this is the case the calculation is very materially shortened. Thus, in the above example, suppose we already know log. a and log. b. Then

$$\text{L. } \tan. \theta = \log. b - \log. a + 10.$$

which immediately enables us to find L. cos. 2θ; and therefore x, by only using the tables twice.

(*d*) Sin. A = cos. B cos. C, cos. a + sin. B sin. C.

$$\text{Assume } \frac{\cos. C \cos. a}{\sin. C.} = \tan. \phi$$

We obtain

$$\sin. A = \frac{\sin. C. \sin. (\phi + B.)}{\cos. \phi}$$

(*e*) If $x = \frac{p}{2} \left\{ 1 + \sqrt{1 - \frac{4q}{p^2}} \right\}$ where $p^2 > 4q$.

$$\text{Assume } \frac{4q}{p^2} = \sin.^2 \theta. \quad \text{Then}$$

$$x = p . \sin.^2 \frac{\theta}{2}.$$

(*f*) If $x = \frac{1 - \sqrt{1 - e^2}}{1 + \sqrt{1 - e^2}}$ $\quad e \angle 1.$

$$\text{Assume } e = \sin. \theta. \quad \text{Then}$$

$$x = \tan.^2 \frac{\theta}{2}.$$

(*g*) Such an example as the following frequently occurs in Astronomy:

If $x = m \cos. \theta + n \cos. (\theta + a)$. Express x in the form A. cos. $(\theta + B)$.

$$x = m \cos. \theta + n \cos. a \cos. \theta - n \sin. a \sin. \theta$$

$$= (m + n \cos. a) \cos. \theta - n \sin. a \sin. \theta$$

$$= (m + n \cos. a) \left(\frac{\cos. \phi \cos. \theta - \sin. \phi \sin. \theta}{\cos. \phi} \right)$$

$$= \frac{m + n \cos. a}{\cos. \phi} . \cos. (\theta + \phi).$$

$$\text{where } \tan. \phi = \frac{n \sin. a}{m + n \cos. a}$$

It will be observed that the expression for tan. ϕ, is not expressed in products and quotients only; to effect this we must introduce another angle, ϕ'. Thus:—

$$\text{Assume} \quad \tan \phi' = \frac{n}{m} \cos. a$$

$$\text{Then} \quad m + n \cos. a = m (1 + \tan. \phi')$$

$$= \frac{m (\cos. \phi' + \sin. \phi')}{\cos. \phi'}$$

$$= \frac{m (\sin. \phi' \cos. 45^\circ + \cos. \phi' \sin. 45) \sqrt{2}}{\cos. \phi'}$$

$$= \frac{m \sin. (\phi' + 45^\circ) \sqrt{2}}{\cos. \phi'}$$

$$\therefore \tan. \phi = \frac{n \sin. a \cos. \phi'}{m \sin. (\phi' + 45^\circ) \sqrt{2}}$$

$$\text{and} \quad x = \frac{m \sqrt{2} . \sin. (\phi' + 45^\circ) \cos. (\theta + \phi}{n . \sin. a \cos. \phi \cos. \phi'}$$

Then x is in the form required.

THE RELATION BETWEEN THE SIDES AND ANGLES OF TRIANGLES.

In the following articles, abc represent the sides of a triangle, and A B C the angles which they subtend.

(36). *To show that in every triangle* $\frac{a}{b} = \frac{\sin. A}{\sin. B}$

Let A B C be the triangle, from C draw C N perpendicular to A B. Then whether A be acute or obtuse,

Fig. 16.

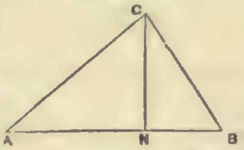


Fig. 17.

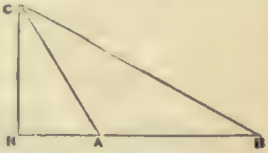


$$\text{Sin. } A = \frac{CN}{AC} \text{ and } \sin. B = \frac{CN}{CB}.$$

$$\therefore \frac{\text{Sin. A}}{\text{Sin. B}} = \frac{\text{CN}}{\text{AC}} \div \frac{\text{CN}}{\text{CB}} = \frac{\text{CN}}{\text{AC}} \times \frac{\text{CB}}{\text{CN}} = \frac{\text{CB}}{\text{CA}}$$

$$\therefore \frac{\text{Sin. A}}{\text{Sin. B}} = \frac{a}{b} \ldots\ldots (30)$$

$$\text{Similarly } \frac{\text{Sin. B}}{\text{Sin. C}} = \frac{b}{c}.$$

N.B.—These relations manifestly can be written in the form

$$\frac{\text{Sin. A}}{a} = \frac{\text{Sin. B}}{b} = \frac{\text{Sin. C}}{c} \ldots\ldots (31)$$

(37). *To prove the Formula.*

$$a^2 = b^2 + c^2 - 2\,bc.\cos.\text{A}.$$

If A be an acute angle. Let A B C be the triangle, draw C N perpendicular to the base of the triangle A B. Then (Euclid ii. 12);

$$\text{BC}^2 = \text{AC}^2 + \text{AB}^2 - 2\,\text{BA}\cdot\text{AN}.$$
$$\text{Now, AN} = \text{AC}.\cos.\text{CAB} = b\cos.\text{A}.$$
$$\therefore a^2 = b^2 + c^2 - 2bc.\cos.\text{A}.$$

Again, if A be an obtuse angle. Then drawing C N perpendicular to AB produced, we have by Euclid, ii. 13,

$$\text{BC}^2 = \text{AB}^2 + \text{AC}^2 + 2\,\text{BA}.\text{AN}$$
$$\text{and AN} = \text{CA}\cos.\text{CAN} = b\cos.(180^\circ - \text{A})$$
$$= -\,b\cos.\text{A}.$$
$$\therefore a^2 = b^2 + c^2 - 2\,ab\cos.\text{A}.$$

Hence whether A be acute or obtuse

$$a^2 = b^2 + c^2 - 2bc\cos.\text{A}\ldots\ldots (32).$$

Similarly,

$$b^2 = c^2 + a^2 - 2ca.\cos.\text{B}.$$
$$c^2 = a^2 + b^2 - 2ab.\cos.\text{C}.$$

(38). *To deduce the Formulas of Articles* 37 *from those of* 36.

These formulas can be immediately deduced from the formula—

$$\frac{\sin.\text{A}}{a} = \frac{\sin.\text{B}}{b} = \frac{\sin.\text{C}}{c}$$

without reference to Euclid's demonstration. Thus, since the three angles of a triangle are together equal to two right angles, we have

$$\text{A} + \text{B} + \text{C} = 180.^\circ$$
$$\therefore \sin.(\text{A} + \text{B}) = \sin.(180^\circ - \text{C}) = \sin.\text{C}.$$
$$\therefore \sin.\text{A}\cos.\text{B} + \sin.\text{B}\cos.\text{A} = \sin\text{C}.$$
$$\therefore \frac{\sin.\text{A}}{\sin.\text{C}}\cos.\text{B} + \frac{\sin.\text{B}}{\sin.\text{C}}.\cos.\text{A} = 1;\text{ or}$$
$$\frac{a}{c}\cos.\text{B} + \frac{b}{c}\cos.\text{A} = 1.$$
$$\therefore a\cos.\text{B} + b\cos.\text{A} = \text{C}.$$
$$\therefore a^2\cos.^2\text{B} + b^2\cos.^2\text{C} + 2\,a\,b\cos.\text{A}\cos.\text{B} = c^2.$$
$$\text{Now } \frac{a}{b} = \frac{\sin.\text{A}}{\sin.\text{B}}$$
$$\therefore a\sin.\text{B} - b\sin.\text{A} = 0$$
$$\therefore a^2\sin.^2\text{B} + b^2\sin.^2\text{A} - 2\,a\,b\sin.\text{A}\sin.\text{B} = 0$$

adding these two equations together, and remembering that $\sin.^2\text{A} + \cos.^2\text{A} = 1$, we have

$$a^2 + b^2 + 2\,ab\,(\cos.\text{A}\cos.\text{B} - \sin.\text{A}\sin.\text{B}) = c^2$$
$$\text{But }\cos.\text{A}\cos.\text{B} - \sin.\text{A}\sin.\text{B} = \cos.(\text{A} + \text{B}).$$
$$\text{Now, }\cos.(\text{A} + \text{B}) = \cos.(180^\circ - \text{C}) = -\cos.\text{C}.$$
$$\therefore a^2 + b^2 - 2\,ab\cos.\text{C} = c^2.$$

The other formulas can be derived in the same manner.

(39). *Certain Derived Formulas.*

(*a*) Again, since

$$a^2 = b^2 + c^2 - 2bc\cos.\text{A}.$$
$$\therefore \cos.\text{A} = \frac{b^2 + c^2 - a^2}{2bc}$$
$$\therefore 1 + \cos.\text{A} = 1 + \frac{b^2 + c^2 - a^2}{2bc}$$
$$\text{And } 1 - \cos.\text{A} = 1 - \frac{b^2 + c^2 - a^2}{2bc}$$
$$\therefore 1 + \cos.\text{A} = \frac{b^2 + 2bc + c^2 - a^2}{2bc}$$
$$1 - \cos.\text{A} = \frac{a^2 - b^2 + 2bc - c^2}{2bc}$$
$$\therefore 2\cos.^2\frac{\text{A}}{2} = \frac{(b + c)^2 - a^2}{2bc.}$$
$$2\sin.^2\frac{\text{A}}{1} = \frac{a^2 - (b - c)^2}{2bc.}$$
$$\therefore \cos.^2\frac{\text{A}}{2} = \frac{(b + c + a)(b + c - a)}{4bc}$$
$$\sin.^2\frac{\text{A}}{2} = \frac{(a - b + c)(a + b - c)}{4bc}$$

$$\text{Now suppose}\quad 2s = a + b + c$$
$$\therefore 2(s - a) = b + c - a$$
$$2(s - b) = a - b + c$$
$$2(s - c) = a + b - c.$$

$$\therefore \cos.\frac{\text{A}}{2} = \sqrt{\frac{s.(s - a)}{bc}}\ldots\ldots (33)$$
$$\sin.\frac{\text{A}}{2} = \sqrt{\frac{(s - b)(s - c)}{bc}}\ldots\ldots (34)$$
$$\text{Now, }\sin.\text{A} = 2\sin.\frac{\text{A}}{2}\cos.\frac{\text{A}}{2}.$$
$$\therefore \sin.\text{A} = \frac{2}{bc}\sqrt{s.(s - a)(s - b)(s - c)}\ldots\ldots (35)$$

In regard to these formulas it will be observed that the angle and the denominators are always the three letters, *i.e.*, if the angle is A the denominator is *bc*; if B, the denominator is *ca*, and so on. Again, in (33) it will be seen that the sides in the numerator correspond to the angle, and in (34) the sides in the numerator correspond to those in the denominator. Hence we can always adapt these formulas to any angle, thus :—

$$\sin.\text{B} = \frac{2}{ac}\sqrt{s.(s - a)(s - b)(s - c)}$$
$$\cos.\frac{\text{C}}{2} = \sqrt{\frac{s.(s - c)}{ab}}$$

(*b*) The following relations are important :—

$$\text{Since } \frac{a}{b} = \frac{\sin.\text{A}}{\sin.\text{B}}.$$
$$\therefore \frac{a + b}{b} = \frac{\sin.\text{A}. + \sin.\text{B}}{\sin.\text{B}}$$
$$\frac{a - b}{b} = \frac{\sin.\text{A} - \sin.\text{B}}{\sin.\text{B}}$$
$$\therefore \frac{a - b}{a + b} = \frac{\sin.\text{A} - \sin.\text{B}}{\sin.\text{A} + \sin.\text{B}}$$
$$= \frac{2\sin.\frac{\text{A} - \text{B}}{2}\cos.\frac{\text{A} + \text{B}}{2}}{2\cos.\frac{\text{A} - \text{B}}{2}\sin.\frac{\text{A} + \text{B}}{2}}$$
$$= \tan.\frac{\text{A} - \text{B}}{2}\cot.\frac{\text{A} + \text{B}}{2}.$$
$$\text{Now}\quad \text{A} + \text{B} = 180^\circ - \text{C}.$$
$$\therefore \cot.\frac{\text{A} - \text{B}}{2} = \cot.\left(90^\circ - \frac{\text{C}}{2}\right) = \tan.\frac{\text{C}}{2}$$
$$\therefore \tan.\frac{\text{A} - \text{B}}{2}\tan.\frac{\text{C}}{2} = \frac{a - b}{a + b}.\ldots (36)$$

(40). *To obtain Formula* (32) *in a form adapted for Logarithmic calculation.*

The above formulas, expressing the relation between the sides and angles of a triangle, are in a form adapted for logarithmic computation, except

$$c^2 = a^2 + b^2 - 2ab \text{ cos. C.}$$

This can easily be written in such a form, by introducing a subsidiary angle. Thus,

$$\begin{aligned} c^2 &= a^2 + b^2 - 2ab \text{ cos. C.} \\ &= a^2 + b^2 + 2ab - 2ab - 2ab \text{ cos. C.} \\ &= a^2 + b^2 + 2ab - 2ab\,(1 + \text{cos. C}). \\ &= (a+b)^2 - 4ab \text{ cos.}^2 \frac{C}{2} \\ &= (a+b)^2 \left\{ 1 - \frac{4\,ab \text{ cos.}^2 \frac{C}{2}}{(a+b)^2} \right\} \end{aligned}$$

$$\text{Now } a + b > \sqrt{2ab}. \quad \therefore \frac{2\sqrt{ab.} \text{ cos. } \frac{C}{2}}{a+b} < 1.$$

We may therefore assume

$$\frac{2\sqrt{ab.} \text{ cos. } \frac{C}{2}}{a+b} = \text{cos. } \theta.$$

$$\therefore c^2 = (a+b)^2\,(1 - \text{cos.}\ ^2\theta) = (a+b)^2 \text{ sin.}\ ^2\theta$$

$$\therefore c = (a+b) \text{ sin. } \theta \ldots\ldots (37)$$

Or we may proceed as follows,

$$\text{Since } 1 = \text{cos.}^2 \frac{C}{2} + \text{sin.}^2 \frac{C}{2}$$

$$\text{And cos. C} = \text{cos.}^2 \frac{C}{2} - \text{sin.}^2 \frac{C}{2}$$

$$\begin{aligned} \therefore c^2 &= (a^2 + b^2)\left(\text{cos.}^2 \frac{C}{2} + \text{sin.}^2 \frac{C}{2}\right) \\ &\quad - 2\,ab\left(\text{cos.}^2 \frac{C}{2} - \text{sin.}^2 \frac{C}{2}\right) \\ &= (a^2 + 2\,ab + b^2) \text{ sin.}^2 \frac{C}{2} + (a^2 - 2\,ab + b^2) \text{ cos.}^2 \frac{C}{2} \\ &= (a+b)^2 \text{ sin.}^2 \frac{C}{2} + (a-b)^2 \text{ cos.}^2 \frac{C}{2}. \\ &= (a+b)^2 \text{ sin.}^2 \frac{C}{2} \left\{ 1 + \left(\frac{a-b}{a+b}\right)^2 \text{ cotan.}^2 \frac{C}{2} \right\}. \end{aligned}$$

$$\text{Assume tan. } \theta = \frac{a-b}{a+b} \text{ cotan. } \frac{C}{2}.$$

$$\therefore c^2 = (a+b)^2 \text{ sin.}^2 \frac{C}{2}. \ (1 + \text{tan.}^2\ \theta)$$

$$\text{or } c = \frac{(a+b) \text{ sin. } \frac{C}{2}}{\text{cos. } \theta} \ldots\ldots (38).$$

Also the calculation of $\text{tan.} \frac{A-B}{2} = \frac{a-b}{a+b} \text{ cotan. } \frac{C}{2}$ can be simplified, if we have already log. a and log. b; by introducing a subsidiary angle. Thus,

$$\frac{a-b}{a+b} = \frac{1 - \frac{b}{a}}{1 + \frac{b}{a} + \frac{b}{a}}$$

$$\text{Assume} \qquad \text{tan. } \theta = \frac{b}{a}.$$

$$\therefore \frac{a-b}{a+b} = \frac{1 - \text{tan. } \theta}{1 + \text{tan. } \theta} = \frac{\text{tan. } 45° - \text{tan. } \theta}{1 + \text{tan. } 45° \text{ tan. } \theta}$$

$$\text{for tan. } 45° = 1.$$

$$\therefore \frac{a-b}{a+b} = \text{tan. } (45° - \theta)$$

$$\text{and tan. } \frac{A-B}{2} = \text{tan. } (45° - \theta) \text{ cotan. } \frac{C}{2} \ldots\ldots (39)$$

There are several Theorems which can be deduced by means of the relations proved above. The following are a few.

(41). *To find the Area of a Triangle in terms of its sides.*

In figure (16) we evidently have

$$\text{Area triangle} = \tfrac{1}{2}.\ \text{C N. A B.}$$

$$\text{Now C N.} = \text{A C sin. A} = b \text{ sin. A.}$$

$$\begin{aligned} \therefore \text{area} &= \frac{bc}{2} \text{ sin. A} \\ &= \frac{bc}{2} \times \frac{2}{bc} \sqrt{s.\ (s-a)\ (s-b)\ (s-c)}. \ \ldots (35). \\ &= \sqrt{s.\ (s-a)\ (s-b)\ (s-c)} \end{aligned}$$

N.B.—If $a = b = c$. or triangle equilateral, then $s = \frac{3a}{2}$

$$\therefore \text{area} = \frac{a^2\sqrt{3}}{4}$$

If $a = b$. or triangle isosceles

$$s = a + \frac{c}{2}\ s - a + s - b + \frac{c}{2}$$

$$s - c = a - \frac{c}{2}.$$

$$\therefore \text{area} = \frac{c}{2}\sqrt{\frac{a^2 - c^2}{4}}$$

(42). *To find the Radius of Inscribed Circle on terms of sides.*

Let A B C be the triangle.
O the centre of inscribed circle
Join O A, O B, OC.
Now area A B C = area B O C + area C O A + area A O B.
Let r = required radius.

$$\text{Then, area B O C} = \frac{ra}{2}$$

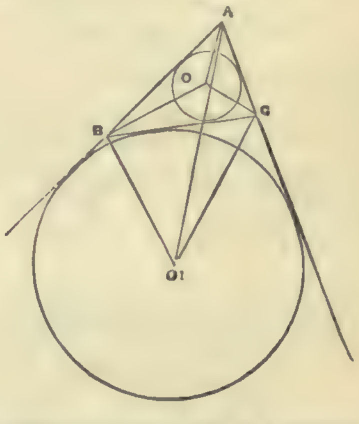
$$\text{area C O A} = \frac{rb}{2}.$$

$$\text{area } \frac{\text{A O B}}{2} = \frac{rc}{2}.$$

$$\therefore r\frac{a+b+c}{2} = \text{area.}$$

$$\therefore r = \frac{\sqrt{s\,(s-a)\,(s-b)\,(s-c)}.}{s}$$

Fig. 18.



The circles which touch one side of a triangle, and the two other sides produced, are sometimes called the *susscribed* circles. Let r_a r_b r_c be the radii of those circles which touch the sides a b c respectively.

Then if O_1 be the centre of the circle which touches the side B C, join O_1A, O_1B, O_1C. We clearly have

$$- \text{Area B } O_1,\ \text{C} + \text{area C } O_1,\ \text{A} + \text{area A } O_1,\ \text{C} = \text{area A B C.}$$

$$\therefore -\frac{r_a\ a}{2} + \frac{r_a\ b}{2} + \frac{r_a\ c}{2} = \text{area.}$$

$$\therefore r_a\ (s-a) = \sqrt{s.\ (s-a)\ (s-b)\ (s-c)}$$

$$r_a = \frac{\sqrt{s.\ (s-a)(s-b)(s-c)}}{(s-a)}$$

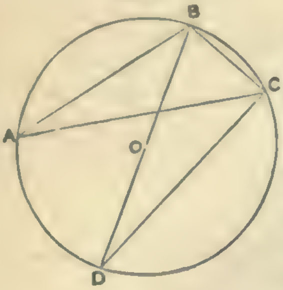
Similarly

$$r_b = \frac{\sqrt{s.\ (s-a)\ (s-b)\ (s-c)}}{(s-b)}$$

$$r_c = \frac{\sqrt{s.\ (s-a\ (s-b)\ (s-c)}}{(s-c)}$$

(43). *To find the Area of the Circumscribed Circle.*

Fig. 19.



Let A B C be the triangle. Circumscribe a circle about it, the centre of which is O. Join B O and produce it to meet the circumference in D. Join D C. Then (Euclid III.—21) B D C = B A C, and B C D is a right angle. (Euclid III.—31.) Now B D sin. B D C = B C.

∴ If R = radius of circumscribed circle, 2 R. sin. A = a.

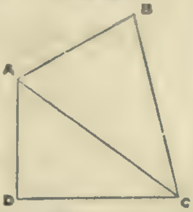
$$\therefore \frac{\mathrm{R}}{bc}\sqrt{s.\ (s-a)\ (s-b)\ (s-c)} = a$$

$$\mathrm{R} = \frac{abc}{\sqrt{s.\ (s-a)\ (s-b)\ (s-c)}}$$

(44). *To find the Area of a Quadrilateral inscribed in a Circle in terms of the sides.*

A B C D a quadrilateral inscriptible in a circle, let the four sides A B, B C, C D, D A, be respectively $a\ b\ c\ d$. Join A C.

Fig. 20.



Now, if A B C = θ A D C = 180° — θ (Euclid III.—22.)

Hence, $\mathrm{A\ C}^2 = a^2 + b^2 - 2ab \cos.\ \theta$

and $\mathrm{A\ C}^2 = c^2 + d^2 - 2cd \cos.\ (180° - \theta)$

$\therefore a^2 + b^2 - 2ab \cos.\ \theta = c^2 + d^2 + 2cd \cos.\ \theta$

$$\therefore a^2 + b^2 - 2ab \cos.\ \theta = c^2 + d^2 + 2cd \cos.\ \theta$$

$$\therefore \cos.\ \theta = \frac{a^2 + b^2 - c^2 - d^2}{2ab + 2cd}.$$

$$\text{Now, } 2 \cos.^2 \frac{\theta}{2} = 1 + \cos.\ \theta$$

$$\therefore 2 \cos.^2 \frac{\theta}{2} = 1 + \frac{a^2 + b^2 - c^2 - d^2}{2ab + 2cd}$$

$$= \frac{(a+b)^2 - (c-d)^2}{2ab + 2cd} = \frac{(a+b+c-d)\ (a+b-c+d)}{2ab + 2cd}$$

$$= \frac{2.\ (s-d)\ (s-c)}{ab + cd} \qquad \text{if } 2s = a + b + c + d.$$

Similarly,

$$2 \sin.^2 \frac{\theta}{2} = 1 - \frac{a^2 + b^2 - c^2 - d^2}{2ab + 2cd}$$

$$= \frac{2.\ (s-b)\ (s-c)}{ab + cd}$$

$$\mathrm{Sin.}^2 \theta = \frac{4\ (s-a)\ (s-b)\ (s-c)\ (s-d)}{(ab + cd)^2}$$

But area of triangle A D C

$$= \frac{\mathrm{AD,\ DC}}{2} \sin.\ \mathrm{A\ D\ C} = \frac{dc}{2} \sin.\ (180° - \theta)$$

$$= \frac{dc}{2} \sin.\ \theta$$

$$\text{Area of triangle A B C} = \frac{\mathrm{AB,\ BC}}{2} \sin.\ \mathrm{BC}.$$

$$= \frac{ab}{2} \sin.\ \theta.$$

$$\therefore \text{The whole area} \frac{\sin.\ \theta}{2} (ab + dc).$$

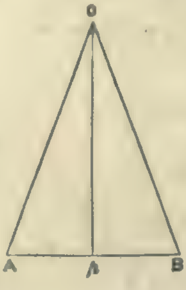
Hence area of quadrilateral

$$= \sqrt{(s-a)\ (s-b)\ (s-c)\ (s-d)}.$$

(45). *To find the Area of a Polygon of (n) sides inscribed in a given Circle.*

If A B be one side of the polygon, O the centre of the circle, let r be the radius, and n the number of sides. Then area of polygon = n × (area triangle O A B).

Fig. 21.



Now angle $\mathrm{A\,O\,B} = \frac{360°}{n}$.

Draw Op perpendicular to A B, Then

$$\mathrm{A\,O}p = \tfrac{1}{2}\,\mathrm{A\,O\,B} \therefore \mathrm{A\,O}p = \frac{180°}{n}.$$

Then area of triangle

$$= \frac{\mathrm{A\,B} \times \mathrm{O}p}{2} = \mathrm{A}p \times \mathrm{O}p.$$

$$\mathrm{A}p. = r \sin.\ \frac{180°}{n}.\quad \mathrm{O}p. = r \cos.\ \frac{180°}{n}.$$

$$\therefore \text{Area triangle} = r^2 \sin.\ \frac{180°}{n} \cos.\ \frac{180°}{n}.$$

$$= \tfrac{1}{2}\, r^2 \sin.\ \frac{360°}{n}.$$

If a be one side of the polygon,

$$\text{Then } \frac{a}{2} = r \sin.\ \frac{180°}{n}.$$

$$\therefore r = \frac{a}{2 \sin.\ \frac{180°}{n}}$$

$$\therefore \text{area of triangle} = \frac{a^2}{4 \sin.^2 \frac{180}{n}} \times \sin.\ \frac{180°}{n} \cos.\ \frac{180°}{n}$$

$$= \frac{a^2}{4} \text{cotan.}\ \frac{180°}{n}.$$

Hence area of polygon $= \frac{n}{2} r^2 \sin.\ \frac{360°}{n}$. when radius is given,

And area of polygon $= \frac{na^2}{4} \text{cotan.} \frac{180°}{n}$ when side is given.

The area of circumscribed polygon can in like manner be proved to equal

$$n r^2 \tan.\ \frac{180°}{n}.$$

CHAPTER XII.

TRIGONOMETRICAL SERIES AND TABLES.

(46) GENERAL EXPLANATIONS.

THE preceding pages give the theory of plane trigonometry. To complete this branch of mathematical science it remains to explain the mode of deducing numerical results from the above theory, and to perform the actual calculations of the parts of triangles from which the science derives its name. We have already seen that the trigonometrical ratios of certain angles are known; for example, we know that $\sin. 45^\circ = \frac{1}{\sqrt{2}}$, $\sin. 60^\circ = \frac{\sqrt{3}}{2}$, and some others, and knowing these values we can determine log. sin. 45°, log. sin. 60°, and so on. Now instead of knowing only the trigonometrical functions of certain angles, we want to know the trigonometrical functions of every angle from 0° up to 90°. And as the calculations are for the most part carried on by means of logarithms, we require to know also the logarithms of these functions. These values have been calculated and arranged in tables in a similar manner to the tables of logarithms as before explained; we purpose in the following pages to explain the principles on which this calculation has been effected.*

In our article on series and logarithms, we found it necessary to investigate certain algebraical series before proceeding to discuss the nature of logarithms; in like manner we shall find it now necessary to investigate certain trigonometrical series before explaining the construction of trigonometrical tables. In the following article on trigonometrical series we shall always keep this object strictly in view, a circumstance that will account for the absence of certain series that are often given in treatises of trigonometry. There is a very large number of such series; we treat the series here simply as the *means of arriving at the numerical results*, and on this principle make the following selection from that large number. The student will do well to observe, in studying any branch of mathematics, in which algebraical formulas occur, that unless he understands the method of obtaining arithmetical results from his formulas, he has not as yet mastered the subject.

The first article is an example of a limiting value. We would recommend the student to consider it very carefully. The proposition to be proved is that the limiting value of $\frac{\sin. \theta}{\theta} = 1$, where, of course, θ is in circular measure. The following will sufficiently explain the meaning of the statement. When θ becomes very small, $\frac{\sin. \theta}{\theta}$ becomes very nearly equal to 1, and the smaller θ becomes the more nearly $\frac{\sin. \theta}{\theta}$ becomes equal to 1; but so long as θ has any value, however small, $\frac{\sin. \theta}{\theta}$ can never actually equal 1. Then the value which limits the value of $\frac{\sin. \theta}{\theta}$ is 1, while the value which limits the values of θ is 0, and we *assume* that if θ actually equals 0, $\frac{\sin. \theta}{\theta}$ actually equals 1. The assumption is in point of fact *an axiom*. We cannot, however, discuss the questions here that this statement gives rise to. There are several methods by which the proposition can be proved. The following is a modification of Newton's sixth Lemma.

(47). *To show that when $\theta = 0$ we must have $\frac{\sin. \theta}{\theta} = 1$*

Let AP_1P be the arc of a circle, the centre of which is O. AT a tangent, AP a chord. Produce AP to p, and AT to t, draw PT and pt parallel to AO, draw po parallel to PO. Then angle $Apo = APO = PAO$. Since $AO = PO$, and therefore $Ao = op$, with centre o and radius op describe a circular arc, Ap. Then the angle AOP being equal to Aop, we have—

$$\frac{\text{arc } AP}{AO} = \frac{\text{arc } Ap}{Ao},$$

since each measures the equal angles.

Again, draw PN and pn parallel to At.

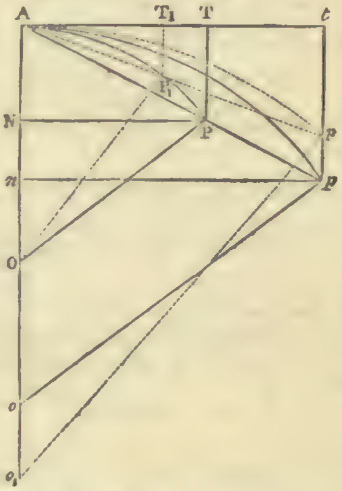
$$\text{Then } \frac{AT}{AO} = \frac{PN}{PO} = \sin. AOP.$$

$$\frac{At}{Ao} = \frac{pn}{po} = \sin. Aop.$$

$$\therefore \frac{AT}{AO} = \frac{At}{Ao}$$

$$\therefore \frac{\text{arc } AP}{AT} = \frac{\text{arc } Ap}{At}. \qquad (a)$$

Fig. 22.



Now, suppose P to move along the arc to P_1, and suppose pt to remain fixed, produce the chord AP_1, to meet pt in p, make the chord AP_1 to meet pt in p_1, make the angle $AP_1O = Ap_1o_1$. Then as before—

$$\frac{\text{arc } AP_1}{AT_1} = \frac{\text{arc } Ap_1}{At}.$$

so that in all cases the equation (a) holds good. Now when P moves up to A, p moves up to t, and when P coincides with A, p coincides with t, and then p and t coinciding, the changing arc Ap coincides with At, and therefore in the extreme or limiting case.

$$\frac{\text{arc } Ap}{At} = 1.$$

and hence on the limiting case, when AP vanishes,

$$\frac{\text{arc } AP}{AT} = 1.$$

Now let $AOP = \theta$, where θ is in circular measure, then—

$$\frac{\text{arc } AP}{AO} = \theta.$$

$$\text{and} \qquad \frac{AT}{AO} = \frac{PN}{PO} = \sin. \theta.$$

$$\text{Now} \qquad \frac{\text{arc } AP}{AT} = \frac{\frac{\text{arc } AP}{PO}}{\frac{AT}{PO}} = \frac{\sin. \theta}{\theta}.$$

---

* Tables of natural sines and cosines, and logarithmic sines, cosines, tangents, &c., will be found at the end of this section.

Hence, in the limit when θ equals zero,

$$\frac{\sin.\ \theta}{\theta} = 1. \qquad \text{Q. E. D.}$$

Cor. Under all circumstances—

$$\frac{\tan.\ \theta}{\theta} = \frac{\sin.\ \theta}{\theta} \times \frac{1}{\cos.\ \theta}.$$

Now when $\theta = 0$ $\quad \dfrac{\sin.\ \theta}{\theta} \times \dfrac{1}{\cos.\ \theta} = 1.$

Hence, in the limiting case, when $\theta = 0$.

$$\frac{\tan.\ \theta}{\theta} = 1.$$

(48). *De Moivre's Theorem.*

(*a*). To prove that $(\cos.\ \theta + \sqrt{-1}\sin.\ \theta) \times (\cos.\ \phi + \sqrt{-1}\sin.\ \phi) = \cos.\ (\theta+\phi) + \sqrt{-1}\sin.\ (\theta+\phi)$.

For by actual multiplication—

$(\cos.\ \theta + \sqrt{-1}\sin.\ \theta)(\cos.\ \phi + \sqrt{-1}\sin.\ \phi) = \cos.\ \theta\cos.\ \phi + \sqrt{-1}\sin.\ \theta\cos.\ \phi + \sqrt{-1}\cos.\ \theta\sin.\ \phi - \sin.\ \theta\sin.\ \phi = \cos.\ \theta\cos.\ \phi - \sin.\ \theta\sin.\ \phi + \sqrt{-1}\left\{\sin.\ \theta\cos.\ \phi + \cos.\ \theta\sin.\ \phi\right\} = \cos.\ (\theta+\phi) + \sqrt{-1}\sin.\ (\theta+\phi)$.

Hence—

$(\cos.\ \theta + \sqrt{-1}\sin.\ \theta)(\cos.\ \phi + \sqrt{-1}\sin.\ \phi)(\cos.\ \psi + \sqrt{-1}\sin.\ \psi) = \left\{\cos.\ (\theta+\phi) + \sqrt{-1}\sin.\ (\theta+\phi)\right\}(\cos.\ \psi + \sqrt{-1}\sin.\ \psi) = \cos.\ (\theta+\phi+\psi) + \sqrt{-1}\sin.\ (\theta+\phi+\psi)$.

And generally if we had n angles $\theta_1 \ldots \theta_2 \ldots \theta_n$, we should have—

$$\left\{\cos.\ \theta_1 + \sqrt{-1}\sin.\ \theta_1\right\}\left\{\cos.\ \theta_2 + \sqrt{-1}\sin.\ \theta_2\right\} \ldots \left\{\cos.\ \theta_n + \sqrt{-1}\sin.\ \theta_n\right\} = \cos.\ (\theta_1 + \theta_2 + \ldots\ldots \theta_n) + \sqrt{-1}\sin.\ (\theta_1 + \theta_2 + -\ldots + \theta_n) \ldots\ldots (40).$$

(*b*) To show that $(\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^n = \cos.\ n\theta + \sqrt{-1}\sin.\ n\theta$ for all integral and positive values of n.

In equation (40), suppose $\theta_1\ \theta_2 \ldots \theta_n$ to be each equal to one another and to θ.

Then— $\quad \theta_1 + \theta_2 - \ldots + \theta_n = n\theta.$

And—

$(\cos.\ \theta_1 + \sqrt{-1}\sin.\ \theta_1)(\cos.\ \theta_2 + \sqrt{-1}\sin.\ \theta_2) \ldots (\cos.\ \theta_n + \sqrt{-1}\sin.\ \theta_n) = (\cos.\ \theta + \sqrt{-1}\sin.\ \theta)(\cos.\ \theta + \sqrt{-1}\sin.\ \theta) \ldots (\cos.\ \theta + \sqrt{-1}\sin.\ \theta) = (\cos.\ \theta + \sqrt{-1}\sin.\ \theta)_n.$

And $\cos.\ (\theta_1 + \theta_2 + \ldots + \theta_n) + \sqrt{-1}\sin.\ (\theta_1 + \theta_2 + \ldots + \theta_n)$

$= \cos.\ n\theta + \sqrt{-1}\sin.\ n\theta$

Hence

$(\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^n = \cos.\ n\theta + \sqrt{-1}\sin.\ n\theta.$

(*c*). To prove the same theorem when n is a negative whole number.

For by multiplication, $(\cos.\ n\theta + \sqrt{-1}\sin.\ n\theta)$, $(\cos.\ n\theta - \sqrt{-1}\sin.\ n\theta) = \cos.^2 n\theta + \sin.^2 n\theta = 1$.

$$\text{now } 1 = \frac{(\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^n}{(\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^n}$$

$= (\cos.\ \theta + \sqrt{-1}\sin.\ \theta),^n (\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^{-n}$

$= (\cos.\ n\theta + \sqrt{-1}\sin.\ n\theta), (\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^{-n}$

$\therefore (\cos.\ n\theta - \sqrt{-1}\sin.\ n\theta), (\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^{-n} =$

$(\cos.\ n\theta + \sqrt{-1}\sin.\ n\theta), (\cos.\ n\theta - \sqrt{-1}\sin.\ n\theta)$;

$\therefore (\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^{-n} = \cos.\ n\theta - \sqrt{-1}\sin.\ n\theta)$

$= \cos.\ (-n\theta) + \sqrt{-1}\sin.\ (-n\theta).$

Since $\quad \cos.\ (-n\theta) = \cos.\ n\theta$
$\qquad\quad \sin.\ (-n\theta) = -\sin.\ n.\ \theta.$

Hence the theorem is true when n is negative.

(*d*). To prove the same theorem when n is fractional.

Let $n = \dfrac{p}{q}$

$$\text{Now } \left(\cos.\ \frac{p\theta}{q} + \sqrt{-1}\sin.\ \frac{p\theta}{q}\right)^q = \cos.\ p\theta + \sqrt{-1}\sin.\ p\theta.$$

$$= (\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^p$$

$$\therefore \cos.\ \frac{p\theta}{q} + \sqrt{-1}\sin.\ \frac{p\theta}{q} = \sqrt[q]{(\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^p}$$

$$= (\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^{\frac{p}{q}}$$

and hence, in all cases—

$$(\cos.\ \theta + \sqrt{-1}\sin.\ \theta)^n = \cos.\ n\theta + \sqrt{-1}\sin.\ n\theta \ldots\ldots (41).$$

Whether n be positive or negative, integral or fraction; which theorem is called De Moivre's theorem.

(49). *To express sin. m θ and cos. m θ in terms of powers of sin. θ and cos. θ.*

Since

$$(\cos.\ m\theta + \sqrt{-1}\sin.\ m\theta) = (\cos\ \theta + \sqrt{-1}\sin.\ \theta)^m$$

$$= \cos.^m\theta - \frac{m.\ \overline{m-1}}{1 \cdot 2}\cos.^{m-2}\theta\sin.^2\theta$$

$$+ \frac{m.\ \overline{m-1}.\ \overline{m-2}.\ \overline{m-3}}{1.2.3.4} \times \cos^{m-4}\theta\sin.^4\theta - \&c.$$

$$+ \sqrt{-1}\left\{m.\ \cos.^{m-1}\theta\sin\theta - \frac{m.\ \overline{m-1}\ \overline{m.-2}}{1.2.3}\cos.^{m-3}\theta\sin.^3\theta + \right\}$$

Hence equating possible and impossible quantities,

$$\cos.\ m\theta = \cos.^m\theta - \frac{\overline{m\ m-1}}{1.2}\cos.^{m-2}\theta\sin.^2\theta$$

$$+ \frac{m.\ \overline{m-1}.\ \overline{m-2}.\ \overline{m-3}}{1.2.3.4}\cos.^{m-4}\sin.^4\theta - \&c. \ldots (42).$$

and

$$\text{Sin. } m\theta = m\cos.^{m-1}\theta\sin.\ \theta - \frac{m.\ \overline{m-1}.\ \overline{m-2}}{1.2.3}\cos.^{m-3}\theta\sin.^3\theta + \ldots (43)^*$$

(50). *To express sin. φ, and cos. φ, in terms of φ.*

Let $m\theta = \phi$, and $\therefore \theta = \dfrac{\phi}{m}$.

Hence in the expression of the last article for cos. $m\theta$, we have

$$\cos.\ \phi = \left(\cos.\ \frac{\phi}{m}\right)^m - \frac{m.\ (m-1)}{1.2}\left(\cos.\ \frac{\phi}{m}\right)^{m-2}\sin.^2\frac{\phi}{m}$$

$$+ \frac{m.\ (m-1)(m-2)(m-3)}{1.2.3.4}\left(\cos.\ \frac{\phi}{m}\right)^{m-4}\sin.^4\frac{\phi}{m}\ \&c.$$

$$= \left(\cos.\ \frac{\phi}{m}\right)^m - \frac{\left(1-\frac{1}{m}\right)}{1.2}\left(\cos.\ \frac{\phi}{m}\right)^{m-2}\left(\sin.^2\frac{\phi}{m}\right)m^2$$

$$+ \frac{\left(1-\frac{1}{m}\right)\left(1-\frac{2}{m}\right)\left(1-\frac{3}{m}\right)}{1.2.3.4}\left(\cos.\ \frac{\phi}{m}\right)^{m-4}\left(\sin.^4\frac{\phi}{m}\right)m^4$$

$$- \&c.$$

* We assume in this article that if $a + \sqrt{-1}.\ b = A + \sqrt{-1}\ B$. where $a.\ b.\ A.\ B.$ are *real*. Then $a = A$ and $B = b$. To prove this, suppose A to be unequal to a and let $A = a + x$. and $B = b + y$.

$$\therefore a + b\sqrt{-1} = a + x + (b+y)\sqrt{-1}$$
$$\therefore o = x + y\sqrt{-1}$$
$$\therefore -x = y\sqrt{-1}$$
$$\therefore x^2 = -y^2$$
$$\therefore x^2 + y^2 = o.$$

Now x^2 and y^2 must each be positive.

$$\therefore x = o \text{ and } y = o$$
$$\therefore A = a.\ \text{and } B = b.$$

$$= \left(\cos.\ \frac{\phi}{m}\right)^m - \frac{1-\frac{1}{m}}{1\cdot2}\left(\cos.\ \frac{\phi}{m}\right)^{m-2}\left(\frac{\sin.\ \frac{\phi}{m}}{\frac{\phi}{m}}\right)^2\phi^2$$

$$+\frac{\left(1-\frac{1}{m}\right)\left(1-\frac{2}{m}\right)\left(1-\frac{3}{m}\right)}{1.2.3.4}$$

$$\left(\cos.\ \frac{\phi}{m}\right)^{m-4}\left(\frac{\sin.\ \frac{\phi}{m}}{\frac{\phi}{m}}\right)^4\phi^4 - \&c.$$

This formula is true for every value of m, however large m may be; but if we suppose m to become very large, then in the limiting or extreme case when m is infinity $\frac{\phi}{m}$ is zero, and hence in this limiting case

$$\frac{\sin.\ \frac{\phi}{m}}{\frac{\phi}{m}} = 1.$$

Also $1-\frac{1}{m}=1.\quad 1-\frac{2}{m}=1.\qquad \&c.$

Also $\quad \left(\cos.\ \frac{\phi}{m}\right)^m = 1.$

And therefore

$$\cos.\ \phi = 1-\frac{\phi^2}{1.2}+\frac{\phi^4}{1.2.3.4}-\&c.\ \ldots (44).$$

By reasoning in precisely the same way from the formula for sin. $m\,\theta$ we shall obtain

$$\sin.\ \phi = \phi - \frac{\phi^3}{1.2.3} + \frac{\phi^5}{1.2.3.4.5} - \&c.\ \ldots (45).$$

Cor.—If ϕ be so small that we can omit ϕ^3, we shall clearly have

$$\sin.\ \phi = \phi \text{ and } \cos.\ \phi = 1 - \frac{\phi^2}{2}$$

(51). *To obtain sin. θ. cos. θ. and tan. θ in terms of Exponentials.*

Since

$$\sin.\ \theta = \theta - \frac{\theta^3}{1.2.3} + \frac{\theta^5}{1.2.3.4.5} - \&c.$$

$$\&\ \cos.\ \theta = 1 - \frac{\theta^2}{1.2} + \frac{\theta^4}{1.2.3.4} - \&c.$$

$$\therefore \sqrt{-1}.\ \sin.\ \theta = \theta\sqrt{-1} - \frac{\theta^3\sqrt{-1}}{1.2.3}$$

$$+\frac{\theta^5\sqrt{-1}}{1.2.3.4.5} - \&c.$$

$$\therefore \cos.\ \theta + \sqrt{-1}.\ \sin.\ \theta = 1 + \theta\sqrt{-1} - \frac{\theta^2}{1.2}$$

$$+\frac{\theta^3\sqrt{-1}}{1.2.3} - \frac{\theta^4}{1.2.3.4} + \frac{\theta^5\sqrt{-1}}{1.2.3.4.5}$$

$$\&\ \cos.\ \theta - \sqrt{-1}.\ \sin.\ \theta = 1 - \theta\sqrt{-1} + \frac{\theta^2}{1.2}$$

$$-\frac{\theta^3\sqrt{-1}}{1.2.3} + \frac{\theta^4}{1.2.3.4} - \frac{\theta^5\sqrt{-1}}{1.2.3.4.5}$$

Now

$(\sqrt{-1})^2 = -1.$
$(\sqrt{-1})^3 = (\sqrt{-1})^2\sqrt{-1} = -\sqrt{-1}.$
$(\sqrt{-1})^4 = (\sqrt{-1})^2(\sqrt{-1})^2 = (-1)(-1) = 1.$

$$\therefore \cos.\ \theta + \sqrt{-1}\sin.\ \theta = 1 + \theta\sqrt{-1} + \frac{(\theta\sqrt{-1})^2}{1.2}$$

$$+\frac{(\theta\sqrt{-1})^3}{1.2.3} + \cdots$$

and

$$\cos.\ \theta - \sqrt{-1}\sin.\ \theta = 1 - \theta\sqrt{-1} + \frac{(\theta\sqrt{-1})^2}{1.2}$$

$$-\frac{(\theta\sqrt{-1})^3}{1.2.3} + \cdots\ \theta\sqrt{-1}.$$

$$\therefore \cos.\ \theta + \sqrt{-1}\sin.\ \theta = e\ \ldots (46).$$

And $\cos.\ \theta - \sqrt{-1}\sin.\ \theta = e^{-\theta\sqrt{-1}}\ \ldots (47).$

by the exponential theorem (Art. on Series)*

$\therefore$ dividing the former by the latter

$$\frac{\cos.\ \theta + \sqrt{-1}\sin.\ \theta}{\cos.\ \theta - \sqrt{-1}\sin.\ \theta} = e^{\theta\sqrt{-1}} + e^{-\theta\sqrt{-1}}$$

$$\therefore \frac{1+\sqrt{-1}\tan.\ \theta}{1-\sqrt{-1}\tan.\ \theta} = e^{2\theta\sqrt{-1}}\ \ldots (48).$$

Also adding (46) and (47) we obtain

$$2\cos.\ \theta = e^{\theta\sqrt{-1}} + e^{-\theta\sqrt{-1}}\ \ldots (49).$$

and subtracting (47) from (46) we obtain

$$2\sqrt{-1}\sin.\ \theta = e^{\theta\sqrt{-1}} - e.^{-\theta\sqrt{-1}}\ \ldots (50)$$

(52). *To obtain an expression for θ in terms of tan. θ and its powers.*

Since from equation (48)

$$e^{2\theta\sqrt{-1}} = \frac{1+\sqrt{-1}\tan.\ \theta}{1-\sqrt{-1}\tan.\ \theta}$$

Taking logarithms on both sides.

$$2\,\theta\sqrt{-1} = \log.\ (1+\sqrt{-1}\tan.\ \theta) - \log.\ (1-\sqrt{-1}\tan.\ \theta)$$

$$= \frac{\sqrt{-1}\tan.\ \theta}{1} - \frac{(\sqrt{-1}\tan.\ \theta)^2}{2} + \frac{(\sqrt{-1}\tan.\ \theta)^3}{3}. - \&c.$$

$$-\left\{-\frac{\sqrt{-1}\tan.\ \theta}{1} - \frac{(\sqrt{-1}\tan.\ \theta}{1.2} - \frac{(\sqrt{-1}\tan.\ \theta)^3}{3}\ \ldots\right\}$$

$$= 2\left\{\frac{\sqrt{-1}\tan.\ \theta}{1} + \frac{(\sqrt{-1}\tan.\ \theta)^3}{3} + \frac{(\sqrt{-1}\tan.\ \theta)^5}{5} + \cdots\right\}$$

$$= 2\sqrt{-1}\left\{\tan.\ \theta - \frac{\tan.^3\theta}{3} + \frac{\tan.^5\theta}{5} - \&c.\right\}$$

$$\therefore \theta = \tan.\ \theta - \frac{\tan.^3\theta}{3} + \frac{\tan.^5\theta}{5} - \&c.$$

---

* See *ante*, p. 516.

or if, $\theta = \tan.^{-1} x$. Then

$$\tan.^{-1} x = x - \frac{x^3}{3} + \frac{x^5}{5} - \&c. \qquad \ldots (51).$$

If x be positive, this value of $\tan.^{-1} x$ is, of course, that value which is less than $\frac{\pi}{2}$. Hence, if we wish to express *all* the values of $\tan.^{-1} x$ in terms of x, we ought to use the formula

$$\tan.^{-1} x = m\,\pi + \left\{ x - \frac{x^3}{3} + \frac{x^5}{5} - \&c. \right\}$$

Where m is any positive or negative integer

(53). *To calculate the value of π. i. e., the ratio which the Arc of a Semicircle bears to its Radius.*

Let a be the arc to radius r subtending an angle of 45°. Then since the semicircle subtends an angle of 180°, $\frac{\pi}{4} = \frac{a}{r}$. Hence $\frac{\pi}{4}$ is the circular measure of an angle of 45°.

$$\therefore \tan.\frac{\pi}{4} = 1$$

and

$$\frac{\pi}{4} = \tan.^{-1} 1$$

Hence, from equation (51).

$$\frac{\pi}{4} = \tan.^{-1} 1 = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \ldots$$

and from this we might obtain the numerical value of π. But it is much more expeditiously determined in the following manner,

$$2\tan.^{-1}\frac{1}{5} = \tan.^{-1}\frac{\frac{2}{5}}{1-\frac{1}{25}} = \tan.^{-1}\frac{5}{12}$$

$$4\tan.^{-1}\frac{1}{5} = 2\tan.^{-1}\frac{5}{12} = \tan.^{-1}\frac{\frac{5}{6}}{1-\frac{25}{144}} = \tan.^{-1}\frac{120}{119}$$

$$\mathrm{Tan.}^{-1}\frac{120}{119} - \tan.^{-1} 1 = \tan.^{-1}\frac{\frac{120}{119}-1}{1+\frac{120}{119}} = \tan.^{-1}\frac{1}{239}$$

$$\therefore \tan.^{-1} 1 = \tan.^{-1}\frac{120}{119} - \tan.^{-1}\frac{1}{239}$$

$$= 4\tan.^{-1}\frac{1}{5} - \tan.^{-1}\frac{1}{239}$$

$$\therefore \frac{\pi}{4} = 4\tan.^{-1}\frac{1}{5} - \tan.^{-1}\frac{1}{239}$$

$$= 4\left\{\frac{1}{5} - \frac{1}{3}\cdot\frac{1}{5^3} + \frac{1}{5}\cdot\frac{1}{5^5} - \&c.\right\}$$

$$- \left\{\frac{1}{239} - \frac{1}{3}\cdot\frac{1}{239^3} + \frac{1}{5}\cdot\frac{1}{239^5} - \&c.\right\}$$

The expression, it will be observed, consists of the difference between two series. Their values can be calculated separately, and the value of π. be found from thence in the following manner :—

(1). We obtain the value of $\frac{1}{5} - \frac{1}{3}\cdot\frac{1}{5^3} + \frac{1}{5}\cdot\frac{1}{5^5} -$ &c., to the 12th place of decimals in the following manner.

$$\frac{1}{5} = \cdot2$$

$$\frac{1}{5^3} = \cdot008$$

$$\frac{1}{5^5} = \cdot00032$$

$$\frac{1}{5^7} = \cdot0000128$$

$$\frac{1}{5^9} = \cdot000000512$$

$$\frac{1}{5^{11}} = \cdot00000002048$$

$$\frac{1}{5^{13}} = \cdot000000000819$$

$$\frac{1}{5^{15}} = \cdot000000000032$$

$$\frac{1}{5^{17}} = \cdot000000000001.$$

From these we can easily obtain, first, the negative, and then the positive part of the expression ; and subtracting we obtain the whole value required.

$$\frac{1}{3}\cdot\frac{1}{5^3} = \cdot\,002666666666$$

$$\frac{1}{7}\cdot\frac{1}{5^7} = \cdot\,000001828571$$

$$\frac{1}{11}\cdot\frac{1}{5^{11}} = \cdot\,000000001861$$

$$\frac{1}{15}\cdot\frac{1}{5^{15}} = \cdot\,000000000002$$

$$.\,002668497100$$

Again

$$\frac{1}{5} = \cdot\,2.$$

$$\frac{1}{5}\cdot\frac{1}{5^5} = \cdot\,000064$$

$$\frac{1}{9}\cdot\frac{1}{5^9} = \cdot\,000000056888$$

$$\frac{1}{13}\cdot\frac{1}{5^{13}} = \cdot\,000000000063$$

$$.\,200064056951$$

$$.\,002668497100$$

$$.\,197395559851$$

$$4$$

$$.\,789582239404$$

Which is the value of decimals

$$4\left\{\frac{1}{5} - \frac{1}{3}\cdot\frac{1}{5^3} + \&c.\right\} \text{ to 12 places.}$$

(2). To calculate the value of $\left\{\frac{1}{239} - \frac{1}{3}\cdot\frac{1}{239^3} + \ldots\right\}$

$$\frac{1}{239} = \cdot004184100418$$

$$\frac{1}{239^3} = \cdot000000073249$$

$$\frac{1}{239^5} = \cdot000000000001$$

$$\therefore \frac{1}{239} = \cdot004184100418$$

$$\frac{1}{3}\cdot\frac{1}{239^3} = \cdot000000024416$$

$$\cdot004184076002$$

Which is the value of $\left\{\frac{1}{239} - \frac{1}{3}\cdot\frac{1}{239^3} + -\right\}$ to 12 places of decimals.

If we subtract this from the result last found we shall obtain $\frac{\pi}{4}$. and ∴ multiplying that difference by 4, we shall obtain the value of π. required. Thus,

$$\begin{array}{r} {\cdot}789582239404 \\ {\cdot}004184076002 \\ \hline {\cdot}785398163402 \\ 4 \\ \hline 3{\cdot}141592653608 \end{array}$$

The calculation is carried to 12 places of decimals, but is not trustworthy beyond the first 10.

Hence (to 10 places of decimals)

$$\pi = 3{\cdot}1415926536$$

If we had wanted to obtain the value of π to a larger number of places of decimals, we should have had to carry the calculations throughout to a correspondingly greater extent.

Thus, we can show that

$$\pi = 3{\cdot}141592653589794^{*}$$

We can very conveniently apply De Moivre's formula to the solution of Binomial Equations, *i.e.*, equations of the form $x^n + a = 0$

(54). *To explain what we mean by the roots of a Binomial Equation.*

If we take the case $x^n + a = 0$, and if a be b^n, then the equation becomes $0^n + b^n = 0$, and if $x = by$. $x^n = b^n y^n$, and then the equation becomes

$$y^n + 1 = 0$$

where the 1 may be either positive or negative. It might seem at first sight that this has only one *root*, *viz.*, unity, but to conclude so would be an error, as a little consideration will make quite plain; for take the case

$$x^2 - 1 = 0$$

Then x is either $+1$, or -1; *i.e.*, has two values. And if we take the case

$$x^3 - 1 = 0$$

Then because

$$x^3 - 1 = (x - 1)(x^2 + x + 1)$$

we shall have

$$(x - 1)(x^2 + x + 1) = 0$$

whence x will have values corresponding to

$$x - 1 = 0$$
$$x^2 + x + 1 = 0$$

From the former of them we find that $x = 1$, and from the second that

$$x^2 + x + \tfrac{1}{4} = -\tfrac{3}{4}$$
$$\therefore x = \frac{-1 \pm \sqrt{-3}}{4}$$

And hence x has the three values.

$$1. \quad \frac{-1 + \sqrt{-3}}{2} \text{ and } \frac{-1 - \sqrt{-3}}{2}$$

which are three roots of the binomial equation

$$x^3 - 1 = 0$$

And hence we manifestly have that the roots of

$$x^3 - a^3 = 0$$

are

$$a. \quad \frac{-1 + \sqrt{-3}}{2}\, a \text{ and } \frac{-1 - \sqrt{-3}}{2}\, a.$$

In like manner

$$x^n + 1 = 0$$

has n different roots, which indeed follows from the general principle, that every equation of the n^{th} degree has n different roots, real or imaginary.

(55). *To find the roots of the Equation,* $x^n + 1 = 0$.

Since, $\cos. (2p + 1)\pi + \sqrt{-1} \sin. 2p + 1)\pi = -1$ whatever be the value of p. provided it be an integer. And since

$$x^n = -1$$

we must have

$$x^n = \cos. (2p + 1)\pi + \sqrt{-1} \sin. (2p + 1)\pi.$$

$$\therefore \quad x = (\cos. \overline{2p + 1}\,\pi + \sqrt{-1} \sin. \overline{2p + 1}\,\pi)^{\frac{1}{n}}$$

$$\text{or } x = \cos. \frac{2p + 1}{n}\pi + \sqrt{-1} \sin. \frac{2p + 1}{n}\pi.$$

Hence $\cos. \frac{2p + 1}{n}. \pi + \sqrt{-1} \sin. \frac{2p + 1}{n} \pi$. is a root of the binomial equation whatever integral value we may give to p.

We shall prove that there are n different values of this formula, corresponding to the different values of p, viz. : 0, 1, 2, 3. . . . $\overline{n - 1}$, and that there are *no more* than n values.

(*a*). Let p and q be two values, each $< n$; and if possible let

$$\cos. \frac{2p + 1}{n}. \pi + \sqrt{-1} \sin. \frac{2p + 1}{n}. \pi$$
$$= \cos. \frac{2q + 1}{n} \pi + \sqrt{-1} \sin. \frac{2p + 1}{n} \pi.$$

Hence equating possible and impossible terms,

$$\cos. \frac{2p + 1}{n}. \pi = \cos. \frac{2q + 1}{n} \pi.$$
$$\sin. \frac{2p + 1}{n} \pi = \sin. \frac{2q + 1}{n}. \pi.$$

Hence the angles must differ by some multiple of 2π, say by $k \times 2\pi$.

$$\therefore \frac{2p+1}{n}. \pi = \frac{2q+1}{n}. \pi \pm 2k\pi.$$

$$\therefore p - q = k.n. \text{ a multiple of } n,$$

and therefore either p or q must be greater than n. Hence all the values of x which correspond to the values of $p \angle n$, viz., 0, 1, 2, 3, ... $n - 1$, are different from each other.

(*b*). Again, if we give p a value r greater than n, then the corresponding value of x will be the same as one of those which is given by some value of p, that is less than n, as for instance q.

For suppose $p = kn + q$.

where k is a whole number, and q is less than n.

Then, $\cos. \frac{2p+1}{n}\pi + \sqrt{-1} \sin. \frac{2p+1}{n}\pi =$

$$\cos. \frac{2kn + 2q + 1}{n}\pi + \sqrt{-1} \sin. \frac{2kn + 2q + 1}{n}\pi =$$
$$\cos. \left(2k\pi + \frac{2q+1}{n}\pi\right) + \sqrt{-1} \sin. \left(2k\pi + \frac{2q+1}{n}\pi\right) =$$
$$\cos. \frac{2q+1}{n}\pi + \sqrt{-1} \sin. \frac{2q+1}{n}\pi.$$

Hence by giving to p. successively the values of 0.1.2.3 . . . . . $n - 1$. in the formula

$$x = \cos. \frac{2p+1}{n}\pi + \sqrt{-1} \sin. \frac{2p+1}{n}\pi.$$

we obtain all the roots of the Equation

$$x^n + 1 = 0.$$

Thus. To find the roots of the Equation

$$x^6 + 1 = 0.$$

the roots are given by the formula

$$x = \cos. \frac{2p+1}{6}\pi + \sqrt{-1} \sin. \frac{2p+1}{6}\pi.$$

and are therefore respectively

---

* In connection with this, the student may advantageously peruse the remarks of Professor Young, in Chapter IV. on Geometry, in which he refers to the quadrature of the circle. (See p. 577).

$$\cos.\frac{\pi}{6}+\sqrt{-1}\sin.\frac{\pi}{6}.=\cos.30^\circ+\sqrt{-1}\sin.30^\circ=\frac{\sqrt{3}+\sqrt{-1}}{2}$$

$$\cos.\frac{3\pi}{6}+\sqrt{-1}\sin.\frac{3\pi}{6}.=\cos.90^\circ+\sqrt{-1}\sin.90^\circ=\sqrt{-1}$$

$$\cos.\frac{5\pi}{6}+\sqrt{-1}\sin.\frac{5\pi}{6}.=\cos.150^\circ+\sqrt{-1}\sin.150^\circ=\frac{-\sqrt{3}+\sqrt{-1}}{2}$$

$$\cos.\frac{7\pi}{6}+\sqrt{-1}\sin.\frac{7\pi}{6}.=\cos.210^\circ+\sqrt{-1}\sin.210^\circ=\frac{-\sqrt{3}-\sqrt{-1}}{2}$$

$$\cos.\frac{9\pi}{6}+\sqrt{-1}\sin.\frac{9\pi}{6}.=\cos.270^\circ+\sqrt{-1}\sin.270^\circ=-\sqrt{-1}$$

$$\cos.\frac{11\pi}{6}+\sqrt{-1}\sin.\frac{11\pi}{6}.=\cos.330^\circ+\sqrt{-1}\sin.330^\circ=\frac{\sqrt{3}-\sqrt{-1}}{2}$$

Similarly if we have to find the roots of the Equation $x^n-1=0$. Since $\cos.2p\pi+\sqrt{-1}\sin.2p\pi=1$ we shall have all the roots given in the formula $x=\cos.\frac{2p\pi}{n}+\sqrt{-1}\sin.\frac{2p\pi}{n}$.

(56). *To resolve x^{2n-1} into factors.*[*]

If $a_0\ a_1\ a_2\ \ldots\ldots\ a^{2n-1}$ are the roots of the Equation $x^{2n}-1=0$. Then $x^{2n}-1=(x-a_0)(x-a_1)(x-a_2)\ldots\ldots(x-a^{2n-1})$.

Now all the roots of the Equation are included in the expression $\cos.\frac{2p\pi}{2n}+\sqrt{-1}\sin.\frac{2p\pi}{2n}$.

If then we suppose $p\angle n$. and a_p be the corresponding root $a_p=\cos.\frac{p\pi}{n}+\sqrt{-1}\sin.\frac{p\pi}{n}$.

Now observe that there will be another root a^{2n-p}. which will equal $\cos.\frac{\overline{2n-p}\,\pi}{n}+\sqrt{-1}\sin.\frac{\overline{2n-p}\,\pi}{n}$

$$=\cos.\left(2\pi-\frac{p\pi}{n}\right)+\sqrt{-1}\sin.\left(2\pi-\frac{p\pi}{n}\right).$$

Hence $a^{2n-p}=\cos.\frac{p\pi}{n}-\sqrt{-1}\sin.\frac{p\pi}{n}$. where $p\angle n$, and so we have a pair of factors $x-a^p$ and $x-a^{2n-p}$

$$\text{which are equal to}\left(x-\cos.\frac{p\pi}{n}-\sqrt{-1}\sin.\frac{p\pi}{n}\right)\left(x-\cos.\frac{p\pi}{n}+\sqrt{-1}\sin.\frac{p\pi}{n}\right)$$

$$=x^2-2x\cos.\frac{p\pi}{n}+1,\text{ by multiplication.}$$

Where p may take any value, $1\cdot2\cdot3\ldots\ldots n-1$. It will be observed that $\left\{\begin{array}{l}x-a_0=x-1.\\x-a_n=x+1.\end{array}\right.$ $\therefore(x-a_0)(x-a_n)=x^2-1$

$$\text{and}\ \therefore x^{2n}-1=(x^2-1)\left(x^2-2x\cos.\frac{\pi}{n}+1\right)\left(x^2-2x\cos.\frac{2\pi}{n}+1\right)\ldots\left(x^2-2x\cos.\frac{\overline{n-1}\,\pi}{n}+1\right)\ (52)$$

$$\text{Corol. Hence, } x^{2n}-a^{2n}=(x^2-a^2)\left(x^2-2ax\cos.\frac{\pi}{n}+a^2\right)\ldots\ldots+\left(x-2ax\cos.\frac{\overline{n-1}\,\pi}{n}+a^2\right)\ldots(53)$$

$$\text{For since } y^{2n-1}=(y^2-1)\left(y^2-2y\cos.\frac{\pi}{n}+1\right)\left(y^2-2y\cos.\frac{2\pi}{n}+1\right)\ldots\ldots\left(y^2-2y\cos.\frac{\overline{n-1}\,\pi}{n}+1\right)$$

Let $y=\frac{x}{a}$.

$$\therefore\frac{x^{2n}}{a^{2n}}-1=\left(\frac{x^2}{a^2}-1\right)\left(\frac{x^2}{a^2}-2\frac{x}{a}\cos.\frac{\pi}{n}+1\right)\ldots\left(\frac{x^2}{a^2}-2\frac{x}{a}\cos.\frac{\overline{n-1}\,\pi}{n}+1\right)$$

Now as there are n factors, if we clear the equation of fractions, multiplying the right-hand side by a^{2n} will be the same thing as multiplying each factor by a^2.

Hence :—

$$x^{2n}-a^{2n}=\left(x^2-a^2\right)\left(x^2-2ax\cos.\frac{\pi}{n}+a^2\right)\ldots\left(x^2-2ax\cos.\frac{\overline{n-1}\,\pi}{n}+a^2\right)$$

By a precisely similar process we shall be able to prove that

$$x^{2n}+1=\left(x^2-2x\cos.\frac{\pi}{2n}+1\right)\left(x^2-2x\cos.\frac{3\pi}{2n}+1\right)\ldots\ldots\left(x^2-2x\cos.\frac{\overline{2n-1}\,\pi}{2n}+1\right)\ldots.(54).$$

And hence

$$x^{2n}+a^{2n}=\left(x^2-2ax\cos.\frac{\pi}{2n}+a^2\right)\left(x^2-2ax\cos.\frac{3\pi}{n}+a^2\right)\ldots..\left(x^2-2ax\cos.\frac{\overline{2n-1}\,\pi}{2n}+a^2\right)\ldots..(55).$$

---

[*] If $a_1, a_2, a_3\ldots\ldots a_n$ are the roots of the equation, $x^{n-1}=0$ Then $x^{n-1}=(x-a_1)(x-a_2)(x-a_3)\ldots\ldots(x-a_n)$ for all values of x.

For if we actually divide x^{n-1} by $x-a_1$, we shall obtain a remainder $a_1{}^{n-1}$; now, since a_1 is a root of the equation $x^{n-1}=0$, we have $a_1{}^{n-1}=0$, *i. e.*, x^{n-1} is divisible by $x-a_1$, or $x-a_1$, is a factor of x^{n-1}. Similarly $x-a_2$. $x-a_3\ldots x-a_n$ are each factors of x^{n-1}, and since x^{n-1} cannot have more than n factors, it is plain that

$$x^{n-1}=(x-a_1)(x-a_2)\ldots\ldots(x-a_n).$$

(57). *To prove that* $2^{2n-1} \sin.^2 \frac{\pi}{2n} \sin.^2 \frac{2\pi}{2n} \sin.^2 \frac{3\pi}{2n} \ldots \sin.^2 \frac{\overline{n-1}\,\pi}{2n} = 2n.$

We have by actual division—

$$\frac{x^{2n}-1}{x-1} = x^{2n-1} + x^{2n-2} + x^{3n-3} + \ldots x + 1.$$

Hence, when $x = 1$. The limiting value of $\frac{x^{2n}-1}{x-1}$ will equal $1+1+1+\ldots+1+1$ to $2n$ terms $= 2n$.

Again by the last article—

$$\frac{x^{2n}-1}{x-1} = (x+1.)\left(x^2 - 2x\cos.\frac{\pi}{n}+1\right)\left(x^2-2x\cos.\frac{2\pi}{n}+1\right)\ldots\left(x^2-2x\cos.\frac{\overline{n-1}\,\pi}{n}+1\right)$$

and hence when $x = 1$, the limiting value of $\frac{x^{2n}-1}{x-1}$.

$$\text{is } 2\left(2-2\cos.\frac{\pi}{n}\right)\left(2-2\cos.\frac{2\pi}{n}\right)\ldots\left(2-2\cos.\frac{\overline{n-1}\,\pi}{n}\right)$$

and therefore these two limiting values are equal, and

$$2n = 2^n\left(1-\cos.\frac{\pi}{n}\right)\left(1-\cos.\frac{2\pi}{n}\right)\ldots\left(1-\cos.\frac{\overline{n-1}\,\pi}{n}\right)$$

$$= 2^n \times 2\sin.\frac{2\pi}{2n}\,2\sin.^2\frac{2\pi}{2n}\,2\sin.^2\frac{3\pi}{2n}\ldots 2\sin.^2\frac{\overline{n-1}\,\pi}{2n} = 2^n \times 2^{n-1}\sin.\frac{2\pi}{2n}.\sin.^2\frac{2\pi}{2n}.\sin.^2\frac{3\pi}{2n}\ldots\sin.^2\frac{\overline{n-1}\,\pi}{2n}$$

$$= 2^{2n-1}\sin.^2\frac{\pi}{2n}\sin.^2\frac{2\pi}{2n}\sin.^2\frac{3\pi}{2n}\ldots\sin.^2\frac{\overline{n-1}\,\pi}{2n}. \quad \ldots (56).$$

In the same manner we may prove that

$$2 = 2^{2n}\sin.^2\frac{\pi}{4n}\sin.^2\frac{3\pi}{4n}\sin.^2\frac{5\pi}{4n}\ldots\sin.^2\frac{\overline{2n-1}\,\pi.}{4n}. \quad \ldots (57).$$

For

$$x^{2n}+1 = \left(x^2-2x\cos.\frac{\pi}{2n}+1\right)\left(x^2-2x\cos.\frac{3\pi}{2n}+1\right)\ldots\left(x^2-2x\cos.\frac{\overline{2n-1}\,\pi.}{2n}+1\right)$$

Let $x = 1$, and then observing that

$$x^2 - 2x\cos.\frac{p\pi}{2n}+1 = 2\left(1-\cos.\frac{p\pi.}{2n.}\right)$$

$$= 2^2\sin.^2\frac{p\pi.}{4n.}$$

We shall obtain the required formula.

(58). *To express* sin. x *in a series of factors.*

The above formula (53) for the factors of $x^{2n} - a^{2n}$ is true for all values of x and a

Suppose $x = 1 + \frac{z}{2n}$ and $a = 1 - \frac{z}{2n}$.

$$\text{Then } x^2 - 2ax\cos.\frac{p\pi}{n} + a^2 = 1 + \frac{z}{n} + \frac{z^2}{4n^2} - 2\left(1-\frac{z^2}{4n^2}\right)\cos.\frac{p\pi}{n} + 1 - \frac{z}{n} + \frac{z^2}{4n^2}$$

$$= 2\left(1+\frac{z^2}{4n^2}\right) - 2\left(1-\frac{z^2}{4n^2}\right)\cos.\frac{p\pi}{n}.$$

$$= 2\left(1-\cos.\frac{p\pi}{n}\right) + 2\frac{z^2}{4n^2}\left(1+\cos.\frac{p\pi}{n}.\right)$$

$$= 4\sin.^2\frac{p\pi}{2n} + 4.\frac{z^2}{4n^2}.\cos.^2\frac{p\pi.}{2n}$$

$$= 4\sin.^2\frac{p\pi}{2n}.\left(1+\frac{z^2}{4n^2}\cot an.^2\frac{p\pi}{2n}\right)$$

Hence the factors on the right-hand side of Equation (53) will be equal to

$$\frac{2z}{n}.4\sin.^2\frac{\pi}{2n}\left(1+\frac{z^2}{4n^2}.\text{cotan.}^2\frac{\pi}{2n}\right)4\sin.^2\frac{2\pi}{2n}\times$$

$$\left(1+\frac{z^2}{4n^2}\text{cotan.}^2\frac{\pi}{2n}\right)\ldots 4\sin.^2\frac{(n-1)\pi}{2n}\left(1+\frac{z^2}{4n^2}\text{cotan.}^2\frac{\overline{n-1}\,\pi}{2n}\right)$$

$$= \frac{2z}{n}.4\sin.^2\frac{\pi}{2n}4\sin.^2\frac{2\pi}{2n}4\sin.^2\frac{3\pi}{2n},\ldots 4\sin.^2\frac{\overline{n-1}\,\pi}{n}$$

$$\times\left(1+\frac{z^2}{4n^2}.\text{cotan.}^2\frac{\pi}{2n}\right)\left(1+\frac{z^2}{4n^2}\text{cotan.}^2\frac{2\pi}{2n}\right)\cdot\left(1+\frac{z^2}{4n^2}\text{cotan.}^2\frac{\overline{n-1}\,\pi}{2n}\right)$$

$$= \frac{z}{n}.2^{2n-1}\sin.^2\frac{\pi}{2n}.\sin.^2\frac{2\pi}{2n}\ldots\sin.^2\frac{\overline{n-1}\,\pi}{2n}\times$$

$$\left(1+\frac{z^2}{4n^2}.\text{cotan.}^2\frac{\pi}{2n}\right)\left(1+\frac{z^2}{4n^2}.\text{cotan.}^2\frac{2\pi}{2n}\right)\ldots\left(1+\frac{z^2}{4n^2}\text{cotan.}^2\frac{\overline{n-1}\,\pi}{2n}\right)$$

$$= 2z\left(1+\frac{z^2}{4n^2}\text{cotan.}^2\frac{\pi}{2n}\right)\left(1+\frac{z^2}{4n^2}\text{cotan.}^2\frac{2\pi}{2n}\right)\ldots\left(1+\frac{z^2}{4n^2}\text{cotan.}^2\frac{\overline{n-1}\,\pi}{2n}\right)\ldots (a).$$

Since by the last article

$$2^{2n-1} \sin.^2 \frac{\pi}{2n} \ldots . \sin.^2 \frac{\overline{n-1}\,\pi}{2n} = 2n.$$

Again

$$x^{2n} - a^{2n} = \left(1 + \frac{z}{2n}\right)^{2n} - \left(1 - \frac{z}{2n}\right)^{2n}.$$

and expanding each by the Binomial Theorem.

$$x^{2n} - a^{2n} = \left(1 + 2n.\frac{z}{2n} + \frac{2n.\overline{2n-1}}{1.2}\cdot\frac{z^2}{4n^2} + \frac{2n.\overline{2n-1}\,\overline{2n-2}}{1.2.3}\cdot\frac{z^3}{8n^3} + \right)$$

$$- \left(1 - 2n.\frac{z}{2n} + \frac{2n.\overline{2n-1}}{1.2}\cdot\frac{z^2}{4n^2} - \frac{2n.\overline{2n-1}\,\overline{2n-2}}{1.2.3}\cdot\frac{z^3}{8n^3} + \right)$$

$$= 2\left\{2n.\frac{z}{2n} + \frac{2n.\overline{2n-1}\,\overline{2n-2}}{1.2.3}\cdot\frac{z^3}{8n^3} + \ldots . \right\} \ldots . (b).$$

Now (*a*) and (*b*) are equal under all circumstances, and therefore their limiting values when $2n$ becomes very large are equal, *i. e.*, when $\frac{1}{2n}\,\frac{2}{2n} \ldots . \frac{p}{2n}$ are each equal to zero.

$$\text{Now since } \frac{z^2}{4n^2}\cdot \text{cotan.}^2 \frac{p\pi}{2n} = \frac{z^2}{4n^2}\cdot\frac{1}{\tan.^2 \frac{p\pi}{2n}}$$

$$= \frac{z^2}{p^2\pi^2}\cdot\frac{\frac{p^2\pi^2}{4n^2}}{\tan.^2 \frac{p\pi}{2n}} = \frac{z^2}{p^2\pi^2}\cdot\left\{\frac{\frac{p\pi}{2n}}{\tan. \frac{p\pi}{2n}}\right\}^2.$$

But in the limit when $2n$ is very large $\frac{p\pi}{2n} = 0.$

And the limit of $\frac{\tan.\,\theta}{\theta}$ when $\theta = 0$ is unity.

Hence the limiting value of $\dfrac{\frac{p\pi}{2n}}{\tan.\,\frac{p\pi}{2n}} = 1.$

And therefore the limiting value of $\frac{z^2}{4n^3}$ cotan.$^2 \frac{p\pi}{2n} = \frac{z^2}{p^2\pi^2}$

Hence the limiting value of the expression (*a*) is

$$2z\left\{1 + \frac{z^2}{\pi^2}\right\}\ \left\{1 + \frac{z^2}{4\pi^2}\right\}\ \left\{1 + \frac{z^2}{9\pi^2}\right\} \ldots . -$$

Again since (*b*) can be written

$$2z\left\{1 + \frac{\left(1 - \frac{1}{2n}\right)\ \left(1 - \frac{2}{2n}\right)}{1.2.3}\,z^2 + \frac{\left(1 - \frac{1}{2n}\right)\ldots\left(1 - \frac{4}{2n}\right)}{1.2.3.4.5}\,z^4 \ldots . \right\}$$

The limiting value of (*b*) is $\quad 2z\left(1 + \frac{z^2}{1.2.3} + \frac{z^4}{1.2.3.4.5} + -\right)$

Hence,

$$1 + \frac{z^2}{1\cdot 2\cdot 3} + \frac{z^4}{1\cdot 2\cdot 3\cdot 4\cdot 5} + \ldots = \left(1 + \frac{z^2}{\pi^2}\right)\ \left(1 + \frac{z^2}{2^2\pi^2}\right) \ldots .$$

or writing $-z^2$ for z^2, we have—

$$1 - \frac{z^2}{1\cdot 2\cdot 3} + \frac{z^4}{1\cdot 2\cdot 3\cdot 4\cdot 5} = \left(1 - \frac{z^2}{\pi^2}\right)\ \left(1 - \frac{z^2}{2^2\pi^2}\right)\ \left(1 - \frac{z^2}{3^2\pi^2}\right) \ldots .$$

Multiply both sides by z, and we obtain

$$z - \frac{z^3}{1\cdot 2\cdot 3} + \frac{z^5}{1\cdot 2\cdot 3\cdot 4\cdot 5} = z\left(1 - \frac{z^2}{\pi^2}\right)\ \left(1 - \frac{z^2}{2^2\pi^2}\right) \ldots .$$

But, $\sin.\, z = z - \frac{z^3}{1\cdot 2\cdot 3} + \frac{z^5}{1\cdot 2\cdot 3\cdot 4\cdot 5} - \&c.$

$$\therefore \text{Sin. } z = z\left(1 - \frac{z^2}{\pi^2}\right)\ \left(1 - \frac{z^2}{2^2\pi^2}\right)\ \left(1 - \frac{z^2}{3^2\pi^2}\right) \ldots . - (58).$$

which is the expression required.

In the same manner, by taking $x^{2n} + a^{2n}$ and its factors from formula (55), we can obtain cos. x in factors.

$$\text{Thus, let } x = 1 + \frac{z}{2n}\cdot a = 1 - \frac{z}{2n}\cdot$$

$$\therefore x^{2n} + a^{2n} = 2\left\{1 + \frac{2n.\overline{2n-1}}{1.2}\cdot\frac{{}^2}{4n^2} + \frac{2n.\overline{2n-1}\ \overline{2n-2}\ \overline{2n-3}}{1.2.3.4}\,\frac{2^4}{16n^4} + \ldots \right\}$$

And as before the limiting value of

$x^{2n} + a^{2n}$ is $2\left(1 + \frac{z^2}{1.2} + \frac{z^4}{1.2.3.4} + \dots\right)$. (a)

Again since

$$x^2 - 2ax \cos. \frac{\overline{2p+1}n}{2n} + a^2 = 2\left(1 + \frac{z^2}{4n^2}\right) - 2\left(1 - \frac{z^2}{4n^2}\right) \frac{\cos. \overline{2p+1}\,\pi}{2n}$$

$$= 4 \sin.^2 \frac{\overline{2p+1}\pi}{4n} \left\{ 1 + \frac{z^2}{4n^2} \cot an.^2 \frac{\overline{2p+1}\pi}{4n} \right\}$$

The factors of $x^{2n} + a^{2n}$ become

$$2^{2n} \sin.^2 \frac{\pi}{4n} \sin.^2 \frac{3\pi}{4n} \sin.^2 \frac{5\pi}{4n} \dots \sin.^2 \frac{\overline{2n-1}\pi}{4n} \times$$

$$\left(1 + \frac{z^2}{4n^2} \text{cotan.}^2 \frac{\pi}{4n}\right)\left(1 + \frac{z^2}{4n^2}.\text{cotan.}^2 \frac{3\pi}{4n}\right)\left(1 + \frac{z^2}{4n^2} \text{cotan.}^2 \frac{5\pi}{4n}\right) \dots$$

$$= 2\left(1 + \frac{z^2}{4n^2} \text{cotan.}^2 \frac{\pi}{4n}\right)\left(1 + \frac{z^2}{4n^2}.\text{cotan.}^2 \frac{3\pi}{4n}\right)\left(1 + \frac{z^2}{4n^2} \text{cotan.}^2 \frac{5\pi}{4n}\right) \dots,$$

$$\text{Now, } \frac{z^2}{4n^2} \cdot \text{cotan.}^2 \frac{\overline{2p+1}\,\pi}{4n} = \frac{4z^2}{(\overline{2p+1}\,\pi)^2} \cdot \left\{ \frac{\frac{\overline{2p+1}\,\pi}{4n}}{\tan. \frac{\overline{2p+1}\,\pi}{4n}} \right\}$$

The limiting value of which is $\frac{4z^2}{\overline{2p+1}^2\pi^2}$

Hence the limiting value of $x^{2n} + a^{2n}$ derived from the expression for its factors will be

$$2\left(1 + \frac{4z^2}{\pi^2}\right)\left(1 + \frac{4z^2}{3^2\pi^2}\right)\left(1 + \frac{4z^2}{5^2\pi^2}\right) \dots (b)$$

And the two limiting values (a) and (b) are equal. Hence

$$1 + \frac{z^2}{1.2} + \frac{z^4}{1.2.3.4} + \dots = \left(1 + \frac{4z^2}{\pi^2}\right)\left(1 + \frac{4z^2}{3^2\pi_2}\right)\left(1 + \frac{4z2}{5^2\pi^2}\right) \dots$$

Write $-z^2$ for $+z^2$ (as before) and we obtain

$$1 - \frac{z^2}{1.2} + \frac{z^4}{1.2.3.4} - \&c. = \left(1 - \frac{4z^2}{\pi^2}\right)\left(1 - \frac{4z^2}{3^2\pi^2}\right)\left(1 - \frac{4z^2}{5^2\pi^2}\right)$$

$$\therefore \cos. z = \left(1 - \frac{4z^2}{\pi^2}\right)\left(1 - \frac{4z^2}{3^2\pi^2}\right)\left(1 - \frac{4z^2}{5^2\pi^2}\right) \dots (59)$$

The series given in the preceding articles are sufficient for our purpose. We now proceed to explain the method of calculating trigonometrical tables.

The Tables of the trigonometrical functions are of two kinds. (1). Those which give the numerical values of the sines, cosines of the angles, &c. (2). Those which give the values of the logarithms of the sines, cosines, &c., of the angles. The former are called Tables of natural sines; the latter, Tables of logarithmic sines.

We shall explain the method by which each of these tables is calculated.

(59). *To show that* sin. θ *is less than* θ *and greater than*

$$\theta - \frac{\theta^3}{4}$$

For, $\sin. \theta = 2 \sin. \frac{\theta}{2} \cos. \frac{\theta}{2} = 2 \sin. \frac{\theta}{2}\left(1 - \sin.^2 \frac{\theta}{2}\right)$

Now $1 - \sin.^2 \frac{\theta}{2}$ must be less than 1.

$\therefore \sin. \theta \angle 2 \sin. \frac{\theta}{2}$.

$\therefore \sin. \frac{\theta}{2} \angle 2 \sin. \frac{\theta}{2^2}$.

$\therefore \sin. \frac{\theta}{2^2} \angle 2 \sin. \frac{\theta}{2^3}$.

$\therefore \text{Sin.} \frac{\theta}{2^{n-1}} \angle 2 \sin. \frac{\theta}{2^n}$.

Hence $\sin. \theta \angle 2^n \sin. \frac{\theta}{2^n}$. whatever n may be.

$\frac{\text{Sin. } \theta}{\theta} \angle \frac{\sin. \frac{\theta}{2^n}}{\frac{\theta}{2^n}}$ for all values of n, however large n may be; and therefore, in the limiting case, when n is infinitely large, & $\therefore 2^n$ infinitely large, or when $\frac{\theta}{2^n} = 0$.

But in this case $\frac{\sin. \frac{\theta}{2^n}}{\frac{\theta}{2^n}} = 1$,

$\therefore \frac{\sin. \theta}{\theta} < 1$.

or $\sin. \theta < \theta$

In like manner we can easily prove that $\tan. \theta > \theta$

For $\tan. \theta = \frac{2 \tan. \frac{\theta}{2}}{1 - \tan.^2 \frac{\theta}{2}}$

$\therefore \tan. \theta > 2 \tan. \frac{\theta}{2}$

Hence by same reasoning as before, $\tan. \theta > 2^n \tan. \frac{\theta}{2^n}$

$\therefore \frac{\tan. \theta}{\theta} > \frac{\tan. \frac{\theta}{2^n}}{\frac{\theta}{2^n}}$

Now, when n is infinitely large $\frac{\theta}{2^n} = 0$

and $\frac{\tan. \frac{\theta}{2^n}}{\frac{\theta}{2^n}}$ in this case $= 1$.

$$\therefore \frac{\tan.\,\theta}{\theta} > 1$$

$$\text{or } \tan.\,\theta > \theta$$

(2). To show that $\sin.\,\theta > \theta - \frac{\theta^3}{4}$.

$$\text{For } \sin.\,\theta = 2\sin.\,\frac{\theta}{2}\ \cos.\,\frac{\theta}{2}$$

$$= 2\tan.\,\frac{\theta}{2}\cos.^2\frac{\theta}{2}$$

$$= 2\tan.\,\frac{\theta}{2}\left(1-\sin.^2\frac{\theta}{2}\right)$$

$$=\theta.\,\frac{\tan.\,\frac{\theta}{2}}{\frac{\theta}{2}}\left\{1-\frac{\theta^2}{4}\left(\frac{\sin.\,\frac{\theta}{2}}{\frac{\theta}{2}}\right)^2\right\}$$

Now $\dfrac{\tan.\,\frac{\theta}{2}}{\frac{\theta}{2}}$ being > 1 and $\left\{\dfrac{\sin.\,\frac{\theta}{2}}{\frac{\theta}{2}}\right\}^2$ being $\angle 1$.

$$1-\frac{\theta^2}{4}\ \text{must be} \angle\ 1-\frac{\theta^2}{4}\left(\frac{\sin.\,\frac{\theta}{2}}{\frac{\theta}{2}}\right)^2$$

$$\therefore \sin.\,\theta \text{ must be } > \theta\left(1-\frac{\theta^2}{4}\right)$$

$$\therefore \sin.\,\theta > \theta-\frac{\theta^3}{4}$$

(60). *To calculate the value of* sin. 1′ *and* cos. 1′.

Let θ be an angle of 1′ measured by the circular measure. Then,—

$$\theta = \pi - \frac{1'}{180^\circ} = \frac{\pi}{180 \times 60}.$$

$\therefore$ Taking the value of π previously given,

$$\theta = \cdot 00029088820.$$

$$\frac{\theta^3}{4} = \cdot 00000000006$$

Hence, if we only take in the first *ten* decimal places,

$$\sin.\,1' = \cdot\,0002908882.$$

And since

$$\cos.\,1' = \sqrt{1-\sin.^2 1'} = 1-\frac{1}{2}\sin.^2 1 - \frac{1}{8}\sin.^4 1'\ldots$$

$$= .\ 9999999577.$$

Cor.—Hence, it is plain that if our approximation do not extend beyond ten places of decimals,

Circular measure of angle of 1′ = sin. 1′.
Similarly, Circular measure of angle of 1″ = sin. 1″.
$\therefore$ Circular measure of angle of n'' = n sin. 1″, provided $n \angle 60$.

(61). *To calculate the Sines of* 2′ 3′ 4′. . . . .

Since $\sin.\,(A + B) + \sin.\,(A - B) = 2\cos.\,B, \sin.\,A.$
we have $\sin.\,(n + 1)' + \sin.\,(n - 1)' = 2\cos.\,1' \sin.\,n'.$
Now $\cos.\,1' = 1 - \cdot\,0000000423\ . = 1 - k.$
$\therefore \sin.\,(n + 1)' + \sin.\,(n - 1)' = 2\sin\,n' - 2k \cdot \sin.\,n'.$
$\therefore \sin.\,(n + 1)' - \sin.\,n' = \sin.\,n' - \sin.\,(n - 1)' - 2k\sin\,n'.$

This formula is very convenient for calculating the sines and cosines of successive angles. Thus,

$\text{Sin.}\,2' - \sin.\,1' = \sin.\,1' - 2k\sin.\,1'.$
$\text{Sin.}\,3' - \sin.\,2' = \sin.\,2' - \sin.\,1' - 2k\sin.\,2'$
$\text{Sin.}\,4' - \sin.\,3' = \sin.\,3' - \sin.\,2' - 2k\sin.\,3'.$

and so on. It will be observed that the first member of the right-hand side of each equation is given by the former equation. So that the only term requiring multiplication is $2k\sin.\,1'$, $2k\sin.\,2'$, $2k\sin.\,3'$ in each equation. This multiplication can be greatly facilitated by forming a table in which $2k$ is multiplied by each digit, thus :—

$2k =$	846
2	1692
3	2538
4	3384
5	4230
6	5076
7	5922
8	6768
9	7614

where the seven zeros in front of the significant digits of $2k$ are suppressed. By means of this table, which resembles that of the proportional parts in the table of logarithms, the multiplication can be performed by means of addition only. It will also be observed that in the case of the sines of the first few minutes the products of k will have more than ten zeros, and therefore can be omitted, and that under all circumstances they will have at the least seven, so that the multiplication is soon performed. Thus, suppose

$$\begin{array}{rl} \text{Sin.}\,p' = & \cdot\,3759264827 \\ 2k.\,\sin.\,p' = & \cdot\,0000000253{,}8 \\ & 59{,}3 \\ & 4{,}2 \\ & 7 \\ \hline & .0000000318 \end{array}$$

By this means we can successively obtain the sines 1′ 2′ 3′ 4′, and so on for every minute up to 45°.

(62). *To obtain the Cosines of the Angles* 2′ 3′ 4′, *&c.*

Since $\cos.\,(A + B) + \cos.\,(A - B) = 2\cos.\,A\cos.\,B.$
$\therefore \text{Cos.}\,(n + 1)' + \cos.\,(n - 1)' = 2\cos.\,1\cos.\,n'.$
Hence as before

$$\text{Cos.}\ (n+1)' - \cos.\,n' = \cos.\,n' - \cos.\,\overline{n-1}' - 2k\cos.\,n'.$$

or, since the cosine continually decreases,

$$\text{Cos.}\,n' - \cos.\,\overline{n+1}' = \cos.\,\overline{n-1}' + \cos.\,n' + 2k\cos.\,n'.$$

Hence

$\text{Cos.}\,1' - \cos.\,2' = \cos.\,0' - \cos.\,1' + 2k\cos.\,1'.$
$\text{Cos.}\,2' - \cos.\,3' = \cos.\,1' - \cos.\,2' + 2k\cos.\,2'.$
$\text{Cos.}\,3' - \cos.\,4' = \cos.\,2' - \cos.\,3' + 2k\cos.\,3'.$

The method of calculation is precisely similar to that of the sines. It will be further observed, that since sin. (90°— A) = cos. A, that we need not to continue the calculations of the sines and cosines of the angles beyond 45°. For example, if we know sin. 23° 15′ and cosin. 23° 15′, these are respectively cosin. 66° 45′ and sin. 66° 45′.

(63). *Simplification of calculation in case of certain Angles.*

Again, the calculation of sines and cosines of angles greater than 30° can be very much simplified ; for

$$\text{Sin.}\,(30^\circ + \theta) + \sin.\,(30 - \theta) = 2\sin.\,30^\circ\cos.\,\theta = \cos.\,\theta$$

$$\text{Since } \sin.\,30^\circ = \frac{1}{2}$$

$$\therefore \sin.\,(30^\circ + \theta) = \cos.\,\theta - \sin.\,(30^\circ - \theta)\,;$$

now if $30^\circ + \theta$ be less than 60°, then θ, and $30^\circ - \theta$ are each less than 30°. Hence by our previous calculations we know both cos. θ and sin. $(30^\circ - \theta)$, and therefore obtain sin. $(30^\circ + \theta)$ by subtraction.

Thus sin. (41°. 15′) = cos. (11°, 15′) — sin. (18°. 45′).

It is plain that by this formula we can calculate the sines of angles from 30° to 60°.

And since cos. $(60^\circ - \theta)$ = sin. $(30^\circ + \theta)$ this calculation of the sines from 30° to 60° gives the sines from 30° to 45°, and the cosines from 45° to 30° ; which is what we want to complete the tables from 0 to 45°. Thus if we calculate by the preceding formula, sin. (51°. 33′), this is the same thing as cos. (38°. 27′).

(64). *Method of checking the calculation.*

It will be observed, that according to the method above given, the sine of a given number of degrees or minutes is inferred from the sine of the number preceding. Hence, if an error be made at any one point, say in sin. 3° 15′, it will be propagated into the sines of every succeeding angle ; to arrest the progress of any such error, as well as to verify the correctness of the calculations, at different points of their progress, when no such errors exist, it is usual to interpose the values of any such terms as can be calculated by independent methods. Thus we have already seen that the sines, &c., of the angles 15°. 30°. 45° ... can be readily expressed, as well as those of 18°. 36°. 54°...* And that hence we can obtain the sines, &c., of an angle of 3°. These and others will act as *stops* in the series, and also serve to verify the accuracy of the calculation up to the point where they are inserted.

(65). *The calculation of Tangents and Cotangents.*

By the methods now explained we can calculate the natural sines and cosines of all angles from 0° to 90° for every minute of a degree. The natural tangents of angles between 0° and 45° can be obtained by simple division, since tan. $\theta = \frac{\sin.\ \theta}{\cos.\ \theta}$ From 45° up to 90° we can obtain the tangent by the formula,

$$\text{Tan. } (45° + \theta) = 2 \tan.\ 2\,\theta + \tan.\ (45° - \theta.)$$

To prove this formula.

$$\text{Tan. } (45° + \theta) - \tan.\ (45° - \theta) = \frac{\sin.\ (45° + \theta)}{\cos.\ (45° + \theta)} - \frac{\sin.\ (45° - \theta)}{\cos.\ (45° - \theta)}$$

$$= \frac{\sin.\ (45° + \theta) \cos.\ (45° - \theta) - \sin.\ (45° - \theta) \cos.\ (45° + \theta)}{\cos.\ (45° + \theta) \cos.\ (45° - \theta)}$$

$$= \frac{\sin.\ 2\,\theta}{\cos.\ (45° - \theta) \cos.\ (90° - 45° - \theta)}$$

$$= \frac{2 \sin.\ 2\,\theta}{2 \cos.\ (45° - \theta) \sin.\ (45° - \theta)}$$

$$= \frac{2 \sin.\ 2\,\theta}{\cos.\ (90° - 2\,\theta)} = \frac{2 \sin.\ 2\,\theta}{\cos.\ 2\,\theta}$$

$$= 2 \tan.\ 2\,\theta$$

$$\therefore \tan.\ (45° + \theta) = 2 \tan.\ 2\,\theta + \tan.\ (45° - \theta)$$

Since θ is less than 45°. $2\,\theta$ is less than $45° + \theta$. and hence, whatever be the value of θ, we shall have already calculated tan. $2\,\theta$. before we need tan. $2\,\theta$. for the determination of tan. $(45° + \theta)$.

$$\text{Thus} \quad \tan.\ 81° = 2 \tan.\ 72° + \tan.\ 9°$$

where before we calculate tan. 81° we shall already have calculated tan. 72°.

It is plain that if we know the tangents of angles from 0° to 90°, we also know the cotangents of the angles from 90° to 0°.

(66). *Formulas of verification.*

There are many formulas by which the accuracy of the tables, when calculated, can be tested. The following are some of them :

(1). $\text{Cos. } \theta = \sin.\ (30° + \theta) + \sin.\ (30° - \theta)$.

(2). $\text{Sin. } \theta + \sin.\ (72° + \theta) - \sin.\ (72° - \theta) = \sin.\ (36° + \theta) - \sin.\ (36° - \theta)$.

(3). $\text{Cos. } (90° - \theta) + \cos.\ (18° - \theta) - \cos.\ (18° + \theta) = \cos.\ (54° - \theta) - \cos.\ (54° + \theta)$.

The student will readily verify these formulas if he remember the numerical values found in previous articles for the sines, &c., of 18°.†

(67). *Another method of calculating Tables of natural Sines and Cosines.*

Besides the method already given for calculating the natural sines and cosines of angles, there is another more convenient than that. The following is an account of this second method.

We have $$\text{Sin. } x = x - \frac{x^3}{1.2.3} + \frac{x^5}{1.2.3.4.5} - \&c. \ldots\ldots$$

Now suppose x to be an angle $= \frac{m}{n} \cdot \frac{\pi}{2}$. Then

$$\text{Sin. } \frac{m}{n} \cdot \frac{\pi}{2} = \frac{m}{n} \cdot \frac{\pi}{2} + \left(\frac{m}{n}\right)\left(\frac{\pi}{2}\right)^5 \times \frac{1}{120} + \left(\frac{m}{n}\right)^9 \left(\frac{\pi}{2}\right)^9 \frac{1}{362880} + \ldots\ldots - \left\{ \left(\frac{m}{n}\right)^3 \left(\frac{\pi}{2}\right)^3 \frac{1}{6} + \left(\frac{m}{n}\right)^7 \left(\frac{\pi}{2}\right)^7 \frac{1}{5040} + \cdots\cdots \right\}$$

Now we have already seen that $\frac{\pi}{2} = 1{\cdot}570796326794897$.

Hence if we reduce the coefficients of $\frac{m}{n} \cdot \left(\frac{m}{n}\right)^3 \ldots\ldots$ to numbers, we have

$$\text{Sin. } \frac{m}{n} \cdot 90°$$

$$= \frac{m}{n} \times 1.570796326794897 - \left(\frac{m}{n}\right)^3 \times 0.645964097506246$$

$$+ \left(\frac{m}{n}\right)^5 \times 0.079692626246167 - \left(\frac{m}{n}\right)^7 \times 0.004681754135319$$

$$+ \left(\frac{m}{n}\right)^9 \times 0.000160441184787 - \left(\frac{m}{n}\right)^{11} \times 0.000003598843235$$

$$+ \left(\frac{m}{n}\right)^{13} \times 0.000000056921729 - \left(\frac{m}{n}\right)^{15} \times 0.000000000668804$$

$$+ \left(\frac{m}{n}\right)^{17} \times 0.000000000006067 - \left(\frac{m}{n}\right)^{19} \times 0.000000000000044$$

$$+ \&c. \ldots$$

A similar formula can be calculated for cos. $\frac{m}{n} \cdot 90°$ It will be observed that $\frac{m}{n}$ is always a fraction less than $\frac{1}{2}$, since we only require the sines and cosines of angles less than 45°. Hence these series converge very rapidly, and from them we can easily calculate the sines and cosines for each degree from 1° up to 45°. When these are known, the sines and cosines of the angles for intervals of 1′, or if necessary 10″ or of 1″, can be found by the "method of interpolations."

The method of interpolations involves mathematics of a higher order than is admissible in an elementary course. The advanced reader will find an account of the application of this method to the calculation of Tables of natural sines and cosines in Airy's *Treatise on Trigonometry*, in the *Encyclopædia Metropolitana.*

Calculation of Logarithmic Sines, &c.

We now proceed to give an account of the method of constructing Tables of the logarithms of sines, cosines, &c., of angles.

N. B.—The sines and cosines of angles are never greater than 1. Consequently their logarithms are negative. The numbers printed in the tables are always the logarithms of the sines, &c., with 10 added to them ; thus if L denote the tabular logarithm, and *log.* the ordinary logarithm

$$\text{L. sin. } \theta = \log.\ \sin.\ \theta + 10.$$

This notation will be observed throughout the following pages.

The Tables may be constructed by calculating the logarithms of the natural sines and cosines. And then as we have already found the natural sines and cosines of angles for intervals of 1′ from 0° to 45°, this table will give us the log. sines, and cosines for intervals of 1′ from 0° to 45°.

They are, however, more generally calculated by an independent process, of which the following is an account :

(68). *To obtain an expression for* log. sin. $\frac{m}{n} \cdot 90°$ *in a form adapted for calculation.*

We have already seen (page 634) that

$$\text{Sin. } x = x \left(1 - \frac{x^2}{\pi^2}\right)\left(1 - \frac{x^2}{2^2\,\pi^2}\right)\left(1 - \frac{x^2}{3^2\,\pi^2}\right)\left(1 - \frac{x^2}{4^2\,\pi^2}\right)$$

---

* See *ante*, p. 621.

† See *ante*, p. 621.

hence

$$\text{Sin.}\,\frac{m}{n}.\frac{\pi}{2}=\frac{m}{n}.\frac{\pi}{2}.\left(1-\frac{m^2}{4n^2}\right)\left(1-\frac{m^2}{4^2n^2}\right)\left(1-\frac{m^2}{6^2n^2}\right)\left(1-\frac{m^2}{8^2n^2}\right)$$

taking the logarithms on both sides.

$$\text{Log. sin.}\frac{m}{n}.\frac{\pi}{2}=\text{log.}\,\frac{m}{n}+\text{log.}\,\frac{\pi}{2}+\text{log.}\,\frac{4n^2-m^2}{4n^2}+\text{log.}\left(1-\frac{1}{4^2}.\frac{m^2}{n^2}\right)+\text{log.}\left(1-\frac{1}{6^2}.\frac{m^2}{n^2}\right)+\text{log.}\left(1-\frac{1}{8^2}.\frac{m^2}{n^2}\right)+\ldots$$

$$=\text{log. } m-\text{log. } n+\text{log. }\pi-\text{log. }2+\text{log. }(4m^2-m^2)-\text{log. }4n^2$$

$$-M\left(\frac{1}{4^2}\frac{m^2}{n^2}+\frac{1}{2}.\frac{1}{4^4}.\frac{m^4}{n^4}+\frac{1}{3}\frac{1}{4^6}.\frac{m^6}{n^6}+\ldots\right)$$

$$-M\left(\frac{1}{6^2}.\frac{m^2}{n^2}+\frac{1}{2}.\frac{1}{6^4}.\frac{m^4}{n^4}+\frac{1}{3}.\frac{1}{6^6}.\frac{m^6}{n^6}+\ldots\right)$$

$$-M\left(\frac{1}{8^2}.\frac{m^2}{n^2}+\frac{1}{2}.\frac{1}{8^4}.\frac{m^4}{n^4}+\frac{1}{3}.\frac{1}{8^6}.\frac{m^6}{n^6}+\ldots\right)$$

$$-\&c.$$

Where M is the modulus of the common logarithms.

$$\therefore\ \text{Log. sin.}\,\frac{m}{n}.\frac{\pi}{2}=$$

$$\text{log. } m+\text{log. }(2n-m)+\text{log. }(2n+3)-3\text{ log. } n+\text{log. }\pi-\text{log. }8.$$

$$-M\left(\frac{1}{4^2}+\frac{1}{6^2}+\frac{1}{8^2}+\frac{1}{10^2}+\ldots\ldots\right)\frac{m^2}{n^2}$$

$$-\frac{M}{2}\left(\frac{1}{4^4}+\frac{1}{6^4}+\frac{1}{8^4}+\frac{1}{10^4}+\ldots\ldots\right)\frac{m^4}{n^4}$$

$$-\frac{M}{3}\left(\frac{1}{4^6}+\frac{1}{6^6}+\frac{1}{8^6}+\frac{1}{10^6}+\ldots\ldots\right)\frac{m^6}{n^6}-\&c.$$

Now log. π — log. 8 = 9·594059885702190 — 10
And M = ·434294481903252

Hence reducing the coefficients of $\frac{m^2}{n^2}, \frac{m^4}{n^4}\cdots\cdot$ to numbers (in the same manner as we calculated the value of π in article 53), and remembering that L. sin. $\frac{m}{n}$ 90° = log. sin. $\frac{m}{n}$ 90° + 10 we obtain

$$\text{L. sin.}\frac{m}{n}\cdot 90^\circ=\text{log. } m+\text{log. }(2n-m)+\text{log. }(2n+m)-3\text{ log. } n.+9{\cdot}594059885702190.$$

$$-\frac{m_2}{n^2}\times 0{\cdot}070022826605902-\frac{m^4}{n^4}\times 0{\cdot}001117266441662$$

$$-\frac{m^6}{n^6}\times 0{\cdot}000039229146454-\frac{m^8}{n^8}\times 0{\cdot}000001729270798$$

$$-\frac{m^{10}}{n^{10}}\times 0{\cdot}000000084362986-\frac{m^{12}}{n^{12}}\times 0{\cdot}000000004348716$$

$$-\frac{m^{14}}{n^{14}}\times 0{\cdot}000000000231931-\frac{m^{16}}{n^{16}}\times 0{\cdot}000000000012659$$

$$-\frac{m^{18}}{n^{18}}\times 0{\cdot}000000000000703-\frac{m^{20}}{n^{20}}\times 0{\cdot}000000000000040$$

$$-\&c.$$

It can be proved in the same manner, by means of the expression

$$\text{Cos. } x=\left(1-\frac{4x^2}{\pi^2}\right)\left(1-\frac{4x^2}{9\pi^2}\right)\ldots\ldots\text{ that}$$

L cos. $\frac{m}{n}$90° = 10 + log. $(n-m)$ + log. $(n+m)$ — 2 log. n + terms involving $\frac{m^2}{n^2}, \frac{m^4}{n^4}$ &c., similar to those in L. sin. $\frac{m}{n}$90°

By means of the former of these expressions we may calculate logarithmic sines of angles from 45° to 90°, or by means of the latter logarithmic cosines of angles from 0° to 45°, which clearly comes to the same thing. We can then calculate remaining logarithms by means of the formula

L. sin. A = L. sin. 2A — L. cos. A + 9·698970004336019

To prove this formula

Since sin. 2A = 2 sin. A cos. A
log. sin. 2A = log. 2 + log. sin. A + log. cos. A
∴ L. sin. 2A = L. sin. A + L. cos. A + log. 2 — 10.
And 10 — log. 2 = 9·698970004336019.

Hence the formula.

We may also employ the formula for L sin. $\frac{m}{n}$ 90° to calculate the L. sines for angles of large intervals, as for 1° 2° 3° . . . . and then apply the method of interpolations referred to in article 67.

(69). *Explanations.*

If we take a table of logarithms of numbers we shall observe that the numbers run quite regularly, viz., 10000, 10001, 10002, &c., and the corresponding logarithms are entered in the table. But if we take a table of logarithms of sines, &c., we shall find that the logarithms of the sines and tangents of small angles are given for much smaller divisions of the angle than of the larger angles. Thus, in Hülsse's edition of *Vega's Tables*, we find the logarithmic sines, cosines, tangents, and cotangents for every minute from 6° 0′ up to 45° 0′, while they are given for every 10″ from 0° 0′ 0″, up to 6° 0′ 0″; and to this general table are prefixed two others, the former giving the sines and tangents for every tenth part of a second from 0° 0′ 0″ up to 0° 0′ 59″.9, the latter giving the sines and tangents for intervals of 1″ from 0° 0′ 0″ up to 1° 29′ 59″; the need for these minute calculations appears from the following considerations:—

To show that

$$\text{L. sin.}(\theta+n'')-\text{L.sin.}\,\theta\doteq Mn\,\text{sin. }1''\text{cotan.}\theta\left(1-\frac{n\,\text{sin. }1''}{\text{sin. }2\,\theta}\right)$$

where n is a small number,
we have

$$\text{Log. sin. }(\theta+\delta)-\text{log. sin. }\theta=\text{log. }\frac{\text{sin. }(\theta+\delta)}{\text{sin. }\theta}$$

$$=\text{log. }(\text{cos. }\delta+\text{cotan. }\theta\text{ sin. }\delta).$$

Now if δ be small, so that we may omit δ^3 . . . . *

---

* In this and the following articles are several instances of approximation which must be carefully attended to. We say if δ be so small that we may omit δ^3 and all the higher powers of δ, then cos. $\delta = 1-\frac{\delta^2}{2}$ and sin. $\delta=\delta$. For this, see cor. to article (50).

We then obtain

$$\text{log. sin. }(\theta+\delta)-\text{log.sin. }\theta=M\left\{\left(\text{cotan. }\theta.\,\delta-\frac{1}{2}\delta^2\right)-\frac{1}{2}\left(\text{cotan. }\theta.\delta-\frac{\delta^2}{2}\right)^2\right\}$$

$$\text{which is of course}=M\left(\text{cotan. }\theta.\delta-\frac{\delta^2}{2}-\frac{1}{2}\delta^2\text{ cotan.}^2\,\theta+\frac{1}{2}\text{cotan. }\theta.\,\delta^3-\frac{\delta^4}{8}+\&c.\right)$$

$$\text{which }=M\left\{\text{cotan. }\theta.\delta-\frac{1}{2}.\delta^2\,(1+\text{cotan.}^2\,\theta)\right\}$$

if we omit δ^3, δ^4, &c., and hence the result of the text.

So again in another article. If we omit θ^4, and all higher powers of θ, we have

$$\text{sin. }\theta=\theta-\frac{\theta^3}{6}\qquad\therefore\quad\frac{\text{sin. }\theta}{\theta}=1-\frac{\theta^2}{6}$$

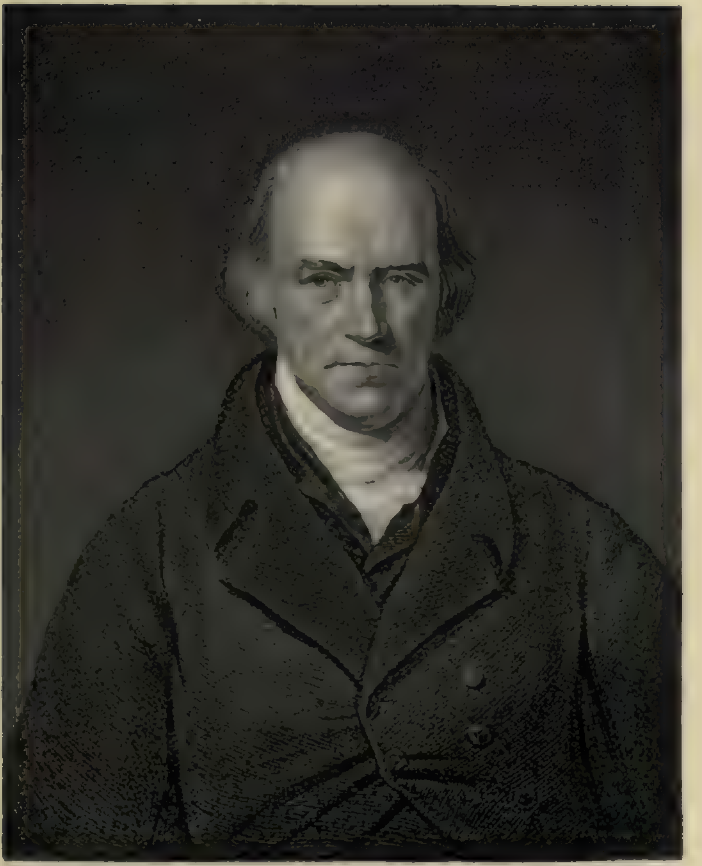
$$\text{Now }\left(1-\frac{\theta^2}{6}\right)^{\frac{1}{3}}=1-\frac{1}{3}.\frac{\theta^2}{2}-\frac{1}{9}.\left(\frac{\theta^2}{2}\right)^2\&c.$$

$$=1-\frac{\theta^2}{6}-\frac{\theta^4}{36}\&c.$$

by the Binomial Theorem

$$\therefore\left(1-\frac{\theta^2}{2}\right)^{\frac{1}{3}}=1-\frac{\theta^2}{6}\text{ if we omit }\theta^4\,\&c.$$

$$\therefore\frac{\text{sin. }\theta}{\theta}=\left(1-\frac{\theta^2}{2}\right)^{\frac{1}{3}}=\left(\text{cos. }\theta\right)^{\frac{1}{3}}$$



DAVIES GILBERT ESQ. M.P. P.R.S.

Davies Gilbert

$$\text{we have cos. } \delta = 1 - \frac{\delta^2}{2} \text{ and sin. } \delta = \delta.$$

$$\therefore \log.\sin.(\theta+\delta) - \log.\sin.\theta = \log.\left(1 + \text{cotan.}.\theta\delta - \frac{\delta^2}{2}\right)$$

$$\text{Now } \log.(1+x) = \text{M.}\left(x - \frac{x^2}{2} + \frac{x^3}{3} - \&\text{c.}\right)$$

$$\therefore \log.\sin.(\theta+\delta) - \log.\sin.\theta.$$

$$\text{M.}\left\{\left(\text{cotan.}\theta.\delta - \frac{\delta^2}{2}\right) - \frac{1}{2}\left(\delta\,\text{cotan.}\,\theta - \frac{\delta^2}{2}\right)^2 \cdots\right\}$$

$$= \text{M.}\left(\delta\,\text{cotan.}\,\theta - \frac{1}{2\sin.^2\theta}\cdot\delta^2\right) \text{ omitting } \delta^3 \cdots$$

$$= \text{M. } \delta\,\text{cotan.}\,\theta\left(1 - \frac{\delta}{\sin.\,2\,\theta}\cdot\right).$$

Now if δ be an angle of n'' then δ the circular measure of this angle, equals $n.\sin.1''$.

$$\therefore \text{L. sin. }(\theta+n'') - \text{L. sin. }\theta = \text{M}\,n\,\sin.1''\ \text{cotan.}\,\theta \times \left(1 - \frac{n\sin.1''}{\sin 2\ \theta}\right). \ (60).$$

In like manner we may prove that

$$\text{L. tan. }(\theta+n'') - \text{L. tan. }\theta = \frac{\text{M}\,n\,\sin.\,1''}{\cos.^2\theta} \times \left(1 - n\sin.\ 1''\tan.\ \theta\right)$$

Now suppose that our tables are calculated for angles that differ by so small an angle δ'', that we can neglect the second term of Equation (60) so that

$$\text{L. sin. }(\theta+\delta'') - \text{L. sin. }\theta = \text{M}\,\delta\,\sin.\,1''\,\text{cotan. }\theta.$$

Also, if $n < \delta$, *à fortiori*,

$$\text{L. sin. }(\theta+n'') - \text{L. sin. }\theta = \text{M}\,n\,\sin.\,1''\,\text{cotan. }\theta.$$

Now, for any value of θ the Tables give us

$\text{L. sin. }(\theta+\delta'') - \text{L. sin. }\theta$ call this $\triangle$

$$\therefore \qquad \triangle = \text{M}\,\delta\,\sin\ 1''\,\text{cotan. }\theta.$$

$$\therefore \text{L. sin. }(\theta+n'') - \text{L. sin. }\theta = \frac{n}{\delta}\triangle$$

i.e., when two angles are nearly equal, difference between log. sines is proportional to the difference of angles.

Now $\frac{\triangle}{\delta}$ is the difference corresponding to $1''$. This can easily be multiplied by n. Also L. sin. θ is given by the Tables, and hence we can find L. sin. $(\theta + n'')$ and conversely having given L. sin. $(\theta + n'')$, where only L. sin. θ is given in tables, we can easily find the n seconds.

If the numerical values of formula (60) are taken for different angles, it will be found that in order to make the difference between two consecutive L. sines, given in the Tables proportional to the number of seconds, we must have $\delta = 1''$ from 0° up to 1°. 30′., and $\delta = 10''$ from 1°. 30′ up to 5°, and $\delta = 60''$ from 5° upward—the log. sines being calculated to 7 places of decimals.*

The practical mode of employing the Tables will be readily understood from the following examples :—

Thus, : (1). Find L. sin. (15° 11′ 16″ · 5).

By tables . . . . . . L. sin. 15° 11′ = 9·4181495

Do. diff. 1″ = 77, 55 × 10″ = 775, 5

6″ = 465, 3

·5 = 38, 7

L. sin. (15° 11′ 16″ · 5) = 9·4182775

(2). Find L. sin. (3° 19′ 37″ · 4).

By tables . . . . . . L. sin. (3° 19′ 30″) = 8·7634252

Do. diff, 1″ = 362.3 × 7″ = 2534, 1

4 = 144, 9

L. sin. (3° 19′ 37″ · 4) = 8·7636931

(3). Find θ. If L. sin. θ = 9·7645827

L. sin. θ = 9·7645827

L. sin. (35° 33′) = 9·7644849

978

Diff. 1″ = 29·45 × 30 893·5

84·5

2 58·9

25·6

·8 23·56

$\therefore \theta = 35°.\ 33'.\ 32''.8.$

We proceed in precisely the same manner with the logarithms of the other trigonometric functions, with this exception, that what is true of the L. sines and L. tangents of small angles, is true of the L. cosines and L. cotangents of angles which are nearly equal to 90°. For, since sin. θ = cos. $(90 - \theta)$ and tan. θ = cotan. $(90 - \theta)$, then if θ be small, $90° - \theta$ is nearly equal to 90°.

(71). *Another way of treating the L. sines of small angles.*

If the tables give the log. sines, *&c.*, for intervals of 1′ throughout, and not the refined tables for small angles before spoken of, we can find the accurate value of a small angle whose L. sine is given, and *vice versâ*, by the following process.

If θ be small, so that we can omit θ^4 θ^5, *&c.*, we have (Art. 50)

$$\sin.\ \theta = \theta - \frac{\theta^3}{6}.$$

$$\&\ \cos.\ \theta = 1 - \frac{\theta^2}{2}$$

$$\text{Hence} \qquad \frac{\sin.\ \theta}{\theta} = 1 - \frac{\theta^2}{6} = \left(1 - \frac{\theta^2}{2}\right)^{\frac{1}{3}} = \cos.^{\frac{1}{3}}\theta$$

Now suppose θ to contain n'' $\therefore \theta = n\sin.\ 1''$

$$\therefore \frac{\sin.\ \theta}{n\sin.\ 1''} = \cos.^{\frac{1}{3}}\theta$$

$$\therefore \log.\sin.\theta - \log.n. - \log.\sin.1'' = \frac{1}{3}\log.\cos.\theta$$

$$\therefore \text{L. sin. }\theta - \log.n - \text{L. sin. }1'' = \frac{1}{3}.\text{L.cos. }\theta - \frac{10}{3}$$

$$\therefore \text{L. sin. }\theta = \log.n + \frac{1}{3}\text{L. cos. }\theta + \text{L. sin. }1'' - \frac{10}{3}$$

$$\&\ \ \text{L. sin. }1'' = 4{\cdot}6855749.$$

$$\therefore \text{L. sin.} = \log.n + \frac{1}{3}\text{L. cos }\theta + 1{\cdot}3522416$$

$$\text{and } \log.n = \text{L. sin. }\theta - \frac{1}{3}.\text{L. cos. }\theta - 1{\cdot}3522416$$

It is to be observed, that when θ is very small, cos. θ changes very slowly. Hence in the term L. cos. θ we may use the number of minutes in θ, omitting the odd seconds, and then, the former formula gives us L. sin. θ, when θ or n'' is given, and the latter gives us the n'' when L. sin. θ is given.

---

* See Tables at page 666, *et seq.*

For instance,

Find θ, having given that L. sin. = 7.2777613. On looking into Tables we find that θ is between 6′ and 7′, hence in this case cos. θ = cos. 6′

$$\begin{array}{lrl} & \text{L. sin.}\,\theta & = 7{\cdot}2777613 \\ & -\tfrac{1}{3}\,\text{L. cos.}\,6' & = 6{\cdot}6666668-10. \\ & -+1{\cdot}3522416 & = \underline{8{\cdot}6477584}-10. \\ & & \ 2{\cdot}5921865 \\ & & \ \underline{\ {\cdot}5921768} \\ 391.00 & & \qquad\quad 97 \\ 8 & & \qquad\quad 90 \\ \underline{6} & & \qquad\quad \overline{7.} \\ 391.0086 = n. & & \therefore \theta = 6',\ 31''\ .0086 \end{array}$$

If we find n'' by more refined tables

$$\begin{array}{rl} \text{L. sin.}\,\theta & = 7{\cdot}2777613 \\ \text{L. sin.}\,6'.31'' & = \underline{7{\cdot}2777514} \\ & \quad 99{,}00 \\ & \quad \underline{75{,}21} \qquad 1 \\ & \quad 23{,}790 \\ & \quad \underline{22{,}563} \qquad 3 \end{array}$$

$\therefore \theta = 6'.31''.013.$

$\therefore$ by this method $\quad n = 391{\cdot}013$

which does not differ materially from the result we obtained by the less refined table and the formula.

Find L. sin. θ when $\theta = 7'.31''.37$.

$$\begin{array}{ll} \text{Here} \quad n = 451.37 & \text{L. cos.}\,\theta = \text{L. cos.}\,7' \\ \text{L. sin.}\,\theta = \log.\,n & = 2{\cdot}6545327 \\ +\dfrac{1}{3}\,\text{L. cos.}\,7' & = 3{\cdot}3333330 \\ +1{\cdot}3522416 & = \underline{1{\cdot}3522416} \\ & \ 7{\cdot}3401073 \end{array}$$

The more refined tables give us at once

$$\begin{array}{lrcr} & \text{L. sin.}\,7'31'' & = & 7{\cdot}3397511 \\ \text{Diff. } 1'' = 9619 \times & {\cdot}3 & = & 2885{,}7 \\ & {\cdot}07 & = & \underline{673{,}33} \\ & & & 7{\cdot}3401070 \end{array}$$

In like manner if we have θ so small an angle that $\theta^4\,\theta^6$ . . . may be omitted, and if θ be an angle of n seconds,

$$\tan.\,\theta = \frac{\sin.\,\theta}{\cos.\,\theta} = \frac{\theta - \dfrac{\theta^3}{6}}{1 - \dfrac{\theta^2}{2}} = \left(\theta - \frac{\theta^3}{6}\right)\left(1 + \frac{\theta^2}{2}\right)$$

$$\therefore \frac{\tan.\,\theta}{\theta} = 1 + \frac{1}{3}\,\theta^2 = \left(1 - \frac{\theta^2}{2}\right)^{-\frac{2}{3}} = (\cos.\,\theta)^{-\frac{2}{3}}.$$

$$\therefore \log.\,\tan.\,\theta - \log.\,n\,\sin.\,1'' = -\frac{2}{3}.\,\log.\,\cos.\,\theta$$

$$\text{L. } \tan.\,\theta = \log.\,n + \text{L. sin. } 1'' + \frac{2}{3}.\,(10 - \text{L. cos. } \theta).$$

$$\text{L. } \tan.\,\theta = \log.\,n + 11{\cdot}3322416 - \frac{2}{3}\,\text{L. cos. } \theta.$$

This formula can be used in the same manner as the one for L. sin. θ.

(72). *Delambre's method for L. sines of small Angles.*

There is another method of treating the L sines of small angles, of which the following is an account.

$$\text{Sin. } \theta = \theta - \frac{\theta^3}{6} + \frac{\theta^5}{120} - \text{\&c.}$$

$$\therefore \log.\,\frac{\sin.\,\theta}{\theta} = \log.\,\left\{1 - \left(\frac{\theta^3}{6} - \frac{\theta^4}{120}\right)\right\} \cdot \text{Omitting } \theta^5$$

$$= -\,\text{M}\left\{\left(\frac{\theta^2}{6} - \frac{\theta^4}{120}\right) + \frac{1}{2}\left(\frac{\theta^2}{6} - \frac{\theta^4}{120}\right)^2 + \ldots .\right\}$$

$$= -\,\text{M}\left(\frac{\theta^2}{6} + \frac{\theta^4}{180}.\right)$$

From this a table for $\log.\,\dfrac{\sin.\,\theta.\,\sin.\,1''}{\theta}$ can easily be calculated. Now suppose θ to contain n''

Then $\quad n\,\sin.\,1'' = \theta$

$$\therefore \quad \frac{\sin.\,n''}{n} = \frac{\sin.\,\theta.\,\sin.\,1''}{\theta}$$

$$\therefore \quad \text{L. sin. } n'' = \log.\,n + \text{L.}\,\frac{\sin.\,\theta.\,\sin.\,1''}{\theta}$$

and since $\text{L.}\,\dfrac{\sin.\,\theta.\,\sin.\,1''}{\theta}$ is given by the Tables, if we know n we can at once find L. sin. n''. And conversely if we have given L. sin. θ, we can find n; for sin. $\theta = \theta = n$ sin. 1″ nearly. $\therefore$ log. n = L. sin. θ — L. sin. 1″ nearly, whence we know n approximately. This will enable us to obtain the value of $\log.\,\dfrac{\sin.\,\theta.\,\sin.\,1''}{\theta}$ from the Tables with sufficient accuracy; which being known, we have $\log.\,n = \text{L. sin. } \theta - \log.\,\dfrac{\sin.\,\theta\,\sin.\,1''}{\theta}$, which gives us n accurately.

It can easily be shown, that in calculating tables for $\log.\,\dfrac{\sin.\,\theta}{\theta}$ from the formula,

$$\log.\,\frac{\sin.\,\theta}{\theta} = -\,\text{M}\left(\frac{\theta^2}{6} + \frac{\theta^4}{180}.\right)$$

that for tables of seven places of decimals up to 5°, θ^4 can be omitted.

For when θ is an angle of 5°, $\theta = \dfrac{5\,\pi}{180}$

$$\therefore \text{M}\,\frac{\theta^4}{180} = \text{M}\,\frac{5^4\,\pi^4}{(180)^5} = .0000001{,}39927 \ldots$$

Let us now look back and consider what we have done in the previous pages. (1). We have investigated the various general relations existing between the trigonometrical functions. (2). We have investigated the general relations existing between the sides and angles of triangles. (3). We have fully discussed the mode of constructing trigonometrical tables, *i. e.*, the means of obtaining numerical results from our trigonometrical formulas.

We now proceed to the actual numerical calculation of the sides and angles of triangles, which we shall find will invariably consist in reducing formulas to numbers. For instance,

Given sin. $(m + x)$ — sin. $(m - x)$ = cos. $(m - n)$ — cos. $(m + n)$

Find x when $m = 12°\cdot 13'$ and $n = 7°\cdot 37'$.

$$\begin{array}{ll} \text{Since} & \sin.\,(m + x) - \sin.\,(m - x) = 2\,\sin.\,x\,\cos.\,m \\ \text{and} & \cos.\,(m - n) - \cos.\,(m + n) = 2\,\sin.\,m\,\sin.\,n. \\ & \therefore 2\,\sin.\,x\,\cos.\,m = 2\,\sin.\,m.\,\sin.\,n. \\ & \therefore \sin.\,x = \tan.\,m.\,\sin.\,n. \\ & \therefore \log.\,\sin.\,x = \log.\,\tan.\,m + \log.\,\sin.\,n. \\ & \therefore \log.\,\sin.\,x + 10 = \log.\,\tan.\,m. + 10 + \log. \\ & \quad \sin.\,n + 10 - 10 \\ \text{and} & \therefore \text{L. sin. } x = \text{L. tan. } m. + \text{L. sin. } n - 10. \\ & \text{L. tan. } m = 9{\cdot}3354823 \\ & \text{L. sin. } n = \underline{9{\cdot}1223624} - 10 \\ & \qquad\qquad 8{\cdot}4578447 \\ \text{L. sin. } 1°\ 38'\cdot 40'' & \qquad\qquad \underline{8{\cdot}4578369} \\ & \qquad\qquad\quad 78 \\ \text{diff. } 1'' = 732{,}8 \times {\cdot}1 & \qquad\qquad\quad \underline{73{\cdot}28} \end{array}$$

Ans. $x = 1°.\,38'.\,40''.\,1.$

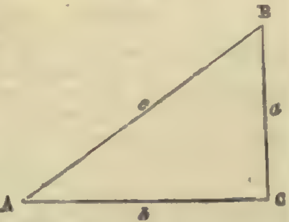
CHAPTER XIII.

THE NUMERICAL SOLUTION OF RIGHT-ANGLED TRIANGLES.

THE parts of a right-angled triangle are the three sides, two angles and the right angle; if any two of the former five, one of the two being a side, are given, we can calculate the remaining three. The following are the methods employed in the various cases, which are these.

(1). Given the base and perpendicular.
(2). Given the hypothenuse and another side.
(3). Given the base or perpendicular and an angle.
(4). Given the hypothenuse and an angle.

Fig. 23.



(1). *Given the Base and Perpendicular; i. e., given a. b. find A. B. c.*

$\tan. A = \frac{a}{b}$ gives A.

$B = 90° - A$. Gives B.

$\text{Cos. } A = \frac{b}{c}$.

or $c = \frac{b}{\cos. A}$. Gives c.

These can be put into forms adapted for logarithmic calculation, as follows :—

$$\log. \tan. A = \log. a - \log. b.$$
$$\therefore 10 + \log. \tan. A = \log. a + 10 - \log. b.$$
$$\text{or, L. } \tan. A = \log. a + \text{ar.: comp.: } \log. b. \quad (a).$$

Similarly,

$$\text{Log. } c = \log. b. - \log. \cos. A.$$
$$= \log. b. + 10 - (10 + \log. \cos. A)$$
$$= \log. b. + 10 - \text{L. } \cos. A.$$
$$\therefore \log. c = \log. b. + \text{ar.: comp.: L. } \cos. A. \quad (b).$$

(*a*) and (*b*) are the formulas actually used in calculation. Thus,

Given $a = 7564 \cdot 5$ yds. $b = 3987 \cdot 4$ yds.
Find A. B. and *c*.

To find A. from (*a*) we have,

$\text{Log. } \tan. A = \log. a + \text{ar.: comp.: } \log. b.$
$= \log. 7564 \cdot 5 = 3 \cdot 8787802$
$+ \text{ar.: comp.: } \log. 3987 \cdot 4 \quad 6 \cdot 3993102$

$10 \cdot 2780904$
$\text{L. } \tan. 62° 12' \quad 10 \cdot 2779915$

diff. for 1″ $= 51 \cdot 05) \; 989 \cdot 00 \; (19$
5105

47850
$\therefore A = 62° 12' 19'' \quad 45945$
90

and $B = 27° 47' 41''$

To find *c* we have,

$\text{Log. } c = \log. b + \text{ar.: comp.: L. } \cos. A$
$\log. b = 3 \cdot 6006898$
$\text{ar.: comp.: L } \cos. 62° 12' 19'' = \text{ar.: comp.: } 9 \cdot 6686623 = \cdot 3313377$

$3 \cdot 9320275$
$8551 \cdot 2 \quad \cdot 9320271$
$08 \text{ diff.} = 4$

$\therefore c = 8551 \cdot 208$

(2). *Given the Hypothenuse and another side.*

e. g., given *a c* to find A B and *b*.

We have. $\sin. A = \frac{a}{c}$.

$$\therefore \log. \sin. A = \log. a - \log. c.$$
$$\therefore \text{L. } \sin. A = \log. a + \text{ar.: comp.. } \log. c \quad (a)$$

which gives A and ∴ B which equals 90° — A.

Again $\cos. A = \frac{b}{c}$.

$$\therefore \quad b = c \cos. A.$$
$$\therefore \quad \log. b = \log. c + \text{L. } \cos. A - 10. \quad (b)$$

Ex. Given $a = 724 \cdot 5$. $c = 1005 \cdot 4$.
We shall have $A = 46° 6' 17''$. $B = 43° 53' 43''$.
$b = 697 \cdot 086$.

(3). *Given the Base or Perpendicular and an Angle.*

e. g., given *a*. A., find B. *b*, *c*.

We have $B = 90° - A$.

Again $c = \frac{a}{\sin. A}$

$$\therefore \log. c = \log. a - \log. \sin. A$$
$$\therefore \log. c = \log. a + \text{ar. : comp. : L. } \sin. A. \quad (a)$$

Again $c = \frac{b}{\cos. A}$

$$\therefore \log. b = \log. c + \text{L. } \cos. A - 10. \quad (b)$$

In using formula (*b*), it must be remembered that in the calculation of formula (*a*) we have already found log. *c*.

Example. Given $a = 7643 \cdot 5$ $A = 37°.18'$.
We shall find $B = 52°.42'$
$c = 12613 \cdot 4$
$b = 10033 \cdot 53$

(4). *Given the Hypothenuse and an Angle.*

e. g., given *c*. A, find B. *b*. *a*.

We have $B = 90° - A$.
$b = c. \cos. A$.

$$\therefore \log. b = \log. c + \text{L. } \cos. A - 10. \quad (a)$$

Again $a = c \sin. A$.

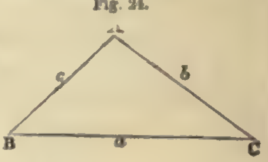
$$\therefore \log. a = \log. c + \text{L. } \sin. A - 10. \quad (b)$$

Example. Given $c = 7234 \cdot 5$ $A = 33°.19'$.
We have $B = 56°.41'$.
$b = 6045 \cdot 493$.
$a = 3973 \cdot 665$.

The cases of oblique triangles are in like manner reducible to four, viz.—

(1). Given three sides to find the angles.
(2). Given two sides and the included angle.
(3). Given two sides and the angle opposite to them.
(4). Given one side and two angles.

Fig. 24.



(1). *Given three sides to find the angles, i. e.,* given *a b. c.* to find A. B. C.

We have $2s = a + b + c$.

$$\therefore \tan.^2 \frac{A}{2} = \frac{(s-b)(s-c)}{s. (s-a)}$$

$$\therefore 2 \log. \tan. \frac{A}{2} = \log. (s - b) + \log. (s - c) - \log. s - \log. (s - a)$$

$$\therefore 2 \log. \tan. \frac{A}{2} + 20 = \log. (s-b) + \log. (s-c) + 10 - \log. s + 10 - \log. (s-a)$$

$$\therefore 2 \text{ L. } \tan. \frac{A}{2} = \log. (s - b) + \log. (s - c) + \text{ar. : comp. : } \log. s + \text{ar. : comp. } \log. (s-a)$$

This formula gives us $\frac{A}{2}$. We shall have to find B from the formula

$$2 \text{ L. } \tan. \frac{B}{2} = \log. (s-c) + \log. (s-a) + \text{ar. : comp. : } \log. s + \text{ar. : comp. : } \log. (s-b)$$

It will be observed that all the logarithms needed for finding B and C have been already used in finding A, whence, when A is known, B and C are found with very little trouble.

Instead of using the formula which gives us tan. $\frac{A}{2}$, we may use those which give sin. $\frac{A}{2}$ or cos. $\frac{A}{2}$.

Example given, $a = 490$ $b = 960$ $c = 660$ we shall find that—

$$\begin{aligned} A &= 28° \,.\, 10' \,.\, 12'' \\ B &= 112 \,.\, 20 \,.\, 40 \\ C &= 39 \,.\, 29 \,.\, 8 \end{aligned}$$

or $$A + B + C = 180 \,.\, 0 \,.\, 0$$
which circumstance is a test of the accuracy of the calculation.

(2). *Given two sides and the included Angle.*
e. g., given $a\ b\ C$, find $A\ B\ c$.

We have
$$\tan. \frac{A - B}{2} = \frac{a - b}{a + b} \tan. \frac{A + B}{2}.$$

$$\therefore \text{L} \tan. \frac{A - B}{2} = \log. (a - b) + \text{ar.: comp.: } \log. (a + b).$$
$$+ \text{L} \tan. \frac{A + B}{2} - 10. \qquad (a)$$

It must be observed that $\frac{A + B}{2} = 90° - \frac{C}{2}$ and is therefore known. Wherefore (a) gives us $\frac{A - B}{2} = a$ a known angle. Then,

$$\frac{A + B}{2} = 90 - \frac{C}{2}$$
$$\frac{A - B}{2} = a$$
$$\therefore \qquad A = 90° + a - \frac{C}{2}$$
$$\text{and } B = 90° - a - \frac{C}{2}.$$

whence A and B are known.

To find c we have
$$c = a \frac{\sin. C}{\sin. A} \qquad (b)$$

$\therefore \log. c = \log. a + \text{L} . \sin. C + \text{ar. : comp. : L} . \sin. A - 10$, which will give us c.

We may employ a subsidiary angle θ in the following manner (see Art. 40).

$$\text{Assume} \qquad \tan. \theta = \frac{a - b}{a + b} \cdot \cot\text{an}. \frac{C}{2}$$
$$\therefore c = \frac{(a + b) \sin. \frac{C}{2}.}{\cos. \theta}$$

$$\log. \tan. \theta = \log. (a - b) + \text{ar. : comp. : } \log. (a + b)$$
$$+ \log. \cot\text{an}. \frac{C}{2} - 10 \qquad (c)$$

$$\log. c = \log. (a + b) + \log. \sin. \frac{C}{2} + \text{ar. : comp. :}$$
$$\log. \cos. \theta - 10. \qquad (d)$$

By using (c) and (d) we can obtain c without first finding A and B.

If we solve by the former methods we require six logarithms, viz. : those of $(a - b)$, $(a + b)$, tan. $\frac{A + B}{2}$ sin. C., and sin A.

If by the latter we require five logarithms $(a - b)$, $(a + b)$, cotan. $\frac{C}{2}$, sin. $\frac{C}{2}$, and cos. θ; therefore the latter method possesses a slight advantage over the former.

The θ in formula (c) is evidently the same as $\frac{A - B}{2}$ in formula (a).

If $b \mathrel{\not<} a$ the formulas become
$$\tan. \frac{B - A}{2} = \frac{b - a}{b + a} \cdot \tan. \frac{A + B}{2}$$
$$\text{and} \qquad \tan. \theta = \frac{b - a}{b + a} \cdot \cot\text{an}. \frac{C}{2}.$$

Example:—Given $a = 562.$ $b = 320.$ $C = 128° 4'$

We shall find
$$\begin{aligned} A &= 33° 34' 40'' \\ B &= 18° 21' 20'' \\ c &= 800 \cdot 008. \end{aligned}$$

If we take the second method we shall find
$$\log. \tan. \theta = 9 \cdot 1258960$$
$$\therefore \log. \cos. \theta = 9 \cdot 9961568$$

And, as before, we shall find,
$$c = 800 \cdot 008.$$

(3). *Given two sides, and an Angle opposite to one of them;*
e. g., given B. b. c. find A. C. a.

$$\text{We have} \qquad \sin. C = \frac{c}{b} \cdot \sin. B.$$

$$\therefore \log. \sin. C = \log. c + \log. \sin. B + \text{ar. : comp.}$$
$$\log. b - 10 \ldots\ldots\ldots (a)$$

which gives C. Then
$$A = 180° - (B + C)$$
which gives A. Then
$$a = b \frac{\sin. A}{\sin. B}$$
or, $\log. a = \log. b + \log. \sin. A + \text{ar. : comp. :}$
$$\log. \sin. B - 10 \ \ldots\ldots (b)$$
which gives a.

N.B.—This is sometimes called the ambiguous case of a triangle; for we have sin. C given us, whence we know $C = a$, where $a \angle 90°$. Now, sin. $a = \sin. (180 - a)$ $\therefore$ C may also equal $180 - a$. Hence this equation may give us *two* triangles, one which has $C = a$, the other having $C = 180° - a$. In many cases, however, this ambiguity does not exist.

(1). $B =$ or $\mathrel{\not<} 90°$. Then $C = 180° - a$ is inadmissible, since C would then be $\mathrel{\not<} 90°$, and $B + C > 180°$, which is impossible.

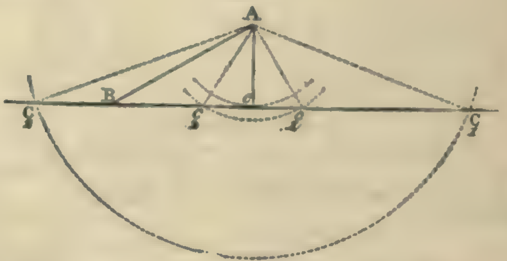
(2). If $B < 90°$. Then

- (a). If $c \sin. B = b$ then $\sin. C = 1$ or $C = 90°$, and the other value of $C = 180° - 90° = 90°$, or in this case there is no ambiguity.
- (β). If $c < b$. Then $C < B$, hence if $C = a$. $a < B$, and $180° - a + B > 180°$, or in this case the angle $180° - a$ is inadmissible, and there is no ambiguity.
- (γ). But if $c > b$. Then both $c = a$, and $c = 180° - a$ are admissible, and there are two triangles determinable from the given values, b. c. B.

This can be illustrated geometrically as follows:—

$AB = c$
$ABc = B.$

Fig. 25.



with centre A and radius b describe a circle. Then,

- (a). If $b = c \sin. B$, the circle will touch Bc in c, and the triangle will be A Bc.
- (β). If $c < b$ the circle will cut Bc, in two points $C_2\,C_1$, on *different* sides B, and the triangle is ABC_1.
- (γ). If $c > b$ the circle cuts Bc in two points c_1 c_2 on the *same* side of B, and the triangle may be either ABc_2 or ABc_1; which is the reason of this case being called ambiguous.

Example:—Given $B = 45°$ $b = 305$ $c = 219 \cdot 5$

$$\begin{aligned} \text{Then} \quad C &= 30° . 36' . 22'' \\ A &= 104° . 23' . 38'' \\ a &= 416.8344. \end{aligned}$$

(4). *Given, one side and two Angles; e.g., given, a B C, to find A. c, b.*

We have $A = 180° - (B + C)$. which gives A.

$$\text{Now,} \qquad \frac{b}{a} = \frac{\sin. B}{\sin. A} \qquad \frac{c}{a} = \frac{\sin. C}{\sin. A}.$$

$\therefore$ log. b = log. a + log. sin. B + ar.: comp.: log. sin. A — 10. and log. c = log. a + log. sin. C + ar. comp.: log. sin. A — 10. Whence we can immediately calculate b, &c.

Example:—

Given B = 49°. C = 29°. 19′ and a = 95·4, we shall find

$A = 101°. 41'$
$b = 73·52255$
$c = 47·69952$

Several practical applications of the science of Trigonometry will be found in the following chapter on Mensuration.

CHAPTER XIV.

MENSURATION.

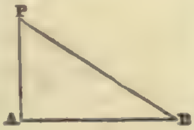
THE object of the following pages is to show the practical application of the truths investigated in previous chapters on Geometry and Trigonometry to solve a variety of questions about measurements such as may frequently occur in practical life. For instance, the determination of the area of a field, the distance between two inaccessible points, the solid content of a pyramid, and others. We shall endeavour in each instance to refer these questions to the principles on which they rest. By doing so, the attentive reader will be able to apply the same principles to cases that may occur practically, but which our limits forbid us to treat of. We shall take in order a variety of questions concerning the determination—(1), of Heights and Distances; (2), of Areas of Surfaces; (3), of Contents of Solids.

I. ON HEIGHTS AND DISTANCES.

In the following articles we are supposed to have the means of measuring the angle subtended at the eye of the observer by the line joining two points. The instrument by which this can be done is called a sextant. For measuring the angle subtended by two objects on a horizontal plane, and for determining the vertical elevation of one point above another, an instrument called a theodolite can be used.

(1). *To determine the height of a Tower standing on a Horizontal Plane, the base of which is accessible.*

Fig. 1.



Let A P be the tower. B any convenient place for the observer. At B measure the angle A B P; also measure the line A B. Then, if A P = x,

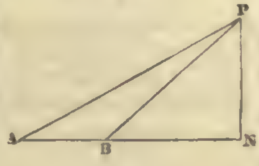
$x = a$ tan. B.

$\therefore$ log. x = log. a + L. tan. B − 10. which gives x.

N.B.—If P be the top of a steeple, half the breadth of the tower must be added to the measurement, which is made to the outside of the tower. It will be observed, moreover, that B is the place of the observer's eye, and $\therefore$ A P, or x, is the height of P, above the horizontal plane passing through the observer's eye. Hence, if h be the height of the eye above the ground, $x + h$ is the height of the summit of the tower above the ground.

(2). *To determine the height of a Tower, the base of which is inaccessible.*

Fig. 2.



Let A B N be the horizontal plane; P N the height required. At B measure angle P B N; move backward to another point, A, taking care that A and B are both on the same vertical plane passing through P, and measure A B, and the angle P A N.

Let P B N = β. P A B = a. A B = a.
B P = x. P N = y.

Now angle A P B = $(\beta - a)$

$$\therefore y = a. \frac{\sin\ a}{\sin. (\beta - a)}$$

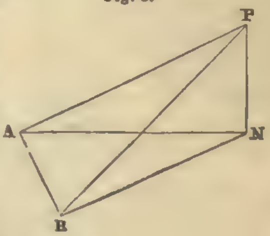
and $x = y \sin. \beta$.

$$\therefore x = a\,\frac{\sin.\ a.\ \sin.\ \beta}{\sin. (\beta - a)}$$

$\therefore$ log. x = log. a + L. sin. a + L. sin. β + ar. comp. L. sin. $(\beta - a) - 20$.

(3). *To determine the height of the Tower in the last article, when the nature of the ground does not admit of the observer moving backward.*

Fig. 3.



Let P N be the vertical height required; place pickets at two points, A and B, APN and B P N being two different vertical planes.

Measure A B = a. Let P N = x.

Measure angle P A N = a.
P A B = A P B A = B.

Then x = A P sin. a.

Now A P B = 180° − (A + B)

$$\therefore A P = a. \frac{\sin. B}{\sin. (A + B)}$$

$$\therefore x = a. \frac{\sin.\ a.\ \sin.\ B}{\sin. (A + B)}.$$

$\therefore$ log. x = log. a + L. sin. a + L. sin. B + ar. comp. L. sin. (A + B) − 20.

In the above case such an angle as P A N being the vertical elevation of P above the horizon, is measured by a theodolite. While the angle P A B, which is not in a horizontal plane, being the angle subtended by the distance between two objects, is measured by a sextant.

If the object be a long way off, we may measure the angle subtended at the eye by the line joining the object and its image in still water, by a sextant; half that angle will be the vertical elevation of the object.

Example:—We observe that the altitude of a hill is 3° 15′. On proceeding $1\frac{3}{4}$ miles towards it, its altitude is 15° 37′. Find the height of that hill, neglecting the sphericity of the earth.

Here (Fig. 2) A B = $1\frac{3}{4}$ miles.
P A B = 3° 15′.
P B N = 15° 37′.
$\therefore$ P B N − P A B = 12° 22′.

Then by the formula proved in Article (2)

$$P N = a. \frac{\sin. PBN \sin. PAB}{\sin. (PBN - PAB)}$$

$\therefore$ log. P N = log. a + L. sin. P B N + L. sin. P A B + ar. comp. L. sin. (P B N − P A B) − 20.

log. 1·75	·2430380
L. sin. 15° 37′	9·4300750
L. sin. 3° 15′	8·7535278
Ar. comp. L. sin. 12° 22′	·6692473 − 20
	1·2958881
19764	2958748
6	133
·197646 of a mile 6 =	132

or $\frac{1}{5}$ of a mile very nearly. (*Answer.*)

(4). *To find the distance between two points, one of which is accessible and the other inaccessible.*

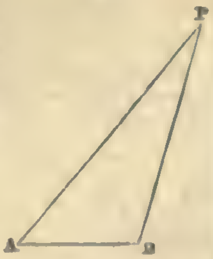


Fig. 4.

Let P be the inaccessible point.

A the accessible.

Drive a picket in at A, and drive in another at any convenient point, B.

Measure the angles P A B and P B A, also measure the line A B.

Then by the fourth case of the solution of triangles

$$\text{A P} = \text{A B}.\frac{\sin.\ \text{APB}}{\sin.\ \text{ABP}}$$

$$= \text{A B}.\frac{\sin.\ (\text{PAB} + \text{ABP})}{\sin.\ \text{ABP}}$$

$\therefore$ calling A B = a. P A B = A. A B P = B. we have

$$\log.\ \text{A P} = \log.\ a + \text{L. sin. } (\text{A} + \text{B}) + \text{ar. comp. L. sin. B} - 10.$$

(5). *To find the distance between two points neither of which is accessible.*

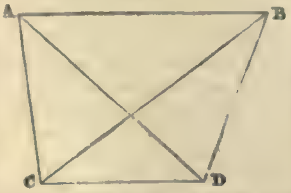

Fig. 5.

Let A, B, be the two points; place on the ground two pickets, C and D, such that the distance between C and D can be measured, and that from each of C and D, the two inaccessible points and the other picket may be visible.

Measure C D = p A C B = C B C D = C′ A D B = D A D C = D′

Then in triangle A C D we know one side and two angles, and therefore can calculate A C.

In triangle B C D we know one side and two angles, and therefore can calculate B C.

And finally in triangle A C B we have already calculated A C, B C, and have measured the angle C, and therefore can determine A B.

Of course, from the first two triangles we can also determine A D and B D, and then in triangle A B D we know two sides, and the included angle, and hence can determine A B, and can use these two calculations for checks upon each other.

The calculation is performed as follows :—

Call the sides and angles of A B C — a. b. c. A. B. C. and observe that C A D = 180° — (C + C′ + D′) and C B D=180° (C′ + D + D′). Then from triangle A C D

$$\text{A C} = \text{C D}\frac{\sin.\ \text{CAD}}{\sin.\ \text{CDA}}$$

$$\therefore \log.\ \text{A C} = \log.\ \text{C D} + \text{L. sin. C A D} + \text{ar. comp. log. sin. C D A} - 10.$$

or

$$\log.\ b = \log.\ p + \text{L. sin. } (\text{C} + \text{C}' + \text{D}') + \text{ar.: comp.: log. sin. D}' - 10 \tag{1}$$

Similarly

$$\log.\ a = \log.\ p. + \text{L. sin. } (\text{C}' + \text{D} + \text{D}') + \text{ar.: comp.: log. sin. C}' - 10 \tag{2}$$

From triangle A C B we have $\frac{\text{A} + \text{B}}{2} = 90° - \frac{\text{C}}{2}$

$$\tan.\ \frac{\text{A} - \text{B}}{2} = \frac{a - b}{a + b}\ \tan.\ \frac{\text{A} + \text{B}}{2}$$

$$\text{assume } \tan.\ \phi = \frac{b}{a}\ \therefore \frac{a - b}{a + b} = \frac{1 - \tan.\ \phi}{1 + \tan.\ \phi} = \tan.\ (45° - \phi)$$

$$\therefore \text{L. tan. } \phi = \log.\ b - \log.\ a + 10 \tag{3}$$

$$= \log.\ b + \text{ar.: comp.: log. } a$$

$$\text{and L. tan.} \frac{\text{A} - \text{B}}{2} = \text{L. tan. } (45° - \phi)$$

$$+ \text{L. tan.} \frac{\text{A} + \text{B}}{2} - 10 \tag{4}$$

whence we obtain $\frac{\text{A} - \text{B}}{2}$ and $\therefore$ A and B since we know $\frac{\text{A} + \text{B}}{2}$

Finally from triangle A B C

$$c = a\frac{\sin.\ \text{C}}{\sin.\ \text{A}}.$$

$$\therefore \log.\ c = \log.\ a + \text{L. sin. C} + \text{ar.: comp.: L. sin. A} - 10 \tag{5}$$

It will be observed that in the above calculation we do not require a and b, but only log. a and log. b, which are given by equations (1) and (2). (Compare Plane Trig., Art. 40).

Example:—Given C D = 372.5 yds. C = 123°.15′. C′ = 13°.42′. D = 129°.11′. D′ = 19°.13′.

(1) Log. b = log. 372.5 = 2.5711263
+ L. sin. 156°.10′ 9.6064647
+ ar. comp. L. sin. 19°.13′ — 10 .4826176 — 10.
2.6602086

(2) Log. a = log. 372.5 2.5711263
+ L. sin. 162°.6′ 9.4876426
+ ar. comp. L. sin. 13°.42′ — 10 .6255483 — 10.
2.6843172

(3) L. tan. ϕ = log. b = 2.6602086
+ ar. comp. log. a 7.3156828
9.9758914
ϕ = 43° 24′ 9.9757318
4218)159600(37.8
12654
ϕ = 43° 24′ 37″ 8 33060
45 29526
45 — ϕ = 1° 35′ 22″ 2 35340

(4) $\text{L. tan. } \frac{\text{A} - \text{B}}{2} = \text{L. tan. } (45° - \phi)$
$+ \text{L. tan. } \frac{\text{A} + \text{B}}{2} - 10.$
= L. tan. 1° 35′ 22″.2 = 8·4432492

827.78 = ·9179149
30
$\therefore$ c = 827.786 yds. 6 = 32
827.786 *Answer.*

II. THE MENSURATION OF AREAS.

(1). *To find the Area of a Rectangle.*

Let A B C D *abcd* be two rectangles. Then (Euclid, VI., 23) the areas of these rectangles are to each other in the ratio compounded of the ratios of the sides, *i. e.*, in the ratio compounded of the two, *ab* : A B and *bc* : B C; and if we suppose these lines to be represented by numbers, this compounded ratio is *ab* × *bc*:

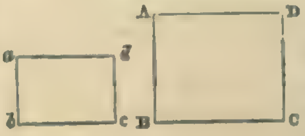

Fig. 6.

A B × B C. Hence rectangle ac : rectangle B C : : $ab \times bc$: A B × B C.

Now suppose $ab = 1$, and $cb = 1$. Then the area ac is the unit of area, *i. e.*, is a square inch, or a square foot, or a square yard, according as ab is an inch, foot, or a yard. In this case

$$\text{Rectangle BC} = \text{AB} \times \text{BC}.$$

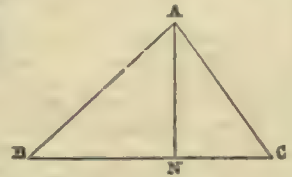
Hence, if a and b be the sides of a rectangle, its area is ab, *i. e.*, it contains as many *units of area* as the product of the number of units of length in one side, by the number of units of length in the other.

Cor.—If a be the side of a square, its area is a^2.

(2). *To find the Area of a Triangle.*

Let A B C be the triangle; from A draw A N perpendicular to B C. Then, since the area of A B C is half that of a rectangle, whose base is B C and height A N, the area of triangle $= \dfrac{\text{BC} \times \text{AN}}{2}$

Fig. 7.



Cor.—(1). If we have given AB. BC and angle B.

$$\text{Area triangle} = \frac{\text{BC} \times \text{AB sin. B}}{2} = \frac{ac \text{ sin. B}}{2}$$

$$\text{Since} \quad \text{AN} = \text{AB sin. B}.$$

(2). If we have given B C and the angles of triangle,

$$\text{Then, since } \frac{c}{a} = \frac{\text{sin. C}}{\text{sin. A}}$$

$$\text{Area triangle} = \frac{a^2 \text{ sin. B sin. C}}{2 \text{ sin. A}}$$

(3). If we have all the sides given (by Trigon., Art. 41)

$$\text{Area triangle} = \sqrt{s.\,(s-a)\,(s-b)\,(s-c)}$$
$$\text{where } 2s = a + b + c.$$

(3). *To find the Area of a Parallelogram.*

If $a.b$ be the sides of the parallelogram, and A the angle contained by those sides, then by the last article the area of half the parallelogram

$$= \frac{ab \text{ sin. A}}{2}$$

∴ Area of parallelogram $= ab$ sin. A.

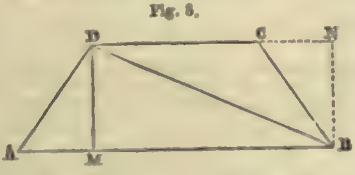
Or, if p is the perpendicular distance between two parallel sides, each of which $= a$, then

$$\text{Area of parallelogram} = ap.$$

(4). *To find the Area of a Trapezoid.*

Let A B C D be the trapezoid of which the side A B is parallel to the side C D. Join B D, draw D M perpendicular to A B, and B N perpendicular to D C, or D C produced, and let $a =$ A B. $b =$ D C and $p =$ D M or B N.

Fig. 8.



Then
$$\text{Area triangle ABD} = \tfrac{1}{2}\,ap$$
$$\text{Area triangle BCD} = \tfrac{1}{2}\,bp$$
$$\therefore \text{Area ABCD} = \tfrac{1}{2}\,p\,(a + b)$$

Or the area of a trapezoid $= \frac{1}{2}$ sum of parallel sides *plus* the perpendicular distance between them.

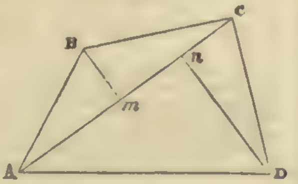
(5). *To find the Area of a Trapezium.*

Let A B C D (Fig. 9), be the trapezium; join AC, from B and D let fall perpendiculars B m, D n, upon AC.

The area of triangle A B C $= \frac{1}{2}$ Bm. A C and area of triangle A D C $= \frac{1}{2}$ Dn. A C.

∴ Area of trapezium $= \frac{1}{2}\,\text{AC}\left(\text{B}m + \text{D}n.\right)$

Fig. 9.

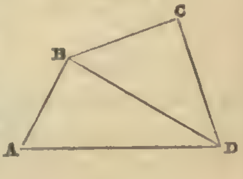


If instead of having the perpendiculars Bm and Dn given, we have the sides A B. B C. C D. D A. and a diagonal, we must find the area of each triangle separately by the formula.

$$\text{Area triangle} = \sqrt{s.\,(s-a)\,(s-b)\,(s-c)}$$

Or, again, if we have the sides and one angle, as A, given, we can proceed as follows.—Let A B. $= a$. B C $= b$. C D $= c$. DA $= d$. Join BD (Fig. 10), then we can calculate B D from triangle A B D by second case of oblique-angled triangles, and having calculated B D we can determine the areas of the triangles as before.

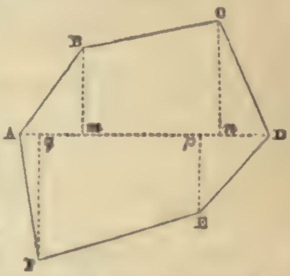
Fig. 10.



(6). *To determine the Area of an irregular Polygon.*

Suppose A B C D E F to be an irregular polygon, its area can be determined by effecting the following measurements; join A D, the longest distance across the figure from B C E F, draw perpendiculars to A D., viz. Bm, Cn, Ep, Fq, respectively; measure Am, mn, nD, Cn, Bm, Aq, qp, pD, Ep, Fq.

Fig. 11.



Then area of polygon $=$ ABm + B$mn$C + CnD + DpE + E$pq$F + FqA.

$+ \frac{1}{2}\,\text{A}m \times \text{B}m + \frac{1}{2}\,mn \times (\text{B}m + \text{C}n) + \frac{1}{2}\,\text{C}n \times n\text{D} + \frac{1}{2}.\,\text{D}p + p\text{E} + \frac{1}{2}\,pq\,(\text{E}p + \text{F}q) + \frac{1}{2}\text{A}q \times q\text{F}.$

(7). *To determine the Area of a regular Polygon.*

Various formulas have been already given for this in Chapter XI., on Trigonometry (Art. 45). It is there shown that if n be the number of sides of the polygon, and a the length of one of the sides,

$$\text{Area} = \frac{na^2}{4} \text{ cotan. } \frac{180^\circ}{n}.$$

Hence in case of pentagon,

$$\text{Area} = \frac{5a^2}{4} \text{ cotan. } 36^\circ = \frac{5\,(\sqrt{5} + 1)\,a^2}{4\sqrt{10 - 2\sqrt{5}}}$$

In case of hexagon,

$$\text{Area} = \frac{3a^2}{2} \text{ cotan. } 30^\circ = \frac{3\sqrt{3} \cdot a^2}{2}$$

And so on in other cases.

(8). *To determine the Area of a Circle.*

If n is the number of sides of a regular polygon inscribed in a circle whose radius is r, then, as we have already seen (Trig., Art. 45),

$$\text{Area polygon} = \frac{nr^2}{2} \text{ sin. } \frac{2\pi}{n}.$$

$$= r^2\pi \, \frac{\text{sin. } \frac{2\pi}{n}}{\frac{2\pi}{n}}$$

Now if we increase the number of sides of the polygon, it becomes more and more nearly equal to the circle, and in the limiting case when the number of sides is infinitely great, it becomes the circle;* but when $n = \infty$ $\therefore \frac{2\pi}{n} = 0$ and (Trig., Art. 47) in this case

$$\frac{\text{sin. } \frac{2\pi}{n}}{\frac{2\pi}{n}} = 1$$

$$\therefore \text{Area of circle} = r^2\pi.$$

Cor.—Hence area of quadrant $= \dfrac{r^2\pi}{4}. = \dfrac{1}{2}\,r\,\dfrac{r\pi}{2}.$

---

* Compare with the statement in the text what is said on p. 577.

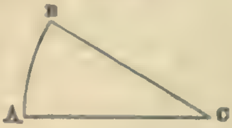
Now $\frac{r\pi}{2}$ = the length of arc on which quadrant stands.

$\therefore$ Area of quadrant $= \frac{r}{2} \times$ arc on which quadrant stands.

(9). *To find Area of a Sector of a Circle.*

Let A O B be any sector of a circle,
O A = r. A O B = θ (in circular measure),
$\therefore$ A B = $r\theta$.

Fig. 12.



Now if A O B were a quadrant, A B would equal $\frac{r\pi}{2}$ and the area of the quadrant = $\frac{r^2\pi}{4}$.

But in equal circles sectors are to each other as the arcs on which they stand.

$$\therefore \text{Area sector} : \text{area quadrant} :: r\theta : \frac{r\pi}{2}.$$

$$\therefore \text{Area sector} : \frac{r^2\pi}{4} :: \theta : \frac{\pi}{2}.$$

$$\therefore \text{Area sector} = \frac{r^2\theta}{2}.$$

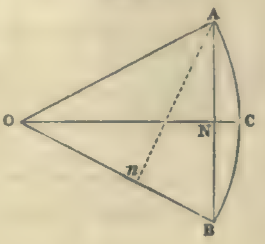
$$= \frac{1}{2} r \times r\theta.$$

$$= \frac{1}{2} r \times (\text{arc on which sector stands}).$$

(10). *To find the Area of a Segment of a Circle.*

Let O A C B be a sector of a circle. Join A B. We are required to find the area of the segment A B C. Draw O N C perpendicular to A B. Let A O B = θ. O B = r.

Fig. 13.



$\therefore$ ON $= r \cos. \frac{\theta}{2}$ AN $= r \sin. \frac{\theta}{2}$.

$\therefore$ area A B O $= r^2 \sin. \frac{\theta}{2} \times \cos. \frac{\theta}{2} = \frac{1}{2} . r^2 \sin. \theta$.

Now area A C B O $= \frac{1}{2} r^2 \theta$.

$\therefore$ area of segment $= \frac{r^2}{2} (\theta - \sin. \theta)$.

Cor.—From A draw A n perpendicular to O B. Then A $n = r \sin. \theta$, also arc A C B $= r\theta$.

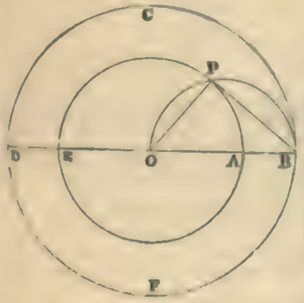
Hence the area of segment

$$= \frac{r}{2} (r\theta - r \sin. \theta)$$

$$= \frac{r}{2} \times (\text{A C B} - \text{A}n)$$

(11). *To find the space between two Concentric Circles, viz.,* A B C E D F.

Fig. 14.



Let O A = r O B = r_1.

Then area of interior circle = πr^2, and area of exterior circle = πr_1^2

$\therefore$ Area of the space between the circles

$$= \pi (r_1^2 - r^2)$$

On O B as a diameter, describe a circle O P B cutting the interior circle in P; join O P. P B, then O P B is a right angle,

BP^2 = OB^2 — OP^2 $= r_1^2 - r^2$

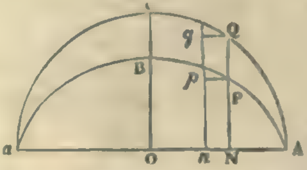
$\therefore \pi$ B P$^2 = \pi (r_1^2 - r^2)$

also since O B P is a right angle, B P touches the circle, or the area of the space in question is equal to the area of a circle whose radius is the length of the line drawn from any point in the exterior circle to touch the interior circle.

The cited cases of areas of plane figures are the chief of those which belong to Elementary Mathematics. The determination of areas bounded by curved lines belongs, of right, to the Integral Calculus; the following propositions, however, are best given here, though the reasoning is not of a strictly elementary character.

(12). *To find the Area of an Ellipse.*[*]

Fig. 15.



Let aB A be a semi-ellipse.

O A its semi-major axis = a.

O B its semi-minor axis = b.

On aA as a diameter describe a semicircle aC A. In A B take any point P and draw an ordinate P N perpendicular to O A, and produce it to meet the circle in Q, and draw another ordinate qpn parallel and near to Q P N, and complete the parallelograms nP, nQ

Now, by a property of the ellipse,

$$\text{NQ} : \text{NP} :: a : b$$
$$\therefore n\text{Q} : n\text{P} :: a : b$$

and hence, if we suppose a series of parallelograms to be described in circle and ellipse, the same proportion will hold good between each of these, and therefore

Sum of parallelograms in semicircle : sum of parallelograms in semi-ellipse :: a : b.; and this being true, however great the number may be, is true in the limit.

Now the semi-ellipse is the limit of the parallelograms inscribed in it, and the semicircle is the limit of parallelograms inscribed in it.

$$\therefore \text{semicircle} : \text{semi-ellipse} :: a : b$$
$$\therefore \text{circle} : \text{ellipse} :: \pi a^2 : \pi a b$$

But area of circle = πa^2

$\therefore$ area of ellipse = πab.

(13). *Let q* P Q *be a portion of a Parabola. It is required to find its Area.* (Fig. 17).

Bisect Qq in V, draw the diameter P V. Through P draw r P R parallel to Q V q, and draw Q R and qr parallel to P V. Then the area q P Q is two-thirds of qr R Q.

Take p and p_1, two points in P Q, and through p_1 draw $p_1 m_1$, $p_1 n_1$ parallel to P V and Q V, and through p draw pm pn also parallel to P V, Q V, and produce them to meet $p_1 n_1$ in q_1 and $p_1 m_1$ in q respectively. Then

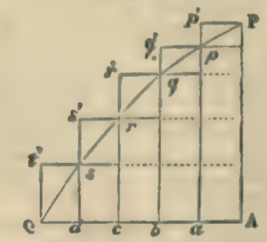
Parallelogram pm_1 : parallelogram pn_1 :: $pn \times nn_1$: $pm \times mm_1$.

$$:: pn \times (\text{P}n_1 - \text{P}n) : \text{P}n \times (p_1 n_1 - pn)$$

---

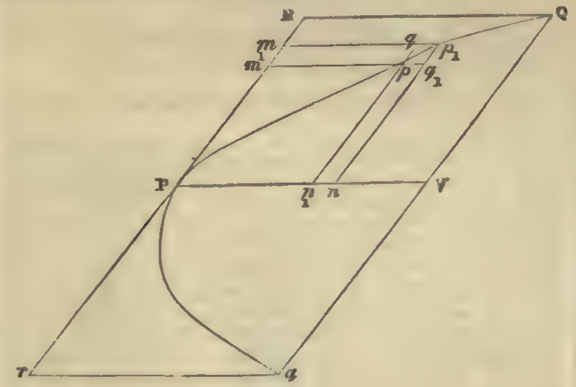
[*] Let A P Q be an area included by two straight lines A B. A P, and the curve P Q; divide A Q into equal parts Aa, ab, bc cd, dQ, and on these lines draw the rectangles Ap, aq, br, cs *within* the curved areas, and complete the parallelograms Ap', aq', br', cs', dt. Then it is plain that the difference between the interior parallelograms (Ap, aq, br, cs) and the exterior parallelograms (Ap', aq', br', cs', dt') will equal Ap'. Now, by making the number of parallelograms very large, Aa, and $\therefore$ Ap' will become very small, and may be made less than any magnitude that may be assigned. Now the curvilinear area is clearly greater than the interior and less than the exterior parallelograms, and therefore differs from the interior parallelogram by a quantity less than Ap'; *i.e.*, a quantity that can be made less than any that can be assigned: and therefore the curvilinear area is the limit to which the sum of the interior parallelograms continually approaches when their number is increased.

Fig. 16.



Now, by a property of the parabola

Fig. 17.



$Pn : P_1 n_1 :: pn^2 : p_1 n_1^2$

$\therefore Pn : Pn_1 - Pn :: pn^2 : p_1 n_1^2 - pn^2$

or $Pn : Pn_1 - Pn :: pn^2 : (p_1 n_1 - pn)(p_1 n_1 + pn)$

$\therefore Pn \times (p_1 n_1 - pn) : (Pn_1 - Pn)\, pn :: pn : p_1 n_1 + pn$

$\therefore$ parallelogram pm_1 : parallelogram $pn_1 :: pn : p_1 n + pn$.

Now in the limit $p_1 n_1$ differs from pn by a quantity less than any that can be assigned.

$\therefore$ In the limit $pn : p_1 n_1 + pn :: 1 : 2$

$\therefore$ In the limit parallelogram pm_1 : parallelogram $pn_1 :: 1 : 2$

which proportion is true for *each* pair of parallelograms inscribed in P Q R and P Q V, and $\therefore$ is true of *all*.

$\therefore$ In the limit sum of parallelograms in P Q R : sum of parallelograms in P Q V :: 1 : 2

But the area P Q R is the limit of the sum of the parallelograms inscribed in it; and P Q V is the limit of the sum of the parallelograms inscribed in it.

$\therefore PQR : PQV :: 1 : 2$

$\therefore PQVR : PQV :: 3 : 2$

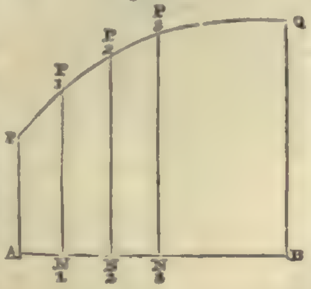
Now P Q V R is the half of qr Q R, and P Q V is the half of P Qq.

$\therefore PQq = \frac{2}{3} rq.\ QR.$ Q.E.D.

(14). *To find approximately the Area of a Plane Figure bounded by a Curve.*

Let A B P Q be the figure; divide A B into equal parts, AN_1, $N_1 N_2$, $N_2 N_3$, &c., and draw ordinates $P_1 N_1$, $P_2 N_2$, $P_3 N_3$, &c., parallel to A P or B Q, and perpendicular to A B.

Fig. 18.



(1). As a first approximation the curved area may be considered as identical with the polygonal area inclosed by P A B Q and the chords PP_1, P_1P_2, P_2P_3, &c. In this case, the area required $= AN_1P_1P + N_1N_2P_2P_1 + N_2N_3P_3P_2$, &c.

$$= AN_1 \times \frac{AP + P_1N_1}{2} + N_1N_2 \times \frac{P_1N_1 + P_2N_2}{2}$$

$$+ N_2N_3 \times \frac{P_2N_2 + P_3N_3}{2}, \text{ \&c.}$$

$$= AN_1\left(\frac{AP}{2} + P_1N_1 + P_2N_2 + P_3 \quad + \dots + \frac{QB}{2}\right)$$

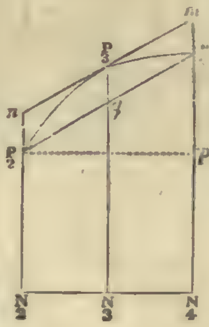
Or the area = (the distance between any two consecutive ordinates) × (half the sum of the extreme ordinates, together with the sum of all the intermediate ordinates)

Or if $AN_1 = \triangle$ $AP = a$ $QB = b$
$P_1N_1 = y_1$ $P_2N_2 = y_2$ $P_3N_3 = y_3$ &c.

$$ABQP = \triangle\left(\frac{a+b}{2} + y_1 + y_2 + y_3 + \dots + y_n\right)$$

(2). The above is a good approximation, but a much better may be found in the following manner. Consider the portion of the curve between any three consecutive P's such as $P_2 P_3 P_4$, through P_3 draw a line nP_3m touching the curve, and let it meet N_2P_2, N_4P_4 produced in n and m. Draw P_2p perpendicular to P_4N_4, join P_2P_4 meeting P_3N_3 in q. Now we may consider $P_2P_3P_4$ a portion of a parabola,* and $\therefore$ the curvilinear area $P_2P_3P_4 = \frac{2}{3}$ of nP_2P_4m.

Fig. 19.



$$= \frac{2}{3} mP_4 \times P_2 p.$$

$$= \frac{2}{3} P_3 q \times P_2 p.$$

Now $N_3 q = \frac{1}{2}(y_2 + y^4)$ and $P_2 p = N_2 N_4 = 2\triangle$

$$\therefore P_3 q = P_3 N_3 - q N_3 = y_3 - \frac{1}{2}(y_2 + y_4)$$

$$\therefore P_2 P_3 P_4 = \frac{4\triangle}{3}\left\{y_3 - \frac{1}{2}(y_2 + y_4)\right\}$$

Now the area $P_2 P_4 N_4 N_2 = \triangle(y_2 + y_4)$

$\therefore$ the whole area $P_2 P_3 P_4 N_4 N_2 = \frac{\triangle}{3}(4y_3 + y_2 + y_4)$

Hence the area of the figure P A B Q (Fig. 18), which equals $PAN_2P_2 + P_2NP_4N_4 + P_4N_4P_6N_6 + \dots$

$$= \frac{\triangle}{3}.\ (a + 4y_1 + y) + \frac{\triangle}{3}(y_2 + 4y_3 + y_4) +$$

$$\frac{\triangle}{3}(y_4 + 4y_5 + y_6) + \dots \quad + \frac{\triangle}{3}.\ (y_{2n} + 4y_{2n-1} + b)$$

reckoning that there are $2n + 1$ (an odd number) ordinates drawn between the two extreme ones P A, Q B.

$$\therefore PABQ = \frac{\triangle}{3}.\left\{a + b + 4(y_1 + y_3 + y_5 + \dots + y_{2n+1} \atop + 2(y_2 + y_4 + y_6 + \dots + y_{2n})\right\}$$

or the area

$= \frac{\triangle}{3} \times$ (sum of extreme sides + 4 sum of odd ordinates + 2 sum of even ordinates).

Hence the Rule :—At equal distances along the base A B draw an odd number of ordinates parallel to the parallel sides of the figure; then take the sum of the parallel sides, of four times the odd ordinates, and twice the even ordinates, and multiply the third part of this sum by the common distance between the ordinates, and this product is the area of the figure.

Besides the above areas of plane surfaces, there are areas of certain solids which will be best given here, viz., the areas of a prism, a cylinder, a pyramid, a cone, and a sphere.

Def. 1.—A prism is a solid bounded by two equal and similar rectilinear figures in parallel planes and by parallelograms.

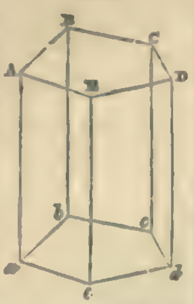
Thus ABCDE, *abcde*, is a prism bounded by two equal and similar pentagons whose planes are parallel (ABCDE, and *abcde*), and by parallelograms A*a*B*b*,

---

* It appears from Newton, (Lemma XI., Lect. 1,) that in any curve of finite curvature, $P_3 q$ is in the limit as the square of qP_4. Now it is the characteristic property of the parabola that $P_3 q$, is as the square of qP_4; hence every curve of finite curvature tends to a parabola as its limit, and so if we take a small arc $P_2 P_3 P_4$ we may consider it to be a parabolic arc, without making any appreciable error.

BbcC, &c. A prism is called a right prism when the planes of the parallelograms are perpendicular to the planes of the base (*i.e.*, *abcde* in the accompanying figure).

Fig. 20.

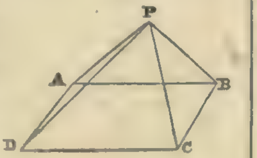


DEF. 2.—A pyramid is a solid bounded by any plane rectilinear figure, and by triangles having a common vertex, and for bases the sides of the rectilinear figure respectively.

Thus (Fig. 21) P A B C D is a pyramid, on a quadrilateral base, A B C D.

DEF. 3.—A cylinder is a solid whose surface is traced out by a straight line which always moves parallel to its first position, and whose extremity is guided by a given curve.

Fig. 21.



Thus (Fig. 22) if *acb* is a circle, and A*a* a straight line perpendicular to the plane of the circle, then ABC *abc* is a cylinder which is traced out by a line C*c*, that is always parallel and equal to A*a*. This cylinder is strictly defined as a "right cylinder with a circular base;" it is, however, in elementary treatises generally called "a cylinder."

DEF. 4.—A cone is a solid, the surface of which is traced out by a straight line, one end of which passes through a fixed point, and the other end through a given plane curve, called its base.

Fig. 22.

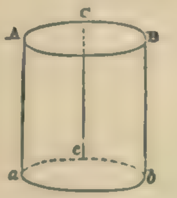


Fig. 23.

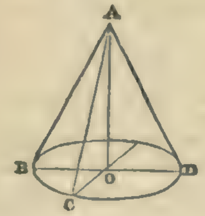


If B C D (Fig. 23) is a circle, and A a fixed point, the surface A B C D is called a cone on a circular base. If O is the centre of the circle, join A; then draw straight lines from A to different points in circumference of circle, making equal angles with A O; or if (which is the same thing) A O is perpendicular to plane of circle, A B C D is strictly defined as "a right cone with a circular base;" or, as it is more generally called in elementary treatises, a "right cone."

N. B.—It is manifest that if a regular polygon be inscribed in the circle B C D, and its angular points are joined with A, that the resulting solid will be a pyramid inscribed in the cone; and also, that if we increase the number of sides in the polygon, the inscribed pyramid will approach more nearly to the cone; and, since the circle is the limit of the inscribed polygon, the cone will be the limit of the inscribed pyramid.

Similarly, the cylinder will be the limit of the inscribed prism.

(15). *To find the Area of a right Prism.*

In figure (20) AE*ea* is a rectangle. Since the planes A*b*, A*e* are perpendicular to the base, their cone of intersection A*a* is also perpendicular to the base, and therefore angle A*ae* is a right angle. Hence the area of AE*ea* is A*a* × A E, similarly of all the other parallelograms. Hence the area of the parallelograms is A*a* (A E + E D + D C + ...) = A E × (the perimeter of the base). Hence the whole area = height × perimeter of base + areas of the two ends.

(16). *To find the Area of the surface of a right Cylinder.*

Since the surface of the cylinder is the limit of the surface of the inscribed prism, and the area of the prism = height × perimeter of base + 2 × base, whatever be the number of sides to the base, this will be true in the limit when base is a circle.

∴ Area of a cylinder = height × perimeter of base + 2 × base.

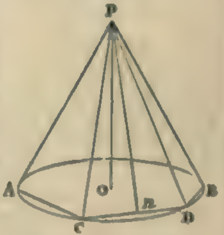
Hence, if h = height, and a = radius of base.

Area of cylinder $= 2\pi ah + 2\pi a^2 = 2\pi a(a+h)$.

(17). *To find the Area of the curved surface of a right Cone.*

Let P A C D B be the cone, A C D B its circular base, O the centre of the circle, then P O is at right angles to plane of the circle. In the circle inscribe any regular polygon, A C D, &c., and join P A, P C, P D, &c. Bisect C D in *n*, join P*n*. Then P*n* is perpendicular to C D, and ∴ the area of triangle P C D = ½ C D, P*n*. Now the line joining P with the bisection of any other side of the polygon is equal to P*n*.

Fig. 24.



Hence area of pyramid inscribed in cone

$$= \tfrac{1}{2}\,\mathrm{PN}\left(\mathrm{AC}+\mathrm{CD}+\mathrm{DB}+\ldots\right)$$

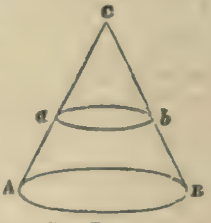
$$= \tfrac{1}{2}\,\mathrm{PN} \times \text{perimeter of polygon.}$$

Now, this is true whatever be the number of sides the polygon may have, and hence is true in the limit; when perimeter of polygon = circumference of circle, and P*n* is drawn to a point in circumference, or is = slant side of cone.

∴ Area of curved surface of cone = ½ slant side × circumference of base.

COR.—If we suppose that the surface of a cone is capable of being unwrapt, it is plain that its surface will be a sector of a circle whose radius is the slant side of cone, and base of the same length as the circumference. It is plain (Mensuration, Art. 9), that the area of this sector is, as it should be, the same as that of the surface of cone.

Fig. 25.

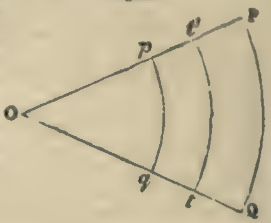


DEF.—The frustum of a cone or pyramid is the portion cut off by a plane parallel to the base; thus, A B *b a* is a frustum of the cone C A B.

(18). *To find the Area of the Frustum of a Cone.*

Suppose a sector, O P Q, (Fig. 26) of a circle is described with radius O P = C A (Fig. 25), and if its base P Q = circumference of A B, we have seen that the area of P O Q is the same as that of the cone C A B. Take O*q* = C*a*, and describe the arc O*qp*. Then as before, area of *opq* = area of C*ab*, and ∴ the area of frustum + *q*QP*p*.

Fig 26.



Let angle POQ $= \theta$. $Oq = r'$ $OQ = r$

$\therefore$ Area $Opq = \tfrac{1}{2} r'^2 \theta$

$\therefore$ Area $OPQ = \tfrac{1}{2} r^2 \theta$

$\therefore$ Area $qOPp = \tfrac{1}{2} \theta (r^2 - r'^2)$

$$= \theta \frac{r+r'}{2} \times (r-r').$$

Bisect qQ in t and draw arc tt'

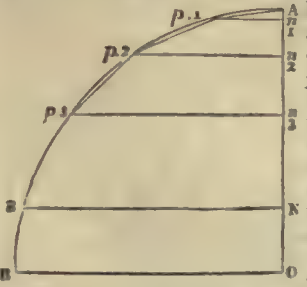
Then $\dfrac{r+r'}{2}\theta = tt'$ and $r - r' = qQ$.

∴ Area of frustum = rectangle between Q*q* and *tt'* or between slant side of cone and circumference of mean section of frustum.

(19). *To find the Area of a portion of the surface of a Sphere.*

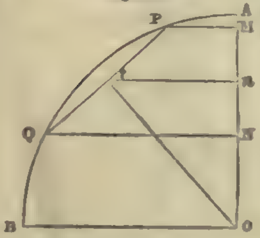
Let A B be a quadrant of a cirle whose radius is A B or O B. If we suppose the quadrant to revolve round A O it will describe a hemisphere; and if we suppose a number of equal chords, Ap_1, $p_1{}'$ p_2, p_2, p_3, &c., to be drawn from point to point of A B, these chords in the revolution will describe frustums of cones: now the arc A R is the limit of the chords $Ap_1 + p_1 p_2 + p_2 p_3 + \ldots$ and hence the area of the portion of sphere described by A R will be the limit of the sum of the frustums of cones described by $Ap_1 \, p_1 p_2 \, p_2 p_3 \ldots$

Fig. 27.



Let P Q (Fig. 28) be one of these chords: draw P M, Q N perpendicular to A O. Draw O perpendicular to P Q, and tn perpendicular to A O. Now tn is the radius of the mean section of the frustum of cone described by P Q, and therefore area of that frustum

Fig. 28.



$$= 2\pi tn \times PQ$$

Now $tn = Ot \sin. tOA.$

and $PQ \sin. PQN = NM.$

or since $PQN = tOA.$

$PQ \sin. tOA = NM$

$\therefore tn. PQ = Ot. NM.$

And area of frustum

$$= 2\pi Ot. NM.$$

In Fig. 27, draw $p_1 n_1 \, p_2 n_2 \, p_3 n_3$ perpendicularly to A O. Then, since, $Ap_1 \, p_1 p_2 \, p_2 p_3$ are all equals, the perpendiculars on them are equal, and therefore the sum of areas of frustum of cone

$$= 2\pi Ot \times (An_1 + n_1 n_2 + n_2 n_3 + \ldots.)$$
$$= 2\pi Ot \times AN.$$

if we only consider the portion of sphere described by A R. This is true, however great the number of chords, and is therefore true in the limit; but in the limit Ot = radius of sphere.

$\therefore$ Area of portion of sphere, whose height is A N.

$$= 2\pi OA. AN.$$

If we take the whole sphere. $AN = 2OA.$

$\therefore$ Area of sphere $= 4\pi. (OA)^2.$

COR.—In the sphere $2\pi \times OA$ = circumference of a great circle.

$\therefore$ Area of portion of a sphere = height of portion × circumference of a great circle.

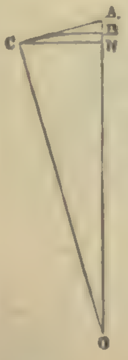
If we imagine a right cylinder to be described about a sphere, its curved area = circumference of a great circle × diameter of sphere = area of sphere.

Hence, "area of sphere = area of circumscribing cylinder."

Exam.:—How many square miles of sea are visible from the top of a mast 80 feet above the surface?

Let O be the centre of the earth; draw O A. O C., so that A C is perpendicular to O C.; draw C N perpendicular to O A. Then, if $BN = x$. $OB = r$. The area visible from A will be the area of the part of the sphere whose depth is B N

Fig. 29.



$$i.e., \text{ will } = 2\pi r x.$$

Now, let $AB = p$. Then, by similar triangles

$$r + p : r :: r : r - x.$$
$$\therefore r - x = \frac{r^2}{r+p}.$$
$$\therefore \quad x = \frac{rp}{r+p}.$$
$$\text{and visible area} = \frac{2\pi r^2 p}{r+p}.$$
$$= 2\pi rp \text{ very nearly.}$$

Now, $\pi = 3{\cdot}14159.$

$r = 3958$ miles

$$p = 80 \text{ feet} = \frac{80}{5250} = \frac{1}{66}$$

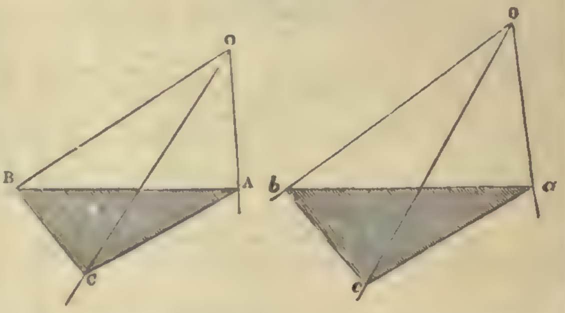
$$\therefore \text{visible area} = 2 \times 3{\cdot}14159 \times 3958 \times \frac{1}{66}$$
$$= 378 \text{ nearly.}$$

III. THE MENSURATION OF SOLIDS.

(1). *If two solid Angles are each contained by three Plane Angles, that are equal each to each, then the inclination of the Planes will be equal, each to each.*

Let O, o, be two solid angles contained by the plane angles A O B, B O C, C O A, and aob, boc, coa, respectively. Then the plane A O B is inclined to plane C O A at the same angle that aob is inclined to aoc. For, take $OA = oa$, and let the plane C A B be perpendicular to O A, and cab perpendicular to oa. Then angles C A O, B A O, cao, bao, are right angles; and C A B, cab, are the inclination of the planes in question.

Fig. 30.



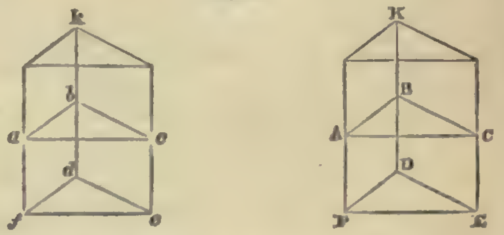
Now in triangles A O B, aob. we have $OA = oa$ and angles B O A, O A B = angles boa, oab, each to each, $\therefore OB = ob$ and $AB = ab$ (Euclid, I., 26); similarly in triangles C O A, coa, we have $OC = oc$ and $AC = ac$.

Then in triangles B O C, boc, we have the sides B O, O C = sides bo, oc, each to each, the included angle $BOC = boc$. $\therefore$ (Euclid, I., 4) the base CB = base cb.

Hence, finally, in triangle A B C, abc, we have the sides B A, A C = the sides ba, ac each to each, and the base BC = base bc. $\therefore$ (Euclid, I., 8) $CAB = cab$. Q. E. D.

COR. 1.—Hence (Fig. 30), if the solid angle O be superimposed on the solid angle o, so that A O coincides with O oa, and the plane A O B with plane aob, then, because angle AOB = angle aob the line O B coincides with ob; and because inclination of plane C O A to A O B equals that of coa to cob, the plane C O A will coincide with coa, and hence O C with oc.

Fig. 31.

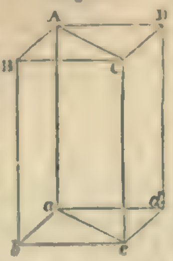


COR. 2.—If A B C D E F and $abcdef$ are two prisms, the edges of which are equal each to each, and the plane angles at B equal those at b, the prisms are equal in all respects. (See Figs. 31 and 32).

For, if the triangle A B C be applied to abc so that A B coincides with ab, and B C with bc, it is plain by the last corollary that B D coincides with bd. And hence the prisms will coincide throughout.

Cor. 3.—If A B C D *abcd* be a parallelepiped[*] (*i. e.*, a prism on a parallelogram for a base), it can be divided into two equal prisms by a plane A C*ca* passing through the diagonals of its bases; for it is obvious that the edges of these prisms are equal, each to each, and also that the plane angles containing the solid angles at D and B are equal. (See Fig. 32).

Fig. 32.



Cor. 4.—Again (in Fig. 31), if we suppose the base D E F of the one prism to be in all respects equal to that of the other *def*, and if the angles at D are equal to the angles at *d*, each to each, then it is plain that if D B is > *db* the prism B D F E is > prism *bdfe*, and if D B < *db*, the prism B D F E < prism *bdfe*. Also if B D is double of *bd*, the prism B D F E is double of the prism *bdfe*; and generally if B D is any multiple of *bd*, then B D F E is the same multiple of *bdfe*.

Cor. 5.—If we suppose (Fig. 31) B D produced to K so that D K is any multiple of D B, the prism K D F E is the same multiple of B D F E; and if we suppose *db* produced to *k* so that *kd* is any multiple of *bd*, then *kdfe* is the same multiple of *bdfe*. But if K D > *kd*, K D F E > *kdfe*; if equal, equal; if less, less ∴ (Euclid, V., p. 136).

B D F E : *bdfe* : : B D : *bd*.

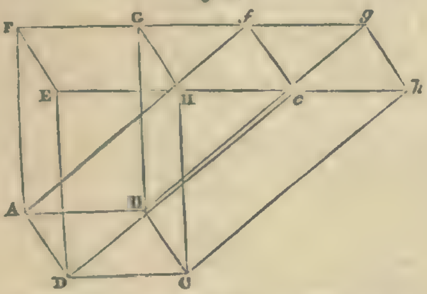
Cor. 6.—The results proved in Cors. 4 and 5 to be true of prisms, are manifestly true of paral^{pps}.

(2). *Parallelepipeds on the same Base and of the same Altitude are equal to one another.*

If the paral^{pps} are on the same base and of the same altitude, it is manifest that the ends opposite the common base are in the same plane.

(*a*) Suppose two of the edges of the ends opposite to the base of each figure to be in the same straight line.

Fig. 33.



Let D B E G, D B*eg*, be the parallelepipeds on the same base B D, and of the same altitudes, and suppose that E H, *eh*, are in the same straight line, and also F G, *fg*, in the same straight line. Then it is obvious that E*e* = H*h*, H C = E D, and angle *h*H C = angle *e*E D.

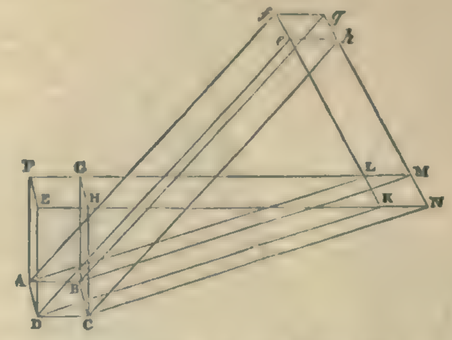
∴ the base *e*E D = base *h*H C, also H G = F E, and the plane angles that form the solid angles at H and E are equal each to each, ∴ the prism *h*C H G = the prism *e*D E F. Hence if we suppose the former prism taken from the whole figure *h*C D E F, and the latter to be taken from the same figure, the remainders will be equal ∴ D B E G = D B*eg*.

(*b*) Suppose that no two of the edges of the side opposite to the base are in the same straight line.

Let D B E G, D B*eg* (Fig. 34), be the paral^{ppd} on the same base B D, and being of the same altitude, their ends E G, *eg*, are in the same plane. Produce E H, F G, *fe*, *gh*, to meet, they will evidently form a parallelogram; let this parallelogram be K L M N, then L K, M N, and F E, G H = A D, B C, each to each, and K N, L M = *eh*, *fg* = D C, A B, each to each, and angle M L K = angle G F E = angle B A D.

∴ L K M N is equal to A B C D. Join A L, B M, C N, D K. Then D B M K is a parallelepiped; and by the first part of this proposition, B D M K is equal to each of B D G E, and B D*ge*. ∴ B D G E = B D*ge*. Q. E. D.

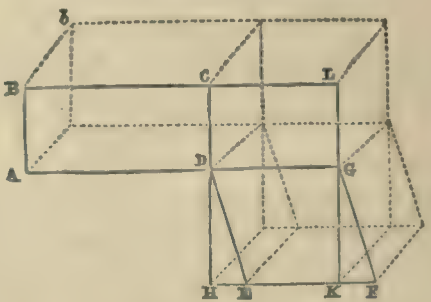
Fig. 34.



(3). *Solid Parallelepipeds on equal Bases and of the same Altitudes are equal to each other.*

(*a*) Suppose the edges to be perpendicular to the bases.

Fig. 35.



To avoid a complicated figure we will only letter the bases, and will call the edges of figure that are perpendicular to the bases by the letters at the angles of the base. Thus the edge B means the edge perpendicular to the base at the point B—*i. e.*, B*b*. Let A C, D F be the bases where we suppose the solids to be so placed as to have a common edge D, and the sides A D, D E in the same straight line; produce C D, and F E to meet in H; through G draw L G K parallel to C D, and produce B C to meet K G in L

Now since D H = G K, and H E is evidently = K F and the angle D H E = G K F ∴ the base D H E = base G K F; and since edges H and K are perpendicular to base, the solid angle at H is contained by plane angles respectively equal to those containing the angle K; and hence the prisms whose bases are D H E and G K F are equal. Add the solid on base D E K G to both, ∴ paral^{ppd} on D K = paral^{ppd} D F.

Now paral^{ppd} B D : paral^{ppd} D L : : A D : : D G : : B D : D L

and paral^{ppd} D L : paral^{ppd} D K : : C D : D H : : D L : D K

∴ (Ex equali).

paral^{ppd} B D : paral^{ppd} D K : : B D : D K

But B D = D K, since (Eucl. I., 35) D K = D F

∴ paral^{ppd} B D = paral^{ppd} D K = paral^{ppd} D F.

(*b*) If the edges are not perpendicular to the bases, call the paral^{ppd} P and Q. If on P's base a paral^{ppd} *p* be described, whose edges are perpendicular to base, and whose altitude is same as P, then *p* = P by last Proposition; and if *q* be in like manner described on same base as Q, but having its edges perpendicular to the base, then (last Proposition) *q* = Q, and by the former part of this Proposition, *q* = *p*, ∴ Q = P. Q. E. D.

Cor. 1.—Hence if there be two paral^{ppd} of the same altitude, but the base of the one be double of the base of the other, the former is double of the latter; and generally if the base of the one be any multiple of the base of the other, the former paral^{ppd} is the same multiple of the latter; and hence, by reasoning similar to that employed in Cor. 5, Prop. I. of the present article, it appears that paral$^{\text{ppds}}$ of equal altitudes are as their bases. And again, if they have equal bases, they are to one another as their altitudes.

---

[*] We shall use throughout the abbreviation paral^{ppd} for parallelepiped.

Cor. 2.—Let there be two paral$^{\text{ppds}}$ P, P′, the base and height of one of which are A and h, and one of the other A′ and h', where Ah A′h' are in numbers. And suppose S to be a third paral$^{\text{ppd}}$ on the base A′ and the height h.

Then
$$P : S :: A : A'$$
$$S : P' :: h : h'$$
$$\therefore P : P' :: Ah : A'h'$$

Cor. 3.—If we suppose P′ to be a cube which has one of its edges equal to unity, then A′ = 1. and h' = 1.

$$\therefore P : P' :: Ah : 1.$$

hence if we consider P′ to be the unit of solid measure (a cubic inch, or foot, for instance) then

$$P = Ah.$$

Hence the volume of a paral$^{\text{ppd}}$ is found by multiplying the area of one face by the distance between that face and the opposite one.

Cor. 4.—We have seen that a prism on a triangular base is half of a paral$^{\text{ppd}}$ of the same altitude, and on a base which is double of the triangle. Hence if A be the area of the triangle, and h the height of the prism, the volume of this paral$^{\text{ppd}}$ = 2A × h, and ∴ the volume of the prism = A × h; or the volume of a prism on a triangular base is found by multiplying the area of the base by the altitude.

Cor. 5.—It is plain that a prism on a polygonal base can be divided by planes passing through one edge of the prism into a number of prisms on triangular bases, each having the same altitude as the original prism.

Let A_1 A_2 A_3 . . . be the areas of these triangles, and h the common altitude, the volumes of all these prisms

$$= (A_1 + A_2 + A_3 + \ldots).\ h$$

But the polygon is equal to all the triangles; hence if A be the area of the polygon,

$$A = A_1 + A_2 + A_3 + \ldots\ \ldots$$

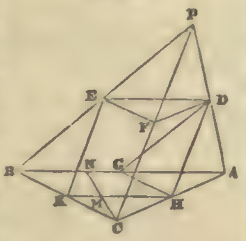
∴ The volume of the prism on a polygonal base = Ah, or is equal to the base multiplied by the altitude.

Cor. 6.—It is plain that Cor. 5 is true of a regular polygon of any number of sides, and therefore is true in limit; now when the number of sides of the polygon is increased, its limit is the circumscribing circle, and the limit of the corresponding prism is the circumscribing cylinder. Hence the volume of a cylinder = Ah, or base × height.

N.B.—When we speak of the volume of a solid, a prism for instance, being equal to the base multiplied by the height, it is of course understood that all the measurements are referred to the same unit. Thus, if we were asked what is the volume of a prism whose base is 2 square feet, and height 18 inches?—the answer is, not 2 × 18, but $2 \times \frac{18}{12} = 3$, and the 3 is in CUBIC FEET. The cubic foot and the square foot being the unit of content and of area corresponding to the linear unit *one foot*.

(4). *If* P, A B C *be any pyramid on a triangular base, and if through the middle point* (D) *of one of the sides* (A P) *we draw planes* (D G H *and* D E F) *parallel to one of the faces* (P B C) *and to the base* (A B C) *of the pyramid, then if we suppose a plane to be drawn through* D E *and* D H, *cutting off a prism* E F D, H K C, *the figure* E D G H C B *is double of the prism* E D F, H K C.

Fig. 36.

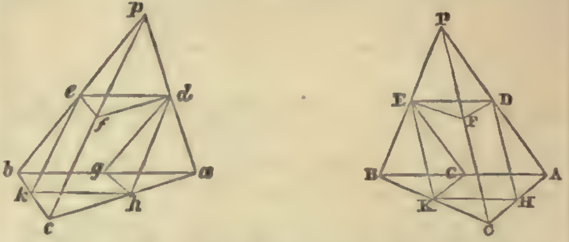


Since the plane E D F is parallel to A B C, E D is parallel to A B. Now A P is bisected in D. ∴ P B is bisected in E. Similarly A C is bisected in H. Also since plane D E F is parallel to A B C. ∴ E D is parallel to K H, and ∴ K H is parallel to A B. Draw C N perpendicular to A B, meeting K H in M; then since C H : H A : : C M : M N (Euclid VI., 2), and C H = H A ∴ C M = M N. Hence, if from N and C perpendiculars are drawn on the plane, D E K H, they are equal. Hence paral$^{\text{ppds}}$ on the base D E K H, with these perpendiculars respectively for altitudes, are equal. Now the prism B E K H D G is half the former, and the prism K C H D F E is half the latter. Hence the prisms are equal, and they are together double of one of them. But the two prisms make up the figure E D G H C B, which is, therefore, double of the prism E D F H K C.

(5). *Pyramids on triangular Bases and of equal Altitudes are to one another as their Bases.*

Let P, A B C, p, abc be the two pyramids, and let them be divided by planes as in the last proposition.

Fig. 37.



Now efd : bca in the duplicate ratio of fd : ca; but fd : ca : : 1 : 2 ∴ efd : bca : : 1 : 4. Similarly E F D : B C A : : 1 : 4 ∴ efd : bca : : E F D : B C A or efd : E F D : : bca : B C A. But the prism $efdkch$: prism E F D K C H : : efd : E F D : : abc : A B C. ∴ (by last proposition)

The double prism $edghcb$: E D G H C B : : abc : A B C.

Now if we suppose pd and P D, and also da and D A to be equal, figures will be formed p,dfe, and P, D F E of the same kind as in p,abc and P, A B C, and also in d,agh and D, A G H, and these figures will have to each other the ratios efd : E F D and agh : A G H respectively; which ratios are each equal to the ratio abc : A B C. And the same will be true, however often we continue to bisect the bisections of the sides, and hence

All the double prisms in
p, abc : all those in P, A B C : : abc : A B C.

And the number of successive bisections being as great as we please, this is true in the limit. Now the pyramids are the limits of the sum of these double prisms. Hence

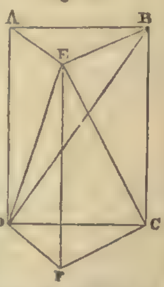
p,abc : P, A B C : : abc : A B C. Q. E. D.

Cor.: Hence pyramids on equal bases and of the same altitude are equal.

(6). *Every Prism on a triangular Base can be divided into three equal Pyramids.*

Let A B E, D F C be the prism; draw a plane through D E and C, cutting off the pyramid E, D F C, and through E D and B draw a plane dividing the remainder into two pyramids E, A B D and E, B C D. Now since these two latter have their vertices coincident at E, and since their bases A B D, B D E are manifestly equal, being halves of the parallelogram A C, the two pyramids E, A B D and E, B D E are equal. Now the pyramid E, A B D is clearly the same as the pyramid D, A B E. But the base ABE = base D E F, and the perpendicular from E on D F E, is equal to that from D on A B E since these planes are parallel; hence the pyramid D, A B E = pyramid E, D F C, and therefore the three pyramids are equal.

Fig. 38.



COR. 1.—Hence if a pyramid and a prism have equal triangular bases and are of equal altitudes, the pyramid is one-third part of the prism.

COR. 2.—Let A = area of base, h = height of pyramid. Then the volume of the prism on base A and of height $h = Ah$. And ∴ the volume of pyramid $= \frac{Ah}{3}$.

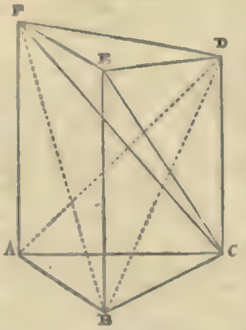
COR. 3.—If we have a pyramid on a polygonal base of which the area is A, it can be divided into triangles whose areas we will suppose to be A_1 A_2 A_3 . . . . so that $A = A_1 + A_2 + A_3 + \ldots$ Now if h be the height of the pyramid, then its volume being clearly the sum of the pyramids whose bases are A_1 A_2 A_3 . . . . and height h, will equal

$$\frac{1}{3}h\left(A_1 + A_2 + A_3 + \cdots\right) = \frac{1}{3}Ah.$$

COR. 4.—This is true, however great the number of sides there are to the polygon, and hence is true in the limit. Now if we suppose the polygon to be regular, its limit is the circumscribing circle, and the limit of the pyramid is the circumscribing cone ∴ volume of cone $= \frac{Ah}{3}$ where A is the area of the circular base.

(7). *To determine the Volume of the Frustum of a right Prism on a triangular Base.*

Fig. 39.

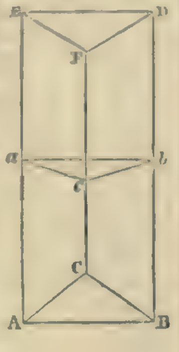


Let A B C, D E F be the frustum, where A B C is perpendicular to the edges. Let A = area of A B C, and let h_1 h_2 h_3 be the edges A F, B E, C D respectively, and V the required volume. Join F C and suppose a plane to pass through F C E, cutting off the pyramid C, FED, and another through E C A cutting off the pyramids E, A B C, E, A C F, these three make up the volume V. Join F B, D B, and D A. Now volume of E, A B C $= A\frac{h_2}{3}$; volume of E, F A C = volume of B, F A C; since perpendiculars from E and B on the plane A C F are clearly equal, and B, F A C is the same pyramid as F, A B C, the volume of which is $A\frac{h_1}{3}$.

Again, since F A is parallel to D C, the triangle A C D is = the triangle F C D; and we have already seen that the perpendiculars from E and B on the plane A C D F are equal, ∴ the pyramid E, C D F = the pyramid B, A C D, *i. e.* = D A B C, the volume of which is $\frac{Ah_3}{3}$.

$$\therefore\ V = A\frac{h_1}{3} + A\frac{h_2}{3} + \frac{h_3}{3}. = A\frac{h^1 + h_2 + h_3}{3}$$

Fig 40.



COR.—If the prism be A B C, F E D, in which neither of the ends is perpendicular to the edges, take *abc* an area whose plane is perpendicular to the edges, and let A = area of *abc*.

Let $AE = h_1$, $BD = h_2$ $CF = h_3$
$aE = x_1$ $bD = x_2$ $cF = x_3$
$aA = y_1$ $bB = y_2$ $cC = y_3$
Then if V = volume required
V = *abc*. D E F + *abc* A B C

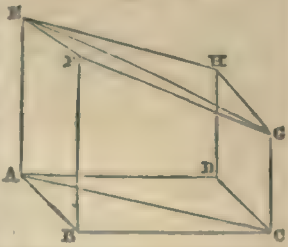
$$= A\frac{x_1 + x_2 + x_3}{3} + A\frac{y_1 + y_2 + y_3}{3}$$

$$= A\frac{x_1 + y_1 + x_2 + y_2 + x_3 + y_3}{3}$$

$$= A\frac{h_1 + h_2 + h_3}{3}$$

(8). *To determine the Volume of a Frustum of a Right Prism on a base which is a Parallelogram.*

Fig. 41.



Let A B C D E F G H be the frustum in question; let h_1 h_2 h_3 h_4 be the edges at A. B. C. D. respectively; draw A C, and if a plane pass through A C and E it divides A B . . . . H into two frustums similar to that in the last proposition. Let V be the required volume, and A_1 the area A B C which is = area ADC (Euclid, I., 34). Now the volumes of the two triangular prisms are respectively

$$A_1\frac{h_1 + h_2 + h_3}{3},\ \text{and}\ A_1\frac{h_3 + h_4 + h_1}{3}$$

$$\therefore V = \frac{1}{3}A_1(h_1 + h_2 + h_3) + \frac{1}{3}A_1(h_3 + h_4 + h_1)$$

If we had divided the figure by a plane passing through B D, we should have had

$$V = \frac{1}{3}A_1(h_2 + h_3 + h_4) + \frac{1}{3}A_1\ (h_4 + h_1 + h_2$$

Similarly if we had divided at C and D, we should have had respectively

$$V = \frac{1}{3}A_1(h_3 + h_4 + h_1) + \frac{1}{3}A_1(h_1 + h_2 + h_3)$$

$$V = \frac{1}{3}A_1(h_4 + h_1 + h_2) + \frac{1}{3}A_1(h_2 + h_3 + h_4)$$

Now let $S = h_1 + h_2 + h_3 + h_4$. Then adding the four values of V we have

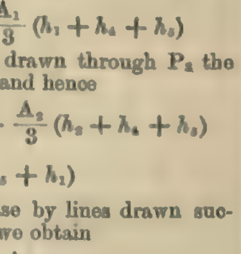
$$4V = \frac{1}{3}A_1\left(S + S + S\right) + \frac{1}{3}A_1\left(S + S + S\right)$$
$$= 2A_1.\ S$$

∴ If A be the whole area A B C D. Since $A = 2A_1$

$$V = A\frac{S}{4} = A\ \frac{h_1 + h_2 + h_3 + h_4}{4}$$

(9). *To find the Volume of a Frustum of a right Prism on a regular Pentagonal Base.*

Fig. 42.



Let P_1 P_2 P_3 P_4 P_5 be the base, and let h_1 h_2 h_3 h_4 h_5 be the edges corresponding to these angles. Join P_1 P_3 and P_1 P_4, and let the areas of P_1 P_2 P_3 and P_1 P_4 P_5, which are equal, be each A_1, and the area of P_1 P_3 P_4 be A_2. Let V be the required volume, then this volume consists of three portions of prisms of the same kind as in article (7) and hence

$$V = \frac{A_1}{3}(h_1 + h_2 + h_3)$$
$$+ \frac{A_2}{3}(h_1 + h_3 + h_4) + \frac{A_1}{3}(h_1 + h_4 + h_5)$$

Now divide the base by lines drawn through P_2 the areas will be the same as before, and hence

$$V = \frac{A_1}{3}(h_2 + h_3 + h_4) + \frac{A_2}{3}(h_2 + h_4 + h_5)$$
$$+ \frac{A_1}{3}(h_2 + h_5 + h_1)$$

and similarly by dividing the base by lines drawn successively through P_3 P_4 and P_5 we obtain

$$V = \frac{A_1}{3}(h_3 + h_4 + h_5) + \frac{A_2}{3}(h_3 + h_5 + h_1)$$
$$+ \frac{A_1}{3}(h_3 + h_1 + h_2)$$

$$V = \frac{A_1}{3}(h_4 + h_5 + h_1) + \frac{A_2}{3}(h_4 + h_1 + h_2)$$
$$+ \frac{A_1}{3}(h_4 + h_2 + h_3)$$

$$V = \frac{A_1}{3}(h_5 + h_1 + h_2) + \frac{A_2}{3}(h_5 + h_2 + h_3)$$
$$+ \frac{A_1}{3}(h_5 + h_3 + h_4)$$

Then adding these together, and writing

$$h_1 + h_2 + h_3 + h_4 + h_5 = S$$

we have $5\,V = \frac{A_1}{3}(S + S + S)$

$$+ \frac{A_2}{3}(S + S + S) + \frac{A_1}{3}(S + S + S)$$
$$\therefore 5\,V = (2A_1 + A_2)\,S = A.\,S.$$

If A = area of base.

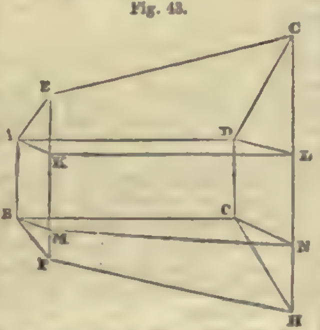
$$\therefore V = A.\,\frac{h_1 + h_2 + h_3 + h_4 + h_5}{5}$$

The student can easily prove that a similar formula is true in the case of a prism on a hexagonal base, or indeed on any base which is a regular polygon.

(10). *To find the Volume of a Prismoid.*

Def.—A prismoid is a solid of the form represented in the accompanying figure. A B C D is a rectangle, and A B F E, D E H G, are planes perpendicular to the planes of the rectangle, E D and C F are planes inclined at given angles to the plane of the rectangle, the lines E F and G H being parallel to A B and C D.

Fig. 43.



Through A D and B C draw planes A D L K and B C N M perpendicular to the plane of the rectangle; then divide the given figure into three—viz., A E K D L G, B D N, and B M F C H N.

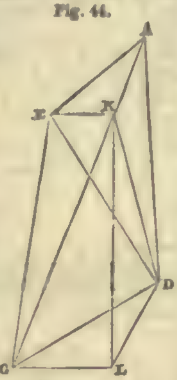
Let A B = a A D = h A K = x D L = x_1 E K = b G L = b_1 M F = c N H = c_1

Then (a) the figure B D N is of the same kind as in Article 8. Now the area D B = ah; if therefore V_1 is its volume,

$$V_1 = \frac{ah}{4}(x + x + x_1 + x_2) = \frac{ah}{2}(x + x_1)$$

(b). Let V_2 be the volume of the figure A E K D L G, (Fig. 44), draw planes through E D,K and G D,K, dividing the figure into three pyramids, D G L,K, A E K,D, and D E G,K.

Fig. 44.



The volume of G L D,K

$$= GLD \times \frac{KL}{3} = \frac{x_1 b_1}{2} \times \frac{h}{3} = \frac{h}{6} x_1 b_1$$

Similarly, volume of A E K,D $= \frac{h}{6} xb$.

Now the volume of G E D,K is to that of A D E,K as G E D is to A D E, or as A E to G D; or since triangles A E K, G D L are similar, these volumes are as A K to D L, or as E K to G L.

$\therefore$ Volume G E D,K

$$= \frac{h}{6} x\,b \times \frac{x_1}{x} \text{ or } = \frac{h}{6} \cdot xb \times \frac{b_1}{b}$$
$$= \frac{h}{6} x_1\,b \text{ or } = \frac{h}{6} \,.\, xb$$
$$= \frac{h}{6} \cdot \frac{x_1 b + x b_1}{2}$$
$$\therefore V_2 = \frac{h}{6}\left(x_1 b_1 + xb + \frac{x_1 b + x b_1}{2}\right)$$

(c). Similarly, if V_3 is the volume of M B F C N H (Fig. 43)

$$V_3 = \frac{h}{6}\left(x_1 c_1 + xc + \frac{xc_1 + xc_1}{2}\right)$$

Now if V be the required volume,

$$V = V_1 + V_2 + V_3.$$
$$\therefore V = \frac{h}{6}\left\{3\,a\,(x + x_1) + x_1\,(b_1 + c_1) + x\,(b + c)\right.$$
$$\left. + x_1\,\frac{b + c}{2} + x\,\frac{b_1 + c_1}{2}\right\}$$

or rearranging the right-hand side of the equation,

$$V = \frac{h}{6}\left\{x\left(a + \frac{b + c}{2}\right) + x_1\left(a + \frac{b_1 + c_1}{2}\right)\right.$$
$$\left. + (x + x_1)\left(2\,a + \frac{b + c}{2} + \frac{b_1 + c_1}{2}\right)\right\}$$

Now in this expression,

$x\left(a + \frac{b + c}{2}\right)$ is the area of A B F E. (Fig. 43).

$x_1\left(a + \frac{b_1 + c_1}{2}\right)$ is the area of D C H G.

and $(x + x_1)\left(2a + \frac{b + c}{2} + \frac{b_1 + c_1}{2}\right)$, which equals

$$4 \times \frac{x + x_1}{2}\left\{\frac{1}{2}\left(a + \frac{b + c}{2}\right) + \frac{1}{2}\left(a + \frac{b_1 + c_1}{2}\right)\right\}.$$

is clearly four times the area of a section made by a plane parallel to A B F E and D E H G, and half way between them.

Hence the solid content of a prismoid is found by the following rule: "To the areas of the ends, add four times the area of the mean section; multiply this sum by one-sixth of the height of the figure; this product is the volume required."

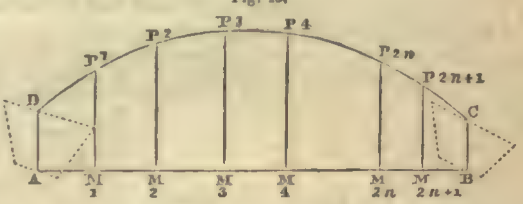
In practical cases it will generally happen that $b = c$, and $b_1 = c_1$. This does not affect the enunciation of *the rule*, but simplifies the formula, which becomes

$$V = \frac{h}{6}\left\{3a\,(x + x_1) + x_1\,(2\,b_1 + b) + x\,(2\,b + b_1)\right\}.$$

(11). *To find the Solid Content of a Railway Cutting.*

In the last article, the figure (Fig. 43) is very nearly that of a portion of a railway cutting, in which A B C D is the road, A G and B H, the sloping sides of the embankment, and hence the solid content required can be found by means of the rule given in the last article. It is to be observed that the rule requires E G and F H to be straight lines, or, as an approximation, to be very nearly straight lines, or E H to be a plane, which is not true if the cutting be a long one. For this case we derive the following rule from the above formula.

Fig. 45.



Let A B C represent a section made by a vertical plane of the hill to be cut through, A B the level of the road, and suppose sections of the cutting to be made by planes perpendicular to A B, at equal distances along that line, viz., at M_1 M_2 M_3 . . . M_{2n+1}, let the terminal sections at A and B be a and b, and the sections at P_1 M_1 P_2 M_2 . . $p_1\,p_2\,p_3 \ldots p_{2n}\,p_{2n+1}$, the number of sections being odd, and let the common distance between the sections be h. Now by last article the volume of portion

$$\text{A M}_2\text{ P}_2\text{ D is }\frac{\text{A M}_2}{6}.\ (a+4p_1+p_2)\text{ or}$$

$$\frac{h}{3}(a+4p_1+p_2)$$

and the volume of the portion $P_2\ M_2\ M_4\ P_4$ is $\frac{h}{3}\ (p_2+4p_3+p_4)$, and so on;

and the volume of $P_{2n}\,M_{2n}$ B C is $\frac{h}{3}.(p_{2n}+4p_{2+1}+b)$. Hence, by addition, the whole volume required is

$$\frac{h}{3}.\left\{(a+b+4(p_1+p_3+\ldots+p_{2n}+_1)+2(p_2+p_4\ldots p_{2n})\right\}$$

which may be expressed as a rule as follows.

Between the first and last sections make an odd number of sections at equal distances along the road, the planes of the section being perpendicular to the road; then one-third part of the common distance multiplied by the sum of the first and last sections, with four times the sum of the odd sections, and twice the sum of the even sections, gives the volume between the first and last section.

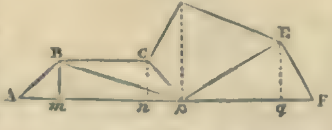
The student will observe that this rule is the same as that for finding the area of a figure bounded by a curve, which has been already given (p. 647), excepting that the ordinates in the former rule are replaced by trapezoidal sections in the latter. The formula given in article 10 is called the prismoidal formula. It will be observed that the material on each side of a cutting being generally the same, is the reason the inclination of the planes A G and B H to B D being generally the same as stated in the last article. Mr. Macneill, to whom the prismoidal formula is due, has constructed tables founded on that formula, by which the volume of a cutting is very readily calculated. The volume of an embankment is to be found by the same formula, since, as a question of mere figure, an embankment is only an inverted cutting. If the calculation be made directly from the formula, it is very tedious; the value of the tables above referred to is therefore very great, and is enhanced by the following circumstance:—In constructing a long line of railway, the earth taken out of the cutting should be sufficient to form the embankment, otherwise land must be purchased for the mere purpose of obtaining earth; to effect this end of making the volume of the embankments equal that of cuttings, the ascents and descents (gradients) of the line of road have to be properly chosen, and this can only be done by trial, so that the calculation may have to be performed two or three times before a right adjustment can be hit upon. It is worth adding that, as a general rule, a cutting is followed not by a long level, but by an embankment; if possible, these two are adjusted to each other, to prevent the need of carrying earth from long distances.

12. *To find the Solid Content of a Military Earth-work.*

The form of a military earth-work will be understood from the following explanations:—

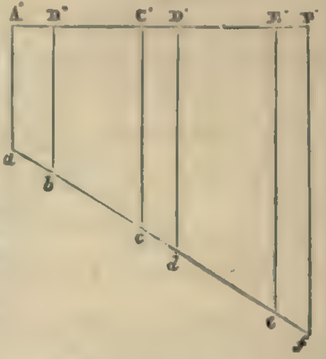
The form of a section of the work made by a vertical plane perpendicular to the face of the work is such as A B C D E F: from B, C, D, E draw perpendiculars to A F, viz., B*m*, C*n*, D*p*, E*q*, then A*m*, *mn*, *np*, *pq*, *q*F, are of known magnitudes, as also are B*m*, C*n*, D*p*, E*q*. The plan of the work will be of the accompanying kind, viz., F′*f* (Fig. 47) is the line corresponding to F (Fig. 46), E′*e* the line corresponding to E, and so on for the others; the lengths of all these lines are known; we will call them *a*, *b*, *c*, *d*, *e*, *f*, respectively.

Fig. 46.



In Fig. 46, join *p*E, *p*C, *p*B, dividing the section of the work into triangles A*p*B, B*p*C, C*p*D, D*p*E, and E*p*F; call these areas respectively $A_1\ A_2\ A_3\ A_4\ A_5$, then the contents of the work are clearly equivalent to the frustums of five prisms (similar to that in the Corol. to article 7), which have the area of perpendicular section A_5, and edges *f*, *e*, *d*, section A_4 and edges *e*, *d*, *d*, section A_3, and edges *d*, *d*, *c*, section A_2 and edges *c*, *d*, *b*, and section A_1 and edges *b*, *d*, *a*, it being evident that the edge through $p=d$. Hence if the whole volume equal V, we have

Fig. 47.



$$V=\frac{A_5}{3}(f+e+d)+\frac{A_4}{3}(e+d+d)+$$

$$\frac{A_3}{3}(d+d+c)$$

$$+\frac{A_2}{3}(c+d+b)+\frac{A_1}{3}(b+d+a)$$

$$\begin{aligned}\therefore 3\,V=a\,A_1+b\,(A_1+A_2)+c\,(A_2+A_3)\\+d(A_3+A_4)+c\,(A_4+A_5)+f\,A_5)\\+d\,(A_1+A_2+A_3+A_4+A_5)\end{aligned}$$

In which formula it will be observed that each line in the plan is multiplied by the triangle, or by the sum of the triangles, which have an angular point in that line, and that the line *d*D′ is also multiplied by the whole area of the section. Hence if these products are formed and added together, the required volume is one-third of the sum.

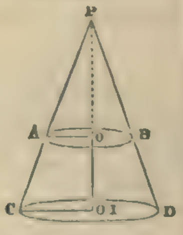
13. *To find the Volume of the Frustum of a right Cone made by a Plane parallel to the Base.*

Let A B C D be the frustum of the cone P C D. Join P O O_1 where O O_1 are the centres of the ends of the frustums. Let A O = *r*, C $O_1 = r_1$, $OO_2 = h$. P O = *x*.

Then volume A B P = $\frac{\pi r^2 x}{3}$, volume

P C D = $\frac{\pi r_1{}^2\,(x+h)}{3}$

Fig. 48.



∴ Volume of frustum =

$$\frac{\pi}{3}\ r_1{}^2 h+\frac{\pi\,(r_1{}^2-r_2{}^2)}{3}x$$

Now $x+h:r_1::x:r$.
$\therefore h:x::r_1-r:r$.

$$\therefore\text{ Volume of frustum}=\frac{\pi}{3}r_1{}^2h+\frac{\pi\,(r_1{}^2-r^2)}{3}\,\frac{hr}{r_1-r}$$

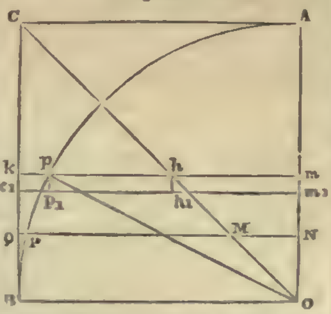
$$=\frac{\pi h}{3}.\ (r_1{}^2+r_1r+r^2)$$

which is the same as the volume of three cones whose common height is *h*, and which have the radii of their bases respectively *r*, r_1 and a mean proportional between *r* and r_1.

14. *To find the Volume of a Portion of a Sphere.*

Let A B O be a quadrant of a circle, draw B C, A C, tangents at A, and B, join O C, and take any point P in A B and draw Q P N parallel to B O; then if the whole figure revolve round A O, the quadrant A B O will clearly describe a hemisphere, the square A O B C will describe a cylinder, on a base whose radius is O B, and height A O, and the triangle A C O will describe a cone on a base whose radius is A C and height A O. Also A P N will describe a portion of a sphere, A C Q N a cylinder whose height is A N and radius A C, and A C M N a frustum of a cone, the radii of whose ends are A C and M N, and height A N. Divide A N into any number of equal parts, of which let $m\,m_1$ be one, through m, draw mk parallel to B O, meeting A B in p, and Q C in k, and through m_1 draw a line $m_1\ k_1$ parallel to mk, and from p and h draw pp_1 and hh_1 perpendicular to $m_1\ k_1$. Join Op. Now $Op^2 = mp^2 + mO^2$ since Omp is a right angle. But since triangle Omh is similar to O A C and A C = A O $\therefore Om = mh$ also $km = BO = Op \therefore mk^2 = mp^2 + mh^2 \therefore \pi \times mk^2 = \pi \times mp^2 + \pi \times mh^2$ or (Mensuration of Areas, Art. 8) the circle, the radius of which is mk, is equal to the sum of those whose radii are mp, and mh; also since $kk_1 = pp_1 = hh_1$ we have

Fig. 49.



$$\pi\ mk^2 \times kk_1 = \pi.\ mp^2 \times pp_1 + \pi\ mh^2 \times hh_1$$

or the cylinder, the radius of whose base is mk and height kk_1, is equal to the cylinder, the radius of whose base is mp, and height pp_1, together with that the radius of whose base is mk, and height hh_1; but these cylinders are those which will be described by mk_1 mp_1 and mh_1, when the whole figure revolves round A O. And the same is true of the cylinders corresponding to any other one of the equal parts into which A N is divided, and therefore is true of all of them. Now all the cylinders corresponding to km_1 make up the cylinder described by A Q, and all those described by m_1p, make up the series of cylinders inside the sphere, and those described by $m_1\,h$ make up those described about the cone. Hence,

Cylinder A Q = sum of cylinders inside portion of sphere + sum of cylinders outside portion of cone.

This being true, however small $m\,m_1$ may be, is true in the limit, but the portion of the sphere is the limit of the inscribed cylinders, and the frustum of cone is the limit of the cylinders outside the cone (compare Note, p. 646). Hence,

Cylinder described by A Q = portion of sphere described by A P N + portion of cone described by A C M N.

Now let r = radius of sphere h = height of A N, and V_1 = volume of portion of sphere N M = O N = $r - h$.

Now the column of cylinder described by A Q = $\pi r^2 h$. And volume of frustum of cone described by A C M N

$$= \frac{\pi h}{3} \times \left\{ r^2 + (r-h)\,r + (r-h)^2 \right\}$$

$$\therefore \pi r^2 h = V_1 + \frac{\pi h}{3} \left\{ r^2 + (r-h)\,r + (r-h)^2 \right\}$$

$$\therefore 3V_1 = 3\pi\,r^2 h - \pi h \left\{ r^2 + (r-h)\,r + (r-h)^2 \right\}$$

$$= \pi h \left(3r\,h - h^2 \right)$$

$$\therefore V_1 = \frac{\pi h^2}{3} \cdot \left(3r - h \right).$$

Hence if V = volume of the whole sphere, in which case $h = 2r$.

$$V = \frac{4\pi\,r^3}{3}$$

Now the volume of cylinder circumscribing sphere $= \pi r^2 \times 2r$.

$$\therefore V = \frac{2}{3}.\ \text{(circumscribing cylinder).}$$

Cor. 1.—The above proposition may be demonstrated in the following manner. Suppose a solid having any number of plane faces to be described in the sphere, and let $A_1\ A_2\ A_3$ &c., be the areas of these faces, and $p_1\ p_2\ p_3$ &c., be the perpendicular distances of these faces from the centre of the sphere; now this inscribed solid may be conceived to be made up of pyramids, the bases of which are the faces of the solids, having the centre of the sphere for their common vertex. Hence, if the volume of the solids is V_1

$$V_1 = \frac{1}{3} A_1\,p_1 + \frac{1}{3} A_2\,p_2 + \frac{1}{3} A_3\,p_3 + \ldots$$

Now this is true, however great the number of faces may be, and $\therefore$ is true in the limit, but in the limit, $p_1\ p_2\ p_3 \ldots$ become equal to one another, and to r the radius of sphere. Hence,

Limit of $A_1\,p_1 + A_2\,p_2 + A_3\,p_3 + \ldots = r \times$ (limit of $A_1 + A_2 \times A_3 \ldots$)

Now the limit of $A_1 + A_2 + A_3 + \ldots$ = surface of sphere = $4\pi\,r^2$ (Mensuration of Areas, Art. 19). Also the limit of $V_1 = V$ the volume of sphere.

$$\therefore V = \frac{1}{3} r \times 4\pi\,r^2 = \frac{4\pi\,r^3}{3}.$$

Cor. 2.—To find the volume of the portion of the sphere corresponding to B P N O. Let the volume be called V, and let h = O N which is = M N. Then

V = cylinder B N — cone O N M.

Now volume of cylinder B N $= \pi r^2 h$

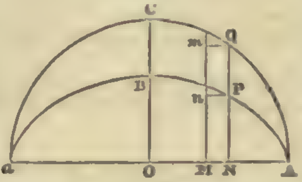
$$\text{Volume of cone M N O} = \frac{1}{3}\ \pi h^3$$

$$\therefore V = \pi r^2 h - \frac{1}{3}\ \pi h^3 = \pi h \left(r^2 - \frac{1}{3}\,h^2 \right)$$

15. *To find the Volume of a Spheroid.*

Def.—A spheroid is a figure formed by the revolution of an ellipse about one of its axes; if about the major axis it is called a prolate spheroid, if about its minor axis it is called an oblate spheroid.

Fig. 50.



Let A Ba be a semi-ellipse, O A its semi-major axis, O B its semi-minor axis. With centre O and radius O A describe a semicircle A Ca, draw Q P N through any point in the ellipse parallel to O C, draw Mnm parallel to N P Q and complete the rectangles M P, M Q (Mensuration of Areas, Art. 12).

Now if the figure revolve round Aa the semi-ellipse will describe a prolate spheroid and the circle a sphere, also M P and M Q will describe cylinders with altitudes M N, and having the radii of the bases N P and N Q respectively, and $\therefore$ having volumes π M N $\times$ P N^2 and π. M N $\times$ N Q^2. Now by a property of the ellipse,

$$QN : PN :: a : b$$
$$\therefore QN^2 : PN^2 :: a^2 : b^2$$

$$\text{But}\quad \text{Cylind. } MQ : \text{cylind. } MP :: MQ^2 : MP^2$$
$$\therefore \text{cylind. } MQ : \text{cylind. } MP :: a^2 : b^2$$

and the same is true of any other cylinders described in like manner within the sphere and spheroid, and $\therefore$ is true of their sum

$\therefore$ all cylinders within sphere : all within spheroid :: $a^2 : b^2$

and this being true, however many cylinders there may be, *i.e.*, however small we suppose M N to be, is true in the limit, but the sphere is the limit of its inscribed cylinders, and the spheroid the limit of its inscribed cylinder,

$$\therefore \text{Sphere : spheroid} :: a^2 : b^2 :: \frac{4\pi a^3}{3} : \frac{4\pi ab^2}{3}.$$

$$\text{But volume of sphere} = \frac{4\pi a^3}{3}.$$

$$\therefore \text{Volume of spheroid} = \frac{4\pi ab^2}{3}.$$

Cor.—In like manner the volume of an oblate spheroid is $\dfrac{4\pi a^2 b}{3}$

16. *To find the Volume of a portion of a Spheroid cut off by a plane Perpendicular to the Axis of Revolution.*

In figure 50, suppose we wish to find the volume of the portion of the spheroid corresponding to the portion A P N of the generating ellipse; then, as in Art. 15, we shall have

Portion of Spheroid : portion of sphere : : $b^2 : a^2$

Now (Mensuration of Solids, Art. 14), if $AN = h$ the volume of the portion of the sphere is equal to $\frac{\pi h^2}{3}(3a - h.)$

$\therefore$ If V_1 is the volume required,

$$V_1 = \frac{\pi h^2 b^2}{3a^2}(3a - h).$$

Similarly, if we wish to find the volume of the portion corresponding to O N P B, and if V_2 is this volume, and $h = ON$,

$$V_2 = \pi h b^2 \left(1 - \frac{1}{3} \cdot \frac{h^2}{a^2}\right)$$

as is evident from Corol. 2, Art. 14, Mensuration of Solids.

17. *To find the Volume of a Cask.*

We may consider a cask to be either the middle portion of a spheroid, or two frustums of equal cones joined together at their bases, though it will not coincide with either of these forms exactly. It is to be observed that excise officers generally consider casks to be of the first form.

The measurements that are most easily made in practice are the diameters of the end, and of the middle section, and the distance between the ends; we will call these d, D, and k, respectively, and investigate the rule in each of the above cases.

(*a*). Suppose the cask to be a portion of a spheroid. Its volume V will be double that of V_2 in the last article

$$\therefore V = 2\pi h b^2 \left(1 - \frac{1}{3}\frac{h^2}{a^2}\right)$$

Also by a property of the ellipse, (See Fig. 50),

$$\frac{PN^2}{OB^2} + \frac{ON^2}{OA^2} = 1.$$

$$\therefore \frac{PN^2}{b^2} + \frac{h^2}{a^2} = 1.$$

$$\therefore \frac{1}{3} \cdot \frac{PN^2}{b^2} + \frac{1}{3} \cdot \frac{h^2}{a^2} = \frac{1}{3}.$$

$$\therefore \frac{2}{3} + \frac{1}{3} \cdot \frac{PN^2}{b} = 1 - \frac{1}{3}\frac{h^2}{a^2}$$

$$\therefore V = 2\pi h b^2 \left(\frac{2}{3} + \frac{1}{3}\frac{PN^2}{b^2}\right)$$

$$\therefore V = \frac{2\pi h}{12}\left(8b^2 + 4\,PN^2\right)$$

Now $2h = k$. $2b = D$ $2.\,PN = d$

$$\therefore V = \frac{\pi}{12} k \left(2.\,D^2 + d^2\right).$$

Also $\frac{\pi}{12} = .2618$ very nearly, hence the rule. "To twice the square of the middle diameter add the square of the end diameter, and multiply the sum by the length of the cask; this product multiplied by .2618 gives the contents of the cask."

(*b*). Suppose the cask to have the form of a double frustum of a cone.

If v be the volume required, v is clearly double of the volume A B C D, Fig. 48. And hence by Article 13, Mensuration of Solids,

$$v = \frac{2\pi h}{3}\left(r_1^2 + r r_1 + r^2\right)$$

Now $D = 2r_1$, $d = 2r$ and $k = 2h$

$$\therefore v = \frac{\pi}{12} \cdot k \left(D^2 + Dd + d^2\right).$$

Hence the rule, "To the product of the diameters add the sum of their squares; multiply this by the length of the cask, then the whole product multiplied by .2618 gives the contents of the cask."

N. B.—If the measurements are made in inches, the above rules give the required contents in cubic inches; to obtain the contents in gallons we must divide by 277.274, since 277.274 cubic inches go to one gallon.

COR.—It is evident that v, the value given by the second rule, is less than the true contents of the cask: it is to be observed, also, that V, the value given by the former rule, is generally greater than the true value; so that the true value will lie somewhere between these two results. Hence we can easily estimate the amount of accuracy in each of the above determinations. Thus, $V - v$ is clearly greater than the difference between the true result, and either of those given by rule, and v is less than the true value of the contents; hence the error committed by either way of making the calculation cannot be so great as the $\left(\frac{V - v}{v}\right)^{\text{th}}$ of the whole. Now

$$V - v = \frac{\pi k}{12}\left(2D^2 + d^2\right) - \frac{\pi k}{12}\left(D^2 + Dd + d^2\right)$$

$$= \frac{\pi k}{12}\left(D^2 - Dd\right) = \frac{\pi k}{12} D(D - d.)$$

$$\therefore \frac{V - v}{v} = \frac{\frac{\pi k}{12} D(D - d)}{\frac{\pi k}{12}\left(D^2 + Dd + d^2\right)} = \frac{D(D - d)}{D^2 + Dd + d^2}.$$

If $D = d + n$. Then $Dd = D^2 - Dn$, and $d^2 = D^2 - 2Dn + n^2$.

$$\therefore \frac{V - v}{v} = \frac{Dn}{3D^2 - 3Dn + n^2} = \frac{\frac{n}{3D}}{1 - \frac{n}{D} + \frac{n^2}{3D^2}}.$$

which is an expression for a limit of the part of the whole, by the approximate, which differs from the true value. *e.g.*, Suppose the diameters to be 18 and 20 inches respectively,

then $n = 2$ inches and $\frac{n}{D} = \frac{1}{10}$, and there the error committed by calculating according to either rule cannot be so much as $\frac{\frac{1}{30}}{1 - \frac{1}{10} + \frac{1}{300}}$ of the whole, or so much as $\frac{10}{271}^{\text{th}}$ or $\frac{1}{27}^{\text{th}}$ (very nearly) of the whole. If the cask in question had an interior length of two feet, then, by the first rule, its contents are 25·47 gallons, and, by the second, its contents are 24.56 gallons. So that the error committed by either way of gauging must be less than one gallon.

CHAPTER XV.

SPHERICAL TRIGONOMETRY.

Before reading the following Chapter, the student will do well to reperuse that on Spherical Geometry already given (p. 596, &c.) He will there find the definitions enunciated, and the chief properties of spherical triangles proved, which are employed as the premises, and whence the formulas of the following pages are deduced. It has been stated that the chief applications of this science are found in practical astronomy and geodesy; also it is observed, on p. 598, that the side of a spherical triangle measures the angle it subtends at the centre of the sphere, and hence is spoken of as an angle. Now it is to be remarked, that in practical astronomy, the measurements made by the various instruments are invariably the angles subtended at the eye of the observer, by arcs of the great sphere; for instance, the altitude of a star is measured directly as an angle,—so that in these cases the radius of the sphere never enters into consideration. But in the case of measurements on the earth's surface, if we have a distance measured along a great circle in miles or yards, which is to enter into our calculations, we must determine the angle these yards or miles subtend at the earth's centre: thus if a be the length in question, r the radius of the earth, θ the angle, then $\theta = \frac{a}{r}$ where θ is in circular measure. If θ contain $n°$, then $n° = \frac{a\,180°}{\pi r}$. Further it will be observed, that in case the sides of a spherical triangle are small compared with the radius of the sphere, the triangle does not differ sensibly from a plane triangle: *e. g.*, a triangle on the earth's surface, the sides of which are each about a mile long, will not differ sensibly from a plane triangle, unless the measurements are made with very refined instruments. Hence it is manifest that the plane triangle is the limit of a spherical triangle, and accordingly we shall find that the formulas for the solution of spherical triangles are quite analogous to those that have been already deduced for the solution of plane triangles (p. 616, *et seq.*), and we shall see that the latter can be deduced from the former by considering the plane triangle as the limit of the spherical triangle.

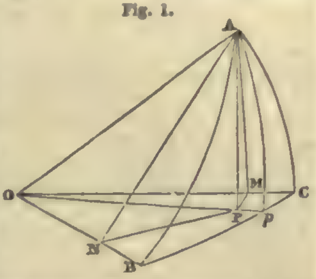
N.B.—The following results already proved on p. 599 are very important. Let A, B, C, a, b, c, be the angles and sides of any spherical triangle, and A′, B′, C′, a', b', c', the angles and sides of the corresponding polar triangle.

$$\text{Then}\quad A + a' = B + b' = C + c' = 180°$$
$$\text{And}\quad A' + a = B' + b = C' + c = 180°$$

We shall employ this notation for the angles and sides of a spherical triangle, and of its polar triangle, throughout the following pages.

(1). *To show that the Sines of the Angles of a Spherical Triangle are proportioned to the Sines of the opposite sides.*

Fig. 1.



Let A B C be the triangle, O the centre of the sphere; join O A, O B, O C; through A draw a plane A N P perpendicular to O B, cutting the plane A O B in A N and B O C in N P, these lines are perpendicular to O B, and the angle A N P measures the inclination of the planes, and is ∴ equal to the angle B of the triangle. Through A draw another plane A M P perpendicular to O C, cutting A O C in A M, C O B in M P, and A M P in A P, then A M and M P are perpendicular to O C, the angle A M P is equal to the angle C of the triangle, and A P is perpendicular to the plane B O A, and ∴ A P N and A P M are each right angles. Hence

$$\text{Sin. B} = \frac{AP}{AN}, \text{ and sin. C} = \frac{AP}{AM}. \quad \therefore \frac{\text{sin. B}}{\text{sin. C}} = \frac{AM}{AN}.$$

Also since c is the angle A O B and b the angle A O C

$$\text{sin. } c = \frac{AN}{OA}, \text{ and sin. } b = \frac{AM}{OA}. \quad \therefore \frac{\text{sin. } b}{\text{sin. } c} = \frac{AM}{AN}$$

$$\therefore \frac{\text{sin. B}}{\text{sin. } c} = \frac{\text{sin. } b}{\text{sin. } c}, \text{ or } \frac{\text{sin. B}}{\text{sin. } b} = \frac{\text{sin. C}}{\text{sin. } c}$$

The same proof holds good of the other sides and angles.

$$\text{Hence}\quad \frac{\text{sin. A}}{\text{sin. } a} = \frac{\text{sin. B}}{\text{sin. } b} = \frac{\text{sin. C}}{\text{sin. } c} \ldots \quad (1). \quad \text{Q.E.D.}$$

Cor. 1.—Suppose a, b, c, to be the lengths of the sides BC, CA, AB, then the angles denoted in formula (1) by a, b, c, are $\frac{a}{r}$, $\frac{b}{r}$, $\frac{c}{r}$ in circular measure, r being the radius of sphere. Hence

$$\frac{\text{sin. B}}{\text{sin. C}} = \frac{\text{sin. }\frac{b}{r}}{\text{sin. }\frac{c}{r}} = \frac{\frac{b}{r}\cdot\frac{\text{sin. }\frac{b}{r}}{\frac{b}{r}}}{\frac{c}{r}\cdot\frac{\text{sin. }\frac{c}{r}}{\frac{c}{r}}} = \frac{b}{c}\cdot\frac{\frac{\text{sin. }\frac{b}{r}}{\frac{b}{r}}}{\frac{\text{sin. }\frac{c}{r}}{\frac{c}{r}}}$$

Now in the limiting case when r is infinite, $\frac{a}{r} = 0$ and $\frac{b}{r} = 0$ and ∴ (Plane Trig., Art. 47)

$$\frac{\text{sin. }\frac{b}{r}}{\frac{b}{r}} = 1, \text{ and } \frac{\text{sin. }\frac{c}{r}}{\frac{c}{r}} = 1. \quad \therefore \text{ in the limit}$$

$$\frac{\text{sin. B}}{\text{sin. C}} = \frac{b}{c}\cdot$$ the formula for plane triangles (p. 627).

Cor. 2.—If through O and A P a plane be drawn cutting the surface of the sphere in Ap, then Ap is perpendicular to B C, and $\frac{AP}{OA}$ equals the sine of A O P: *i. e.*, is equal to the sine of Ap, which we will call p.

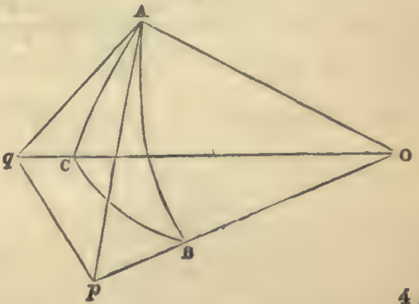
$$\text{Now sin. B sin. } c = \frac{AP}{AN} + \frac{AN}{OA} = \frac{AP}{AO} = \text{sin. A}p.$$

$$\therefore \text{sin. B sin } c = \text{sin. } p. \ldots \quad (2).$$

(2). *To prove the Formula* $\cos. A = \frac{\cos. a - \cos. b \cos. c}{\sin. b \sin. c}$

As before, let O be the centre of the sphere, and A B C

Fig. 2.



the triangle, join O A. O B. O C, and produce the planes A O B, B O C, C O A indefinitely; at A draw a plane Apq perpendicular to O A, cutting the planes A O B, B O C, C O A in Ap, pq, qA respectively, then since pA is on the plane A O B, and perpendicular to O A, and qA is on the plane C O A, and perpendicular to O A, pAq is the angle between the planes, and ∴ is equal to the angle A of the triangle; also the angle pOq is the angle subtended by B C: *i. e.*, is the angle a.

Hence (Plane Trig., Art. 37)

$$Ap^2 + Aq^2 - 2\,Ap.\,Aq\cos.\,A = pq^2 = Op^2 + Oq^2 - 2\,Op.\,Oq\cos.\,a.$$

$$\text{Now}\ \frac{Ap}{OA} = \tan.\,c = \frac{\sin.\,c}{\cos.\,c},\qquad \frac{Aq}{OA} = \tan.\,b = \frac{\sin.\,b}{\cos.\,b}.$$

$$\frac{OP}{OA} = \sec.\,c = \frac{1}{\cos.c}$$

$$\frac{Oq}{OA} = \sec.\,b = \frac{1}{\cos.b}$$

$$\therefore \frac{\sin.^2 c}{\cos.^2 c} + \frac{\sin.^2 b}{\cos.^2 b} - 2\frac{\sin.\,c\sin.\,b}{\cos.\,c\cos.\,b}\cos.\,A = \frac{1}{\cos.^2 c} + \frac{1}{\cos.^2 b} - \frac{2\cos.\,a}{\cos.\,c\cos.\,b}.$$

$$\therefore \frac{2\sin.\,c\sin.\,b}{\cos.\,c\cos.\,b}\cos.\,A = \frac{2\cos.\,a}{\cos.\,c\cos.\,b} - \frac{1}{\cos.^2 c} + \frac{\sin.^2 c}{\cos.^2 c} - \frac{1}{\cos.^2 b} + \frac{\sin.^2 b}{\cos.^2 b}.$$

$$\text{and}\qquad \frac{1}{\cos.^2 c} - \frac{\sin.^2 c}{\cos.^2 c} = \frac{\cos.^2 c}{\cos.^2 c} = 1.$$

$$\text{Similarly}\qquad \frac{1}{\cos.^2 b} - \frac{\sin.^2 b}{\cos.^2 c} = 1.$$

$$\therefore \frac{2\sin.\,c\sin.\,b}{\cos.\,c\cos.\,b}\cos.\,A = \frac{2\cos.\,a}{\cos.\,c\cos.\,b} - 2$$

$$\therefore \sin.\,c\sin.\,b\cos.\,A = \cos.\,a - \cos.\,c\cos.\,b$$

$$\therefore \cos.\,A = \frac{\cos.\,a - \cos.\,b\cos\,c}{\sin.\,b\sin.\,c}\cdot\cdot\cdot\cdot \qquad (3) \qquad \text{Q. E. D.}$$

Cor. 1.—If $a.b.c.$ represent the lengths of the sides of the triangle, and r the radius,

Then $\frac{a}{r}\cdot\ \frac{b}{r}\cdot\ \frac{c}{r}\cdot$ are the angles of formula (3) in circular measure.

Hence, remembering that $\cos.\,\theta = 1 - \frac{\theta^2}{1\cdot 2} + \frac{\theta^4}{1.2.3.4}\cdot\cdot$

and $\sin.\,\theta = \theta - \frac{\theta^3}{1.2.3} + \cdot\cdot\cdot$ we have

$$\text{Cos. A} = \frac{\left(1 - \frac{a^2}{2r^2} + \cdots\right) - \left(1 - \frac{b^2}{2r^2} + \cdots\right)\left(1 - \frac{c^2}{2r^2} + \cdots\right)}{\left(\frac{b}{r} - \frac{b^3}{cr^3} + \cdots\right)\left(\frac{c}{r} - \frac{c^3}{cr^3} + \cdot\cdot\right)}$$

$$= \frac{\left(1 - \frac{a^2}{2r^2}\right) - \left(1 - \frac{b^2}{2r^2} - \frac{c^2}{2r^2}\right) + \text{terms involving}\ \frac{1}{r^4}\cdots -}{\frac{bc}{r^2} + \cdots\ \text{terms involving}\ \frac{1}{r^3} + \cdots} = \frac{b^2 + c^2 - a^2 + \text{terms involving}\ \frac{1}{r}\cdot\ \frac{1}{r^2} + \cdots}{2bc + \text{terms involving}\ \frac{1}{r}\cdot\ \frac{1}{r^2} + \cdots}.$$

Now in the limit when r is infinite, the terms involving $\frac{1}{r}\cdot\ \frac{1}{r^2}\cdot\cdot\cdot\cdot$ will all disappear; hence in the limit,

$$\text{Cos. A} = \frac{b^2 + c^2 - a^2}{2\,bc}$$

$$\text{or}\qquad a^2 = b^2 + c^2 - 2\,bc\cos.\,A.$$

as in the case of the plane triangle. (Page 624).

Cor. 2.—In formula (3) substitute 180° — a' for A. 180° — A′ for a. 180° — B′ for b, and 180° — C′ for C, and we shall have

$$\text{Cos.}\ a' = \frac{\cos.\,A' + \cos.\,B'\cos.\,C'}{\sin.\,B'\sin.\,C'}.$$

This is true of the sides and angles of every polar triangle. Now it appears from Prop. XI., p. 599, that every triangle may be regarded as the polar triangle of some other; hence the above formula is perfectly general, and is true of every triangle, and we have

$$\text{Cos.}\ a = \frac{\cos.\,A + \cos\,B\cos.\,C}{\sin.\,B\sin.\,C}\cdot\cdot\cdot\cdot \qquad (4)$$

Cor. 3.—Formulas similar to (3) and (4) are, of course, true of Cos. B, and Cos. C, and of Cos. b and Cos. c.

(3). *To express the Formulas of the last Article in a Form adapted for Logarithmic Calculation.*

$$\text{Since}\qquad \text{Cos. A} = \frac{\cos.\,a - \cos.\,b\cos.\,c}{\sin.\,b\sin.\,c}$$

$$\therefore 1 + \cos.\,A = 1 + \frac{\cos.\,a - \cos.\,b\cos.\,c}{\sin.\,b\sin.\,c}$$

$$= \frac{\cos.\,a - \cos.\,b\cos.\,c + \sin.\,b\sin.\,c}{\sin.\,b\sin.\,c}$$

$$\text{And}\ 1 - \cos.\,A = 1 - \frac{\cos.\,a - \cos.\,b\cos.\,c}{\sin.\,b\sin.\,c}$$

$$= \frac{\cos.\,b\cos.\,c + \sin.\,b\sin.\,c - \cos.\,a}{\sin.\,b\sin.\,c}$$

$$\therefore 2\cos.^2\frac{A}{2} = \frac{\cos.\,a - (\cos.\,b\cos.\,c - \sin.\,b\sin.\,c)}{\sin.\,b\sin.\,c}$$

$$= \frac{\cos.\,a - \cos.\,(b + c)}{\sin.\,b\sin.\,c}$$

$$\text{And}\qquad 2\sin.^2\frac{A}{2} = \frac{\cos.\,(b - c) - \cos.\,a}{\sin.\,b\sin.\,c}$$

$$\therefore 2\cos.^2\frac{A}{2} = \frac{2\sin.\,\tfrac{1}{2}(a + b + c)\sin.\,\tfrac{1}{2}(b + c - a)}{\sin.\,b\sin.\,c}$$

$$\text{And}\ 2\sin.^2\frac{A}{2} = \frac{2\sin.\,\tfrac{1}{2}(a - b + c)\sin.\,\tfrac{1}{2}(a + b - c)}{\sin.\,b\sin.\,c}$$

Now if $a + b + c = 2\,s$, then $b + c - a = 2\,(s - a)$ $a - b + c = 2\,(s - b)$, and $a + b - c = 2\,(s - c)$.

$$\therefore \cos.^2\frac{A}{2} = \frac{\sin.\,s\sin.\,(s - a)}{\sin.\,b\sin.\,c} \qquad (5)$$

$$\sin.^2\frac{A}{2} = \frac{\sin.\,(s - b)\sin.\,(s - c)}{\sin.\,b\sin\,c} \qquad (6)$$

$$\therefore \tan.^2\frac{A}{2} = \frac{\sin.\,(s - b)\sin.\,(s - c)}{\sin.\,s\sin.\,(s - a)} \qquad (7)$$

$$\text{And since,}\qquad \sin.\,A = 2\sin.\,\frac{A}{2}\cos.\,\frac{A}{2}$$

$$\sin.^2 A = \frac{4}{\sin.^2 b\sin.^2 c}\ \sin,\,s.\ \sin.\,(s - a)\sin.\,(s - b)\sin.\,(s - c) \qquad (8)$$

these formulas are analogous to the formulas on p. 624, of Plane Trigonometry, which can be shown to be the limits of these in the same manner as in Cor. (1), Art. (1), and Cor. (1), Art. (2).

It is to be observed that, since any two sides of a triangle are greater than the third, $s - a$, $s - b$, $s - c$, are positive; and since all the sides of a triangle less than four right angles, s is less than two right angles, and *à fortiori*, $s - a$, $s - b$, $s - c$, are each less than two right angles: so that, sin. $s.$, sin. $(s - a)$, sin. $(s - b)$, sin. $(s - c)$, are each positive, also b and c are each less than 180°; so that sin. b and sin. c are always positive.

Hence, (5), (6), (7), (8), are always positive, and ∴ the values of $\cos. \frac{A}{2}$ $\sin.' \frac{A}{2}$ $\tan. \frac{A}{2}$ and $\sin. A$ derived from them are always real.

COR.—If we consider the case of the polar triangle $A = 180° - a'$ ∴ $\frac{A}{2} = 90° - \frac{a'}{2}$, $a = 180° - A'$, $b = 180° - B'$, $c = 180° - c'$.

$$\therefore s = 270° - \frac{1}{2}(A' + B' + C') = 270° - S'$$

$$\text{if } S' = \frac{1}{2}(A' + B' + C')$$

$$\therefore s - a = 90° - (S' - A')., \; s - b = 90° - (S' - B'),$$
$$s - c = 90° - (S' - C').$$

$$\text{Hence} \quad \sin.^2 \frac{a'}{2} = - \frac{\cos. S' \cos. (S' - A')}{\sin. B' \sin. C'}$$

with similar expressions for $\cos.^2 \frac{a'}{2}$. $\text{cotan.}^2 \frac{a'}{2}$. and $\sin.^2 a'$; and since these are true for all triangles, we shall have

$$\sin.^2 \frac{a}{2} = - \frac{\cos. S \cos. (S - A)}{\sin. B \sin. C} \tag{9}$$

$$\text{Similarly} \quad \cos.^2 \frac{a}{2} = \frac{\cos. (S - B) \cos. (S - C)}{\sin. B \sin. C} \tag{10}$$

$$\therefore \tan.^2 \frac{a}{2} = - \frac{\cos. S \cos. (S - A)}{\cos. (S - B) \cos. (S - C)} \tag{11}$$

$$\text{and } \sin.^2 a = \frac{4}{\sin.^2 B \sin.^2 C} \Big\{ - \cos. S \cos. (S - A) \cos. (S - B) \cos. (S - C) \Big\} \tag{12}$$

where $2S = A + B + C$. It is to be observed that $A + B + C$ must be less than six right angles, and greater than two right angles; ∴ $S > 90° < 270°$. ∴ cos. is *always negative*.[*]

Also $S - A$ being equal to $\frac{1}{2} . \Big(B + C - A\Big) = \frac{1}{2} \Big\{ (180° - (b' + c' - a') \Big\}$ must be $\angle$ 90°, since $b' + c' > a'$ ∴ $\cos. (S - A)$ is always positive, and similarly $\cos. (S - B)$ and $\cos. (S - C)$ are always positive, and ∴ (9), (10), (11), (12), though in appearance negative, are really always positive, and ∴ give us real values for $\sin. \frac{a}{2}$, $\cos. \frac{a}{2}$, $\tan. \frac{a}{2}$, and $\sin. a$.

Similar formulas, of course, exist for $\sin. \frac{b}{2}$. $\sin. \frac{c}{2}$ &c.

(4). *To prove the Formulas,*

$$\text{Tan.} \frac{A + B}{2} = \frac{\cos. \frac{a - b}{2}}{\cos. \frac{a + b}{2}} \text{cotan.} \frac{C}{2} \textit{ and } \text{Tan.} \frac{A - B}{2}$$

$$= \frac{\sin. \frac{a - b}{2}}{\sin. \frac{a + b}{2}} \text{cotan.} \frac{C}{2}$$

$$\text{Since} \quad \tan.^2 \frac{A}{2} = \frac{\sin. (s - b) \sin. (s - c)}{\sin. s. \sin. (s - a)}.$$

$$\tan.^2 \frac{B}{2} = \frac{\sin. (s - c) \sin. (s - a)}{\sin. s. \sin. (s - b)}$$

$$\tan.^2 \frac{C}{2} = \frac{\sin. (s - a) \sin. (s - b)}{\sin. s. \sin. (s - c)}$$

$$\therefore \tan.^2 \frac{B}{2} \tan.^2 \frac{C}{2} = \frac{\sin (s - c) \sin. (s - a)}{\sin. s \sin. (s - b)}$$
$$\times \frac{\sin. (s - a) \sin. (s - b)}{\sin. s. \sin. (s - c)} = \frac{\sin.^2 (s - a)}{\sin.^2 s}$$

$$\therefore \tan. \frac{B}{2} \tan. \frac{C}{2} = \frac{\sin. (s - a)}{\sin. s}$$

$$\text{Similarly,} \quad \tan. \frac{C}{2} \tan. \frac{A}{2} = \frac{\sin. (s - b)}{\sin. s} \text{ and}$$

$$\tan. \frac{A}{2} \tan. \frac{B}{2} = \frac{\sin. (s - c)}{\sin. s.}$$

$$\text{But } \tan. \frac{A + B}{2} \tan. \frac{C}{2} = \frac{\tan. \frac{B}{2} \tan. \frac{C}{2} + \tan. \frac{C}{2} \tan. \frac{A}{2}}{1 - \tan. \frac{A}{2} \tan. \frac{B}{2}}$$

$$= \frac{\frac{\sin. (s - a)}{\sin. s} + \frac{\sin. (s - b)}{\sin. s}}{1 - \frac{\sin. (s - c)}{\sin. s}}$$

$$\therefore \tan. \frac{A + B}{2} \tan. \frac{C}{2} = \frac{\sin. (s - a) + \sin. (s - b)}{\sin. s - \sin. (s - c)}$$

$$= \frac{2 \sin. \frac{1}{2}\Big(2s - a - b\Big) \cos. \frac{1}{2}\Big(b - a\Big)}{2 \sin. \frac{1}{2} c \cos. \frac{1}{2}\Big(2s - c\Big)}$$

$$= \frac{\sin. \frac{1}{2} c \cos. \frac{1}{2}\Big(a - b\Big)}{\sin. \frac{1}{2} c \cos. \frac{1}{2}\Big(a + b\Big)}.$$

$$\therefore \tan. \frac{A + B}{2} = \frac{\cos. \frac{1}{2}(a - b)}{\cos. \frac{1}{2}(a + b)} \text{cotan.} \frac{C}{2}. \tag{13}$$

$$\text{Similarly,} \quad \tan. \frac{A - B}{2} \tan. \frac{C}{2} = \frac{\sin. (s - b) - \sin. (s - a)}{\sin. s + \sin. (s - c)}$$

$$\frac{2 \sin. \frac{1}{2}(a - b) \cos. \frac{1}{2}\Big(2s - a - b\Big)}{2 \sin. \frac{1}{2}(s - c) \cos. \frac{1}{2} c,}$$

$$\therefore \tan. \frac{A - B}{2} = \frac{\sin. \frac{1}{2} (a - b)}{\sin. \frac{1}{2} (a + b)} \text{cotan.} \frac{C}{2} \tag{14}$$

These formulas are clearly analogous to (39) on p. 624, Plane Trigonometry.

COR.—If we take the polar triangle, since $\frac{A + B}{2} = 180° - \frac{a' + b'}{2}$, $\frac{A - B}{2} = \frac{b' - a'}{2}$, $\frac{a + b}{2} = 180° = \frac{A' + B'}{2}$; $\frac{a - b}{2} = \frac{B' - A'}{2}$, and $\frac{C}{2} = 90° - \frac{c'}{2}$.

We have from (13) and (14)

$$- \tan. \frac{a' + b'}{2} = \frac{\cos. \frac{B' - A'}{2}}{- \cos. \frac{B' + A'}{2}}, \tan. \frac{c'}{2},$$

$$\text{and } \tan. \frac{b' - a}{2} = \frac{\sin. \frac{B' - A'}{2}}{\sin. \frac{A' + B'}{2}} \tan. \frac{c'}{2}$$

Hence, remembering that the formulas for the polar triangle are perfectly general, we have

$$\tan. \frac{a + b}{2} = \frac{\cos. \frac{A - B}{2}}{\cos. \frac{A + B}{2}} \tan. \frac{c}{2} \tag{15}$$

$$\tan. \frac{a - b}{2} = \frac{\sin. \frac{A - B}{2}}{\sin. \frac{A + B}{2}} \tan. \frac{c}{2} \tag{16}$$

---

[*] See *ante*, p. 616.

(5). *To prove the Formula* $\text{Cotan. } A \text{ sin. } C = \text{Cotan. } a \text{ sin. } b - \text{Cos. } C \text{ cos. } b$.

This formula is used in certain propositions : *e.g.*, it is employed in the astronomical problem of finding the aberration in declination.

From formula (2) we have

$$\text{Cos. } A \text{ sin. } b \text{ sin. } c = \text{cos. } a - \text{cos. } b \text{ cos. } c.$$

And from formula (3) we have

$$\text{Cos. } c = \text{cos. } a \text{ cos. } b + \text{sin. } a \text{ sin. } b \text{ cos. } C.$$

$$\therefore \text{Cos. } A \text{ sin. } b \text{ sin. } c = \text{cos. } a - \text{cos. } a \text{ cos.}^2 b - \text{sin. } a \text{ sin. } b \text{ cos. } b \text{ cos. } C.$$

$$\therefore \text{Cos. } A \text{ sin. } b \text{ sin. } c = \text{cos. } a \text{ sin.}^2 b - \text{sin. } a \text{ sin. } b \text{ cos. } b \text{ cos. } C.$$

$$\therefore \text{Cos. } a \text{ sin. } c = \text{cos. } a \text{ sin. } b - \text{sin. } a \text{ cos. } b \text{ cos. } C.$$

Also from formula (1) we have

$$\text{Sin. } c = \frac{\text{sin. } C \text{ sin. } a}{\text{sin. } A}$$

$$\therefore \text{Cos } A \frac{\text{sin. } C \text{ sin. } a}{\text{sin. } A} = \text{cos. } a \text{ sin. } b - \text{sin. } a \text{ cos. } b \text{ cos. } C.$$

$$\therefore \text{Cotan. } A \text{ sin. } C \text{ sin. } a = \text{cos. } a \text{ sin. } b - \text{sin. } a \text{ cos. } b \text{ cos. } C.$$

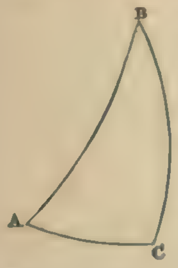
$$\therefore \text{Cotan. } A \text{ sin. } C = \text{cotan. } a \text{ sin. } b - \text{cos. } C \text{ cos. } b.$$

Q. E. D.

THE SOLUTION OF RIGHT-ANGLED SPHERICAL TRIANGLES.

There are as many as six different cases of right-angled spherical triangles, as will appear from the following considerations :—

Fig. 3.



Let A B C be the triangle, having a right angle at C. Then using the ordinary notation, all possible cases are the following :

(1). Given the base and perpendicular, *i.e.*, given a and b.

(2). Given the hypothenuse and another side, *i.e.*, given c and a, or c and b.

(3). Given the base or perpendicular, and an adjacent angle, *i.e.*, given a and B, or b and A.

(4). Given the base or perpendicular and an opposite angle, *i.e.*, given a and A, or b and B.

(5). Given the hypothenuse and an angle, *i.e.*, given c and A, or c and B.

(6). Given the two angles, *i.e.*, A and B.

If these cases be compared with those on p. 641, for plane triangles, it will be seen that the third case of plane triangles diverges into two cases, *viz.*, the third and fourth of spherical triangles, while the sixth case is peculiar to spherical triangles. Both of these differences are due to the circumstance, that in the spherical triangle, $A + B + C$ is not known, whereas in the plane triangle $A + B + C = 180°$

(6). *To investigate the Formulas on which the Solution of Right-angled Spherical Triangles depends.*

From the general formula $\dfrac{\text{sin. } c}{\text{sin. } C} = \dfrac{\text{sin. } b}{\text{sin. } B} = \dfrac{\text{sin. } a}{\text{sin. } A}$

Since $C = 90°$ and $\therefore \text{sin. } C = 1$, we have

$$\text{sin. } c = \frac{\text{sin. } b}{\text{sin. } B} = \frac{\text{sin. } a}{\text{sin. } A}$$

$$\therefore \text{sin. } b = \text{sin. } c \text{ sin. } B \qquad (17)$$

$$\text{Similarly} \quad \text{sin. } a = \text{sin. } c \text{ sin. } A \qquad (18)$$

Again, since $\text{cos. } C = \dfrac{\text{cos. } c - \text{cos. } a \text{ cos. } b}{\text{sin. } a \text{ sin. } b}$ and $\text{cos. } C = 0$, we have

$$\therefore \text{cos. } c = \text{cos. } a \text{ cos. } b \qquad (19)$$

Again, since $\text{cos. } C = \dfrac{\text{cos. } C + \text{cos. } A \text{ cos. } B}{\text{sin. } A \text{ sin } B}$ and $\text{cos. } C = 0$

$$\therefore \text{cos. } c = \text{cotan. } A \text{ cotan. } B \qquad (20)$$

Again, since $\text{cos. } a = \dfrac{\text{cos. } A + \text{cos. } B \text{ cos. } C}{\text{sin. } B \text{ sin. } C}$ and $\text{cos. } C = 0$ and $\text{sin. } C = 1$.

$$\therefore \text{cos. } A = \text{cos. } a \text{ sin. } B \qquad (21)$$

$$\text{Similarly} \quad \text{cos. } B = \text{cos. } b \text{ sin. } A \qquad (22)$$

Again, since $\text{cos. } A = \text{cos. } a \text{ sin. } B$ and $\text{sin. } B = \dfrac{\text{sin. } b}{\text{sin. } c}$

$\therefore \text{cos. } A = \dfrac{\text{sin. } b}{\text{sin. } c} \cdot \text{cos. } a$ and $\text{cos. } a = \dfrac{\text{cos. } c}{\text{cos. } b}$. by (2)

$$\therefore \text{cos. } A = \frac{\text{sin. } b}{\text{sin. } c} \cdot \frac{\text{cos. } c}{\text{cos. } b}.$$

$$\therefore \text{cos. } A = \text{tan. } b \text{ cotan. } c \qquad (23)$$

$$\text{Similarly} \quad \text{cos. } B = \text{tan. } a \text{ cotan. } c \qquad (24)$$

Again from (1) $\text{sin. } a = \text{sin. } c \text{ sin. } A = \dfrac{\text{sin. } b}{\text{sin. } B} \cdot \text{sin. } A$

from (2) and this $= \dfrac{\text{sin. } b \text{ cos. } B}{\text{cos. } b \text{ sin. } B} \times \dfrac{\text{sin. } A \text{ cos. } b}{\text{cos. } B}$

But by (4) $\text{cos. } B = \text{cos. } b \text{ sin. } A$.

$$\therefore \text{sin. } a = \text{tan. } b \text{ cotan. } B \qquad (25)$$

$$\text{Similarly} \quad \text{sin. } b = \text{tan. } a \text{ cotan. } A \qquad (26)$$

(7). *Napier's Rule for the Solution of Right-angled Spherical Triangles.*

The formulas given in the last article can be included in a single rule, which is very easily enunciated and remembered. It is generally called Napier's Rule, having been invented by Napier, who, as we have already stated, was the inventor of logarithms. Leaving out C, which is 90°, there are three sides and two angles in the triangle—*viz.*, a. b. c. A. B. We will call the base, the perpendicular, the complements of the hypothenuse and the angles, circular parts ; if we fix on any of these and call it the middle part, then of the remaining four, two will be adjacent, and the other two opposite: then it will be found that all the formulas of the last article are included in the following rule. "The sine of the middle part equals the product of the tangents of the adjacent parts, and also equals the product of the cosines of the opposite parts ;"

Or, Sin. mid. = tan. ad. = cos. op.

Thus, if $90° - A$ be the middle part, then $90° - c$ and b are the adjacent, and $90° - B$ and a are the opposite part.

The rule gives us $\text{sin. } (90° - A) = \text{tan. } (90° - c) \text{ tan. } b = \text{cos. } (90° - B) \text{ cos. } a$

$$\text{Or} \quad \text{Cos. } A = \text{tan. } b \text{ cotan. } c = \text{cos. } a \text{ sin. } B \qquad (a)$$

Similarly, if $90° - B$ is the middle part, then $90° - c$ and a are the adjacent, and $90° - A$ and b the opposite parts. The rule gives us

$$\text{Cos. } B = \text{tan. } a \text{ cotan. } c = \text{cos. } b \text{ sin. } A \qquad (b)$$

If a be the middle part then $90° - B$ and b are the adjacent, and $90° - c$ and $90° - A$ the opposite part, then the rule gives us

$$\text{Sin. } a = \text{tan. } b \text{ cotan. } B = \text{sin. } c \text{ sin. } A \qquad (c)$$

If b be the middle part then $90° - A$ and a are the adjacent parts, and $90° - c$ and $90° - A$ the opposite parts, then the rule gives us

$$\text{Sin. } b = \text{tan. } a \text{ cotan. } A = \text{sin. } c \text{ sin. } B \qquad (d)$$

Finally, if $90° - c$ be the middle part, then $90° - A$ and $90° - B$ are the adjacent, and a and b the opposite parts, then the rule gives us

$$\text{Cos. } c = \text{cotan. } A \text{ cotan. } B = \text{cos. } a \text{ cos. } b \qquad (e)$$

If the five formulas of the present article be compared with those of Article (6) they will be found identical. Hence Napier's Rule, as was stated, comprises all the formulas of Art. 6. It is a question whether, as a matter of practice, Napier's Rule is really more convenient than the disconnected formulas of Article (6).

(8). *To explain the Method of Solution in the cases of Right-angled Spherical Triangles.*

All the formulas of Art. 6, to which we refer in the present article, are expressed as products, and consequently are adapted for logarithmic calculations. The cases, as we have already seen, are the following:—

(1) Given a and b, find c, A and B
Cos. c is given by (19), then Cos. A is given by (23), and cos. B by (24)

(2) Given c and a, find b, A and B
Cos. b is given by (19), then cos. A is given by (23), and cos. B by (24)

(3) Given a and b, find b, c, and A
Cos. A is given by (21), then cos. b is given by (22), and tan. c by (23)

(4) Given a and A, find b, c, and B
Sin. B is given by (21), then cos. b is given by (22), and cos. c by (19)

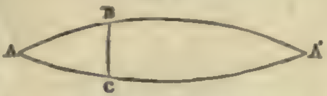
(5) Given c and A, find a, b, and B
Sin. b is given by (17), then cos. a is given by (19), and cos. B by (22)

(6) Given A and B, find a, b, and c
Cos. c is given by (20), cos. a by (21), and cos. b by (22).

It will be observed that each of the above determinations is clearly unambiguous, except the determination of B in (4), and b in (5), for these are the only two determinations made by means of sines; for which reason, if B′ and b' are the values less than 90° which satisfy (4) and (5), then 180° — B′, and 180° — b' also satisfy (4) and (5); and hence it would seem that in the former case there would in general be two values of b and two of c, corresponding to B′ and 180° — B′ respectively; and in the latter case, that there would be two values of a given by (3), and therefore two values of B given by (6). If more closely considered, however, it will appear that there is really no ambiguity in case (5). We will consider the cases separately.

In case (4) we have given A and a. Now AB and AC (Fig. 4), being produced, meet at A′, where A B A′ and A C A′ are each of arc 180° (see Spherical Geometry, pp. 598, 599) and the angle at A′ is equal to the angle at A. Hence the angle A and the side a belong equally to triangle A B C and to A′B C. And if we take the value of B less than 90° to be A B C, then C B A′ is 180° — B′, the second value indicated by the solution.

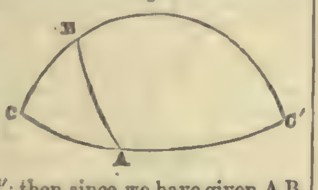
Fig. 4.



In case (5) — from (10) it appears that tan. a = sin. b tan. A.

Now sin. b is always positive, and hence the sign of tan. a must be the same as that of tan A. Hence if A > 90° a must be > 90°, and if a > 90° A must be < 90°, and A is given, hence only one of the two values of a is admissible. This also follows from geometrical considerations. Let C be the right angle, then C A and C B, when produced, meet in C′; then since we have given A B (c) and B A C (A) we determine b, *i.e.*, cA from the equation or 180° — b, *i.e.*, A C′; but A C′ belongs to a triangle on which the angle B A C′ is not A, but 180° — A, and ∴ the value A C′ is inadmissible.

Fig. 5.



THE SOLUTION OF OBLIQUE-ANGLED TRIANGLES.

(9). *To enumerate the Cases of Oblique-Angled Triangles.*

There are six cases of oblique-angled triangles, viz.:—

(1). Given three sides, *e. g.*, a. b. c

(2). Given two sides and the included angle, *e. g.*, a. b. and C.

(3). Given two sides, an angle opposite to one of them, *e. g.*, a. b. A

(4). Given one side and the two adjacent angles, *e. g.*, A. B. c

(5). Given one side, the opposite angle and another angle, *e. g.*, A. C. c

(6). Given the three angles, *e. g.*, A. B. C

As in the case of right-angled triangles, these six cases are analogous to the four cases of plane oblique-angled triangles (p. 641). But the fourth case of a plane triangle diverges on to the fourth and fifth of the spherical triangle, owing to the circumstance that A + B + C is not known in the case of the spherical triangle, whereas in the plane triangle A + B + C = 180°. For the same reason case (6) is peculiar to the spherical triangle.

(10). *To Solve the First Case of Oblique-Angled Triangles.*

We can obtain A from either of the formulas (5), (6), or (7), and then can obtain B and C from similar formulas. Of these formulas (7), which gives tan. $\frac{A}{2}$, is the most convenient if we wish to find both of the other angles. Compare the analogous case of Plane Triangles, p. 641.

(11). *To Solve the Second Case of Oblique-Angled Triangles.*

In this case we will suppose that we have given a b and C. Then from formulas (13) and (14) we can determine $\frac{A+B}{2}$ and $\frac{A-B}{2}$ and hence A and B; and then, knowing A and B, we can determine c from formula (1).

If, however, we wish to determine c directly, *i. e.*, independently of A and B, we can effect our object by introducing a subsidiary angle in a manner analogous to the corresponding case of plane triangles. (See pp. 623 and 642). Thus, from formula (3) we have

$$\text{Cos. C.} = \frac{\text{cos. } c - \text{cos. } a \text{ cos. } b}{\text{sin. } a \text{ sin. } b}$$

$$\begin{aligned} \therefore \quad \text{Cos. } c &= \text{cos. } a \text{ cos. } b + \text{sin. } a \text{ sin. } b \text{ cos. C} \\ \therefore 1 - \text{Cos. } c &= - \text{cos. } a \text{ cos. } b - \text{sin. } a \text{ sin. } b \text{ cos. C} \\ &= 1 - \text{cos. } a \text{ cos. } b + \text{sin. } a \text{ sin. } b \\ &\qquad - \text{sin. } a \text{ sin. } b\,(1 + \text{cos. C}) \\ &= 1 - (\text{cos. } a \text{ cos. } b - \text{sin. } a \text{ sin. } b) \\ &\qquad - \text{sin. } a \text{ sin. } b\,(1 + \text{cos. C}) \\ &= 1 - \text{cos. } (a + b) - \text{sin. } a \text{ sin. } b \\ &\qquad (1 + \text{cos. C}) \end{aligned}$$

Now $1 - \text{cos. A} = 2 \text{ sin.}^2 \frac{A}{2}$ and $1 + \text{cos. A} = 2 \text{ cos.}^2 \frac{A}{2}$

$$\therefore \quad \text{sin.}^2 \frac{c}{2} = \text{sin.}^2 \frac{a+b}{2} - \text{sin. } a \text{ sin. } b \text{ cos.}^2 \frac{C}{2}$$

$$\text{Assume} \quad \text{sin.}^2\,\theta = \text{sin. } a \text{ sin. } b \text{ cos.}^2 \frac{C}{2}$$

$$\begin{aligned} \therefore \quad \text{sin.}^2 \frac{c}{2} &= \text{sin.}^2 \frac{a+b}{2} - \text{sin.}^2\,\theta \\ &= \left(\text{sin. } \frac{a+b}{2} - \text{sin. } \theta\right)\left(\text{sin. } \frac{a+b}{2} + \text{sin. } \theta\right) \\ &= 2 \text{ sin. } \frac{1}{2}\left(\frac{a+b}{2} - \theta\right) \text{cos. } \frac{1}{2}\left(\frac{a+b}{2} + \theta\right) \\ &\times 2 \text{ sin. } \frac{1}{2}\left(\frac{a+b}{2} + \theta\right) \text{cos. } \frac{1}{2}\left(\frac{a+b}{2} - \theta\right) \\ &= 2 \text{ sin. } \frac{1}{2}\left(\frac{a+b}{2} - \theta\right) \text{cos. } \frac{1}{2}\left(\frac{a+b}{2} - \theta\right) \\ &\times 2 \text{ sin. } \frac{1}{2}\left(\frac{a+b}{2} + \theta\right) \text{cos. } \frac{1}{2}\left(\frac{a+b}{2} + \theta\right) \end{aligned}$$

$$\therefore \text{sin.}^2 \frac{c}{2} = \text{sin. } \left(\frac{a+b}{2} - \theta\right) \text{sin. } \left(\frac{a+b}{2} + \theta\right)$$

This latter method is very much easier than the former; for by this we only require five logarithms, whereas by that we require eight, for the determination of c.

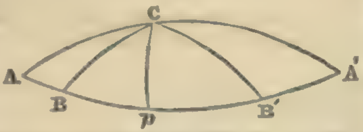
(12). *To Solve the Third Case of Oblique-Angled Triangles.*

In this case we will suppose that we have given a, b, A Then we obtain sin. B by formula (1); and knowing a, b, and A, B, we can determine C, by formula (13); and finally we can determine c by formula (1).

It will be observed that in this case, since the results depend on our determining B from a given value of sin. B, they will be ambiguous, as in the analogous case of plane triangles (p. 619); for if B′ be the value of $B < 90°$, which we derive from formula (1): then $180° - B'$ also satisfies formula (1).

This amount of ambiguity depends on the data. For let A B C be a triangle, having the angle $BAC = A$, $AC = b$ and $BC = c$. Produce A B and A C to meet in A′, draw $CB' = CB$. Then the given data belongs as much to the triangle A C B. as to A C B′. Moreover it is plain that $CBB' = CB'B$, and hence if $CB'A = B'$, we shall have $CBA = 180° - B'$, the same conclusion that we derived from the formula.

Fig. 6.



(13). *To solve the Fourth Case of Oblique-Angled Spherical Triangles.*

In this we suppose that we have given A. B. and C. Then $\frac{a+b}{2}$ is given from formula (15), and $\frac{a-b}{2}$ from formula (16); hence we obtain a and b, and then we obtain C. by formula (1). If we wish to obtain C without the previous calculation of a and b, we must introduce a subsidiary angle θ and proceed as in article (11). From formula (4) we have

$$\text{Cos. } C = -\cos. A \cos. B + \sin. A \sin. B \cos. c,$$

$$\text{Assume} \quad \sin.^2 \theta = \sin. A \sin. B \sin.^2 \frac{c}{2}.$$

And we shall obtain

$$\text{Cos.}^2 \frac{C}{2} = \sin.\left(\frac{A+B}{2} + \theta\right) \sin.\left(\frac{A+B}{2} - \theta\right)$$

(14). *To solve the Fifth Case of Oblique-Angled Triangles.*

In this case we will suppose that A. C. and c, are given. We shall obtain sin. a from formula (1). Now, formula (13) gives us

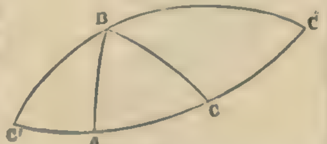
$$\text{Tan. } \frac{A+C}{2} = \frac{\cos. \frac{1}{2}(a-c)}{\cos. \frac{1}{2}(a+c)} \text{ cotan. } \frac{B}{2}$$

Whence we obtain B, and a similar modification of formula (15) will give us b; or, having B, we may obtain b from formula (1).

In this case a is determined from its sine, and therefore has two values, viz. a' and $180° - a'$; and if both these values are admissible, the case is ambiguous.

In the triangle A B C, let $AB = c$, $BAC = A$ and $BCA = C$, and suppose $BC = a$, draw $BC' = a'$; then if a' be greater than c, it is plain that A falls between C and C′; in this case produce C′ B and C′ C to meet in C″. Then the angle $BCC' = BC'C = BC''C$. Hence the data belong equally to the triangle B A C. and B A C″; and the case is ambiguous, provided $c < a$; also it will be observed that $BC'' = 180° - BC' = 180° - BC = 180° - a'$, as previously appeared from the calculation. If B C be less than B A, then C′ would fall between B and A, and the above construction would be no longer possible. Hence if $c > a$, the case is not ambiguous.

Fig. 7.



(15). *To solve the Sixth Case of Oblique-Angled Triangles.*

In this case we have given A, B, C. We shall find a from formula (11), and b and c from similar formulas. This case, however, never occurs in any of the practical applications of spherical trigonometry.

On the Solution of Quadrantal Triangles.

A quadrantal triangle (Spherical Geometry, Def. 14, p. 599) has one *side* of 90°, and ∴ the corresponding polar triangle is a right-angled triangle. From this consideration it would be easy to modify Napier's Rule to suit the case of the quadrantal triangle. In practice, however, it is better to treat them as oblique triangles: on doing so it will be found practically that the circumstance of one side being equal to 90° will introduce important simplifications.

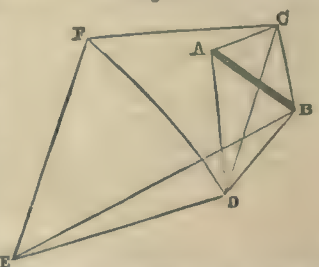
ON THE FORMULAS PECULIAR TO GEODETICAL OPERATIONS.

We have already stated, in general terms, that the science of spherical trigonometry finds one of its applications in Geodesy. It is to be observed that this application possesses some peculiarities in consequence of the sides of the triangles employed in a survey, on even the largest scale, being small compared with the radius of the earth, and consequently small when estimated in degrees or minutes; whereas, in astronomy, there is no limitation imposed on the magnitudes of the sides of the triangles employed. Our object in the present article is to explain concisely the results of this limitation, and to deduce certain formulas depending on it.

(16). *To state the Object of a Trigonometrical Survey of a Country.*

The object of the survey is, (1), to fix accurately the relative positions of certain chief points in the country, so as to lay them down on a map; and, (2), having fixed these chief points, then by means of subsidiary operations, to lay down in detail all the minor features of the country, its roads, rivers, towns, hamlets, &c. The accompanying figure will be sufficient to illustrate this matter for our present purpose, which is from an actual survey. A is a place called Ruckinge, B, High Nook, C, Allington, D, Lydd, E, Fairlight Down, and F, Tenterden. The line A B is measured very accurately, and is called the *base line*; and then the angles C A B, A B C, are measured; from these data, A C, and C B, can be calculated; then C B being known, the angles D C B, and C B D, can be measured, and thus C D, and D B, be determined. This operation is to be continued for any number of triangles whatever. It is usual, in the larger triangles, to measure all the three angles of any triangle, and not merely the two at the base; this is done with a view of keeping a check upon the various errors to which all observations are liable.

Fig. 8.

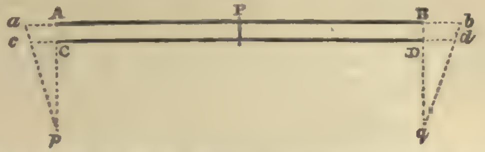


When the triangulating has been continued for some distance, it is necessary to compare the calculated length of a line that has been fixed upon, and then measure it; the coincidence of the two results is a verification of all previous measurements and calculations; hence such a line is called a *base of verification*. It is usual to choose stations that are from ten to twenty miles apart; also it is usual to choose for a *base line* a line of about four or five miles long. In late French surveys only two bases of verification have been used. The accuracy attainable in practice will be appreciated when the fact is stated that, in some English bases of verification, of four or five miles long, the computed and measured lengths have differed only by one or two inches. The operations of a trigonometrical survey are then two,—(1), the measurement of base lines; (2), the measurements of angles. We will proceed to consider each of these.

(17). *The Measurement of a Base Line.*

A space of open ground which is nearly level must be chosen, the line to be measured being indicated by stations, and stages erected, if necessary, to secure the horizontality of the base; the measure may be made by rods of glass, or steel, proper corrections being applied for temperature. A more convenient contrivance for securing accuracy in the measures has been devised of late for the Irish Survey: it is of the following kind:—A B, C D, are rods of platina and iron riveted together at the middle point P, and are exactly the same length for a given temperature: Ap, Bq, are marks affixed to the ends of each. Now the metals have different expansions for the same temperature; suppose then that A B, for a change in temperature, becomes ab, while C D becomes cd, then Ap will assume the position ap, and let $\mathrm{A}a = \delta a$ $\mathrm{C}c = \delta b$, then if Cp be taken so long, that $\frac{\mathrm{A}p}{\mathrm{C}p} = \frac{\delta a}{\delta b}$ then p will not be changed by the change of temperature; since, within very large limits, the expansion of a metal is proportional to the increase of temperature, and $\therefore$ $\frac{\delta a}{\delta b}$ is constant; the same arrangement being made at the end, B D, the distance pq, will not be affected by change of temperature.

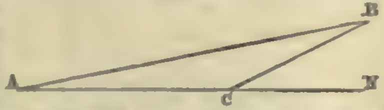
Fig. 9.



(18). *To Correct for want of Straightness in the Base Line.*

The nature of the ground may be such as to render it impossible to measure a perfectly straight base line of sufficient length. This was the case in some of the French surveys, where the actual measurement was of *two straight lines* inclined to each other at an angle of very nearly 180°.

Fig. 10.



Let A B be the line the length of which is required, the measurements are A C = b. C B = a. and B C N = θ in circular measure = n'' suppose. Then it is plain that A B $\angle$ $(a + b)$. Let us suppose A B = $a + b - x$; our object is to find x.

$$\mathrm{A\,B}^2 = a^2 + b^2 - 2\,ab \cos. (\pi - \theta) = a^2 + b^2 + 2\,ab \cos. \theta$$

Now (Plane Trig., Art. 50, cor.) $\cos. \theta = 1 - \frac{\theta^2}{2}$ · if we omit θ'' . . .

$$\therefore \mathrm{A\,B}^2 = a^2 + 2\,ab + b^2 - ab\theta^2 = (a+b)^2 \left\{1 - \frac{ab\theta^2}{(a+b)^2}\right\}$$

$$\therefore \mathrm{A\,B} = (a+b) \left\{1 - \frac{ab\theta^2}{(a+b)^2}\right\}^{\frac{1}{2}} = (a+b) \left\{1 - \frac{ab\theta^2}{2\,(a+b)^2}\right\} \text{ if we omit } \theta^4 \ldots$$

$$\therefore \mathrm{A\,B} = a + b - \frac{ab\theta^2}{2\,(a+b)}$$

$$\therefore x = \frac{ab\theta^2}{2\,(a+b)}$$

$$\text{Now} \quad \frac{\theta}{n} = \frac{\pi}{180 \times 60 \times 60} = \cdot000004848$$

$$\therefore x = \frac{ab}{a+b} \times \cdot0000000001175$$

The correction to be applied to the sum of a and b, to obtain the true distance, A B.

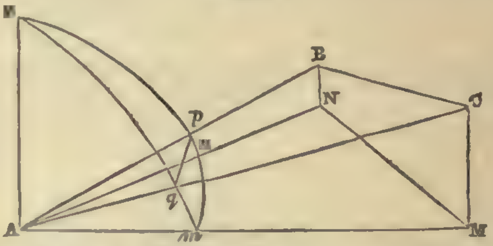
(19). *To measure the Angles of the Triangles of a Survey.*

Any two of the three angular points of one of these triangles are rarely in a horizontal plane passing through the third; the angle required is, of course, such a horizontal angle. Now the angles are measured either by a theodolite, or by a repeating circle—in the case of the former instrument, the vertical elevation of each object is observed, and the horizontal angle between them—that is to say, if A B C (Fig. 11) are the stations, A N M the horizontal plane through A, B N and C M perpendiculars from B and C on A M N, then by the theodolite we observe the angles B A N, C A M, and M A N; the last is the horizontal angle required. The theodolite is the instrument that has been used in the English surveys. But if a repeating circle be employed, the angle B A C is the one observed; and it is necessary to deduce from this the horizontal angle M A N. The repeating circle is the instrument used in the French surveys.

(20). *To determine the Correction for reducing an Angle to the Horizon.*

Let A B C M N be the same as in last article; with centre A and any radius describe a sphere, which meets the lines A B, A C, A N, A M in p, q, n, m, respectively. pn and mq, if joined by great circles, clearly meet in Z vertically over A, since the circles must be perpendicular to the horizontal plane. Then mn, or the angle mZn (Spherical Geometry, Prop. V., Cor. 4) is the angle required, and for its determination we have given pq = A, $pn = h$, $qm = h'$. Suppose $mZn = \mathrm{A} + \delta\mathrm{A}$, then our object is to determine δA.

Fig. 11.



Now in triangle pZq we have, by formula 3,

$$\cos. pZq = \frac{\cos. pq - \cos. pZ \cos. qZ}{\sin. pZ \cos. qZ}$$

Now $pZ = 90° - h$, and $qZ = 90° - h'$

$$\therefore \cos. (\mathrm{A} + \delta\mathrm{A}) = \frac{\cos. \mathrm{A} - \sin. h \sin. h}{\cos. h \cos. h'}$$

Now we will suppose δA so small that we can omit $\delta\mathrm{A}^2$ ... and h and h' so small that we can omit every power and product higher than h^2, hh', and h'^2.

$\therefore$ (Cor. Plane Trig., Art. 50) $\sin. \delta\mathrm{A} = \delta\mathrm{A}$, $\cos. \delta\mathrm{A} = 1$, $\sin. h = h$, $\sin. h' = h'$, $\cos. h = 1 - \frac{h^2}{2}$, and $\cos. h' = 1 - \frac{h'^2}{2}$

Now $\cos. (\mathrm{A} + \delta\mathrm{A}) = \cos. \mathrm{A} \cos. \delta\mathrm{A} - \sin. \mathrm{A} \sin. \delta\mathrm{A}$.

$$\text{Hence } \cos. \mathrm{A} - \delta\mathrm{A} \sin. \mathrm{A} = \frac{\cos. \mathrm{A} - hh'}{1 - \frac{1}{2}(h^2 + h'^2)} = \cos. \mathrm{A}$$

$$\cos. \mathrm{A} - hh' + \frac{h^2 + h'^2}{2} \cos. \mathrm{A}.$$

$$\therefore \delta\mathrm{A} \sin. \mathrm{A} = hh' - \frac{h^2 + h'^2}{2} \cos. \mathrm{A}$$

Now let $h + h' = p$, and $h - h' = q$. $\therefore 2h = p + q$, and $2h' = p - q$

$$\therefore 4hh' = p^2 - q^2, \text{ and } 2\,(h^2 + h'^2) = p^2 + q^2$$

$$\therefore 4\,\delta\mathrm{A} \sin. \mathrm{A} = p^2 - q^2 - (p^2 + q^2) \cos. \mathrm{A} = p^2\,(1 - \cos. \mathrm{A}) - q^2\,(1 + \cos. \mathrm{A})$$

$$\therefore 4\,\delta\mathrm{A}\ 2 \sin. \frac{\mathrm{A}}{2} \cos. \frac{\mathrm{A}}{2} = p^2 \times 2 \sin.^2 \frac{\mathrm{A}}{2} - q^2 \times 2 \cos.^2 \frac{\mathrm{A}}{2}$$

$$\therefore 4\,\delta\mathrm{A} = p^2 \frac{\sin. \frac{\mathrm{A}}{2}}{\cos. \frac{\mathrm{A}}{2}} - q^2 \frac{\cos. \frac{\mathrm{A}}{2}}{\sin. \frac{\mathrm{A}}{2}}$$

$$\therefore \delta A = \frac{1}{4}\left\{ p^2 \tan. \frac{A}{2} - q^2 \text{ cotan. } \frac{A}{2} \right\}$$

Hence, whether we use the theodolite, or the repeating circle, we obtain the same end; namely, the determination of the horizontal angle. It is plain that the horizontal angle being determined at each of the stations, these are the true angles, supposing the triangle spherical; and the triangle so determined is *spherical.*

We may proceed with the triangle thus obtained in either of the following ways:—

(21). *To Explain the Methods of Treating the Triangles thus obtained.*

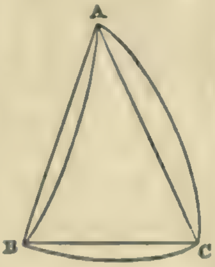
(a). *Delambre's Method.*

It is supposed that we have tables of the kind described in Art. 72, Plane Trigonometry. Now we know a, the length of a side in feet, hence $\frac{a}{r}$ the angle subtended at the centre by a is known, and hence log. $\frac{\sin. a}{a}$ is known; we will suppose the table to give us this for every value of a in feet. Then by simply adding log. a we obtain log sin. a. Now from formula (1). $\frac{\sin. b}{\sin. a} = \frac{\sin. B}{\sin. A}$; hence L. sin. b = L. sin. a + L. sin. B + ar : c : L. sin. A − 10, from whence b can be obtained.

(b). *By the Method of the Chordal Triangle.*

Let A B C be a given triangle, the sides of which are a, b, c, and angles A, B, C, join A B, B C, C D, by straight lines, then the plane triangle formed by these chords is called the chordal triangle. Let C − δC be the angle of the chordal triangle corresponding to the angle C of the spherical triangle. Now, by Plane Trigon., Art. 37,

Fig. 12.



2 (chord B C) (chord C A) cos. (C − δC) = (chord B C)² + (chord CA)² − (chord A B)²

$$\therefore 2 \sin. \frac{a}{2} \sin. \frac{b}{2} \cos. (C - \delta C)$$

$$= \sin.^2 \frac{a}{2} + \sin.^2 \frac{b}{2} - \sin.^2 \frac{c}{2}, \text{ since chord } \theta = 2 \sin. \frac{\theta}{2}$$

Again

$$\text{Sin. } a \sin. b \cos. C = \cos. c - \cos. a \cos. b =$$

$$1 - 2 \sin.^2 \frac{c}{2} - \left(1 - 2 \sin.^2 \frac{b}{2}\right) \left(1 - 2 \sin.^2 \frac{a}{2}\right)$$

$$\therefore 2 \text{ Sin.} \frac{a}{2} \sin. \frac{b}{2} \cos. \frac{a}{2} \cos. \frac{b}{2} \cos. C$$

$$= \sin.^2 \frac{a}{2} + \sin.^2 \frac{b}{2} - \sin.^2 \frac{c}{2} - 2 \sin.^2 \frac{a}{2} \sin.^2 \frac{b}{2}$$

$$= 2 \sin. \frac{a}{2} \sin. \frac{b}{2} \cos. (C - \delta C) - 2 \sin.^2 \frac{a}{2} \sin.^2 \frac{b}{2}$$

$$\therefore \text{Cos. } (C - \delta C) = \cos. \frac{a}{2} \cos. \frac{b}{2} \cos. C + \sin. \frac{a}{2} \sin. \frac{b}{2}$$

Now omitting $(\delta C)^2$ . . . we have cos. C + δ C sin. C

$$\therefore \delta C \sin. C = \sin. \frac{a}{2} \sin. \frac{b}{2} - \left(1 - \cos. \frac{a}{2} \cos. \frac{b}{2}\right) \cos. C.$$

Also $\sin. \frac{a}{2} = \frac{a}{2}$ and $\cos. \frac{a}{2} = 1 - \frac{a^2}{8}$, omitting a^3....

(Plane Trig., Art. 50, Cor.) ∴ δ C sin. C =

$$\frac{ab}{4} - \frac{a^3 + b^2}{8} \cos. C.$$

Let $a + b = e$, and $a - b = f$ ∴ 4 $ab = e^2 - f^2$, and 2 $(a^2 + b^2) = e^2 + f^2$ ∴ 16 δ C sin. C = $(e^2 - f^2) - (e^2 + f^2)$ cos. C = e^2 (1 − cos. C) − f^2 (1 + cos. C)

$$\therefore 32 \delta C \sin. \frac{C}{2} \cos. \frac{C}{2} = 2e^2 \sin.^2 \frac{C}{2} - 2f^2 \cos.^2 \frac{C}{2}$$

$$\therefore \delta C = \frac{1}{16}\left\{ e^2 \tan. \frac{C}{2} - f^2 \text{ cotan. } \frac{C}{2} \right\}$$

In this we suppose the radius of the sphere to be unity; and so if, for instance, e is in feet and equals m feet, we must have $e = \frac{m}{r}$ where r is the earth's radius in feet. If we wish for δC in seconds, let δC = n'' then $\frac{\delta C}{n} = \frac{\pi}{180 \times 60 \times 60}$ = 0·000004848, as we have already seen.

$$\therefore n = \frac{\delta C}{\cdot 000004848}$$

The above is the method used in the English surveys.

(c). *By the Method of Correcting the Angles, and Treating the Triangle as Plane.*

Let a, b, c, be the sides to radius r, then the circular measures of the sides are respectively $\frac{a}{r}$, $\frac{b}{r}$, $\frac{c}{r}$. Now

$$\text{Cos. } C = \frac{\cos. \frac{c}{r} - \cos. \frac{a}{r} \cos. \frac{b}{r}}{\sin. \frac{a}{r} \sin. \frac{b}{r}}$$

But if we suppose that we retain all terms up to the fourth order, *i.e.,* $\left(\frac{a^4}{r}\right) \left(\frac{b^4}{r}\right) \frac{a^2 b^2}{r^4}$ . . . . Then

$$\frac{1}{\text{Sin. } \frac{a}{r} \sin. \frac{b}{r}} = \frac{1}{\left(\frac{a}{r} - \frac{a^3}{6r^3}\right)\left(\frac{b}{r} - \frac{b^3}{6r^3}\right)}$$

$$= \frac{1}{\frac{ab}{r^2}\left(1 - \frac{a^2 + b^2}{6r^2}\right)} = \frac{1}{\frac{ab}{r^2}}\left(1 + \frac{a^2 + b^2}{6r^2}\right)$$

$$\text{and } \cos. \frac{c}{r} - \cos. \frac{a}{r} \cos. \frac{b}{r} = 1 - \frac{c^2}{2r^2} + \frac{c^4}{24r^4}$$

$$- \left(1 - \frac{a^2}{2r^2} + \frac{a^4}{24r^4}\right) \left(1 - \frac{b^2}{2r^2} + \frac{b^4}{24r^4}\right)$$

$$= 1 - \frac{c^2}{2r^2} + \frac{c^4}{24r^4} - \left\{1 - \frac{a^2 + b^2}{2r^2} + \frac{a^4 + b^4 + 6a^2 b^2}{24r^4}\right\}$$

$$= \frac{a^2 + b^2 - c^2}{2r^2} - \frac{a^4 + b^4 - c^4 + 6a^2 b^2}{24r^4}$$

$$\therefore \text{Cos.C} = \frac{1}{2\,ab}\left(1 + \frac{a^2 + b^2}{6r^2}\right)$$

$$\left(a^2 + b^2 - c^2 - \frac{a^4 + b^4 - c^4 + 6a^2 b^2}{12r^2}\right)$$

Taking in every term involving $\frac{1}{r^2}$

$$\therefore \text{Cos. } C = \frac{1}{2ab}\left\{ a^2 + b^2 - c^2 + \frac{(a^2 + b^2)(a^2 + b^2 - c^2)}{6r^2} - \frac{a^4 + b^4 - c^4 + 6a^2 b^2}{12r^2} \right\}$$

$$= \frac{a^2 + b^2 - c^2}{2ab} - \frac{1}{24abr^2}$$

$$\left(2a^2b^2 + 2b^2c^2 + 2c^2a^2 - c^4 - b^4 - a^4\right)$$

Now $2a^2b^2 + 2b^2c^2 + 2c^2a^2 - c^4 - b^4 - a^4 = 2b^2c^2 + 2c^2a^2 - c^4 - (b^2 - a^2)^2 = 4c^2b^2 - 2c^2 (b^2 - a^2) - c^4 - (b^2 - a^2)^2 = 4c^2b^2 - (c^2 + b^2 - a^2)^2 = (2cb + c^2 + b^2 - a^2)(2cb - c^2 - b^2 + a^2) =$

$$\left\{(b + c)^2 - a^2\right\} \left\{a^2 - (b - c)^2\right\}$$

$= (b + c + a)(b + c - a)(a + b - c)(a - b + c) = 16 \text{ A}^2$, if A be the area of a plane triangle whose sides are a, b, c. (Plane Trigon., Art. 41).

$$\therefore \text{Cos. } C = \frac{a^2 + b^2 - c^2}{2\,ab} - \frac{16}{24} \frac{\text{A}^2}{abr^2}$$

Now if δC be the correction to be applied to the triangle, in order that we may be enabled to reckon the triangle plane, so that $C - \delta C$ is the angle of a plane triangle whose sides are a, b, c, then

$$\text{Cos.}\,(C - \delta C) = \frac{a^2 + b^2 - c^2}{2ab} \text{ (Plane Trigon., Art. 37).}$$

$$\text{And} \qquad \text{Cos.}\,(C - \delta C) = \text{Cos. } C + \delta C.\ \text{sin. } C$$

$$\therefore \text{Cos. } C = \text{Cos. } C + \delta C,\ \text{sin. } C - \frac{2}{3}.\ \frac{A^2}{abr^2}$$

$$\therefore \delta C = \frac{2}{3}.\ \frac{A^2}{ab \text{ sin. } C.\ r^2} = \frac{1}{3}.\ \frac{A}{r^2}$$

Since the area of the triangle is $\frac{1}{2}\,ab \text{ sin. } C = A$.

Now if E be the spherical excess, *i.e.*, the excess of the sum of the three observed angles over two right angles, we have (Spherical Geometry, Prop. IX.)

$$A \ : \text{Area of hemisphere} : : E : 2\pi$$

E being in circular measure.

$$\therefore 2\pi A = E + 2\pi r^2$$

$$\therefore E = \frac{A}{r^2}$$

$$\therefore \delta C = \frac{1}{3} E.$$

The same clearly holds good of either of the other angles; hence the rule determines the spherical excess into three equal parts; subtract one part from each of the angles, and the triangle can then be considered plane. If δC be equal to n'' then, as before,

$$n'' = \frac{A}{3r^2 \times \cdot 000004848}.$$

It is to be observed that n is very small, *e.g.*, rarely more than 5 or 6; hence a small error in the area will produce no appreciable error. Hence A can be found on the supposition that the original triangle is plane.

[The remaining pages of this section will be occupied with tables giving the logarithmic sines, cosines, tangents, and cotangents for each minute in the quadrant. We add, however, a small table of natural sines and cosines, which will be useful in connection with other subjects that we shall subsequently have to enter on].

NATURAL SINES AND COSINES FOR EVERY DEGREE IN THE QUADRANT.

SECTION VIII.

MECHANICAL PHILOSOPHY.

CHAPTER I.

STATICS.

Mechanical Philosophy is that branch of Natural Philosophy which investigates the laws that govern the action of force on matter. By the application of the purely mathematical sciences to a few general results, suggested by experiment and universal experience, we demonstrate these laws in their highest degree of generalisation, and under all the various conditions, in which force can produce an effect on matter.

Matter may exist in three states—the solid, liquid, and aëriform. Force is that which either produces, or tends to produce, the motion of matter. Force may therefore be considered in relation to its effects on these three conditions of matter.

When forces produce the rest or equilibrium of the body, or system of bodies to which they are applied, we have the three following distinct subjects :—

1. **Statics**,—the rest, or equilibrium of *solid bodies* under the influence of forces.
2. **Hydrostatics**,—the rest, or equilibrium of *fluid bodies* under the influence of forces.
3. **Aerostatics**,—the rest, or equilibrium of *aëriform bodies* under the influence of forces.

When motion is the result of the application of forces to these conditions of matter, we have then these three subjects :—

1. **Dynamics**,—the motion of *solid bodies* produced by the influence of forces.
2. **Hydrodynamics**,—the motion of *fluid bodies* produced by the influence of forces.
3. **Aerodynamics, or Pneumatics**,—the motion of *aëriform bodies* produced by the influence of forces.

That branch of mechanical philosophy which treats of the rest, or equilibrium of solid bodies, when under the action of any forces, is called Statics. Statics is derived from a Greek word, στατική, the science of weight.

MATERIAL PARTICLE.—The smallest portion into which any solid body can be conceived to be divided by any means whatever, we call a Material Particle. This material particle is an abstract mental conception, altogether independent of any theories of the ultimate division of matter, and does not therefore correspond with the "atom" of the properties of matter. The material particle is a mere geometrical point, which we conceive destitute of every property save one—that of being set in motion, or brought to rest under the influence of forces which are supposed to act upon it. It is conceived to be destitute of form or sensible magnitude.

RIGID BODY.—A rigid body is a collection or assemblage of a number of material particles, held together in an invariable form, by forces of such intensity, that no conceivable force is supposed to be capable of altering the form of the body, or disturbing the position of any of its particles.

This rigid body is also a mental abstraction, having no representative in nature. No material solid, with which we are acquainted, is perfectly rigid, though the unknown molecular forces, which hold the particles of most solid bodies together, are so great, that for many practical purposes we may regard them, within certain limits, as rigid. The various solid bodies which occur in nature, though differing from one another by many properties, seem to possess one property in common—that of being able to transmit any forces applied to any one of their particles, unimpaired in their intensity, through all the particles of their substance, which are in the same straight line with the direction of the application of the force. Experiment shows that most solid bodies possess this property more or less; it is this which distinguishes, in a great measure, solids from fluids,—any force applied to a particle of a fluid being conveyed through every particle throughout its substance in every direction.

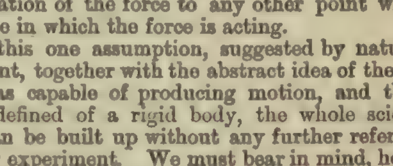
This property, which natural solid bodies possess more or less, we shall assume our rigid body to possess *perfectly*; and this will enable us to enunciate a principle upon which the whole science of Statics may be said to depend.

PRINCIPLE OF THE TRANSMISSION OF FORCE.—When a force, acting in combination with others, holds a rigid body in equilibrium, the equilibrium of the body will not be disturbed if we transfer the point of application of the force to any other point whatever in the line in which the force is acting.

Upon this one assumption, suggested by nature and experiment, together with the abstract idea of the nature of force as capable of producing motion, and the idea already defined of a rigid body, the whole science of Statics can be built up without any further reference to nature or experiment. We must bear in mind, however, when we apply the conclusions to which the science of Statics leads us, that these conclusions will only hold true, for the solid bodies of nature, so far as they possess the properties of perfect rigidity, and the perfect transmission of force. Within these limits we may apply our science to the action of forces on natural bodies with accuracy.

STATICS AN ABSTRACT SCIENCE.—Statics is an abstract mathematical science, and many of its results cannot be directly confirmed by experiment. Thus, one of the simplest propositions, which we shall hereafter prove, is, that if two weights, P and Q (Fig. 1) be suspended from the extremities of a rigid rod, A B, resting on the sharp edge of a support at F, the weights P and Q will balance one another, and the rod A B will be in a state of equilibrium, provided A F be as many inches in length as Q is ounces in weight, and F B as many inches in length as P is ounces in weight. This proposition cannot be proved by experiment, since it is only true on the supposition that A B is destitute of weight, and no bar,

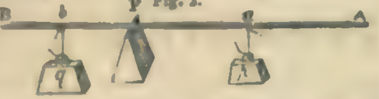
Fig. 1.



whose weight is inappreciable, can be found sufficiently rigid to support the weights P and Q, however small, and still remain perfectly straight under their pressure, and that of the sharp edge at F. It is true that another proposition of Statics would enable us to take into account the weight of the bar A B.

If the bar A B (Fig. 2) were uniform throughout in thickness and material, the bar would balance itself on the edge F, provided a weight q, equal the weight of the portion of the bar A F, were suspended from the point b, F b being equal the half of A F: and a weight, p, equal the weight of the portion of the bar F B, suspended from a, F a being equal the half of B F.

Fig. 2.



Supposing the difficulty of the weight of the bar thus obviated, there would still remain another difficulty in the way of a perfect experimental proof of our simple proposition. According to theory, the slightest additional weight, added to either of the weights P or Q, ought to destroy the equilibrium of the bar A B, and alter its perfectly horizontal position. But this supposes that the edge of the support F will exercise no friction on the surface of the rod A B. By a proper choice of materials, for the rod and the support, and also of the angle of the edge of the support, this friction may be considerably diminished, but it can never be absolutely destroyed. If we could succeed in fulfilling all the conditions we have indicated as necessary for the experimental proof of the very simple proposition of our science, which we have enunciated, we should be able to construct a perfect balance. That these difficulties are real, and not merely imaginary, is proved by the fact that a balance, sufficiently sensitive and accurate to supply the wants of the modern analytical chemist, is a very expensive instrument, and requires great skill and accuracy, as well as scientific knowledge, for its construction.

Though we cannot appeal to experiment for a rigid proof of our propositions, if we make the necessary allowances for the difference between the bodies on which our experiments are conducted, and the imaginary bodies which our science supposes perfectly rigid, and so forth, careful experiments will serve not only to give us clearer views of our science, but also to confirm our confidence in our abstract reasonings, by the approximate coincidence of our experimental results with our theoretical conclusions.

Thus, if in the experiment before alluded to, we make the necessary allowance for the weight of the bar, by applying the small weights p and q to the points a and b, our experiments will approximate to the theoretical proposition in proportion as the friction of F on the bar is diminished, and the bar A B is perfectly straight and accurately divided at the points a and b (Fig. 2).

REST OR EQUILIBRIUM.—Having defined a material particle and a rigid solid body, and their theoretical properties and condition, we must next consider what we mean by their rest or motion. We say that a body or a particle is in motion when we perceive the body or particle to change its position, and that it is at rest when it does not change its position. This clearly implies, however, that we have some means of measuring this alteration or change of position, by reference to other bodies which we conceive to be at rest. Hence it happens that what we suppose to be rest and motion, are generally only apparent rest and motion, and that there is no subject on which our senses more frequently lead us to form erroneous conclusions than when we attempt to discriminate the real or absolute rest and motion of objects from their apparent rest or motion. When we see a body change its position relatively to other bodies, we cannot tell whether the body which seems to move really does so or not, till we know whether the bodies relatively to which it appears to change its position, are themselves in a state of rest, or whether they are all moving together. It may so happen that the bodies may be moving, though we are ourselves unconscious of their motion; and in this case the body which apparently moves may be really at rest. Instances of this kind are of daily occurrence. A person on board ship, where his own body, as well as all the surrounding parts of the ship are apparently at rest, sees all the objects which the ship passes, carried, as it were, past him with great velocity; and were he not conscious, from other considerations, that the ship on which he stands were really in motion, he would have some difficulty in conceiving that the apparent motion of the stationary objects the ship passes by, was not real instead of imaginary. This is strikingly illustrated by looking out of a railway carriage when moving quickly; the objects, such as trees and houses, near the carriage, are apparently carried by the window with great rapidity, while those at a greater distance seem to pass more slowly. If, while waiting at a station, a train pass slowly by, it is often very difficult to tell whether the train in which we are seated be at rest or in motion, unless we correct our impression by looking out of the opposite window, where we can compare the position of the train with the fixed objects of the station.

APPARENT REST OR MOTION OF HEAVENLY BODIES.—A popular knowledge of astronomy is now so common, that we have no difficulty in persuading persons that the apparent motion of the sun and stars in the heavens is not real. Yet this is a fact which can only be demonstrated by a long course of intricate reasoning, founded on an immense number of careful observations.

To an ordinary observer, the vault of heaven, studded with stars, appears to revolve round an imaginary axis, while the earth seems perfectly at rest; each of the fixed stars describes a circle, which brings it back to the position in which it was first observed in an invariable interval of about 23 hours 56 minutes. What are called the fixed stars seem all to move together with the vault of heaven, and never to change their relative positions with respect to one another. The planets and comets, as well as the sun and moon, have an apparent motion among the fixed stars. In the case of the planets, comets, and moon, this apparent motion is exceedingly complex. Sometimes a planet will appear to move forward with great rapidity among the stars of a constellation; then it will come, as it were, to a stand-still, remain some time at rest, and then move backward. Ancient astronomers were well acquainted with the phenomena of real and apparent motion; yet after centuries of painful research and the invention of most complicated motions, to account for the apparent paths of the planets on the vault of heaven without avail, it was reserved for the genius of Copernicus and Kepler to resolve these motions into simpler ones, on the simple hypothesis that all the planets move round the sun in orbits nearly elliptical, and are never at rest.

Astronomy teaches us that every object on the earth's surface which appears to us at rest, is really subject, along with the earth on which it is placed, to two motions; one by which it is carried round the earth's axis by its diurnal rotation, and another by which it describes the earth's orbit round the sun in a year.

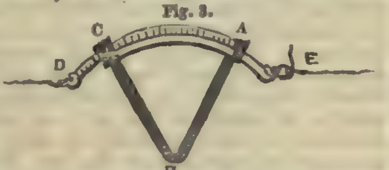
From these considerations it appears that there can be no absolute rest for any particle of matter by which we are surrounded; that perpetual motion is the real condition of all material objects; and that when we apply the reasonings and principles of the science of statics to nature, it is the apparent and not real rest of bodies to which we must have regard.

In the application of the principles and conclusions of statics to nature, we may consider the earth as absolutely fixed and at rest, and neglect its real motion without introducing any sensible error into our experiments. According to the law of inertia, all the bodies on the earth will partake of the earth's motion, and we know of no force which will deprive them of this motion; if, therefore, any forces produce the relative motion or rest of a terrestrial body, compared with bodies fixed with regard to the earth, that relative rest or motion will be the same whether the earth be really at rest or in motion. A familiar instance may make this assertion clear. If a ship under the influence of steam and tide, be moving rapidly through smooth water, all mechanical powers, such as blocks and pulleys, the windlass, and all the parts of the most complicated steam-engine will act under precisely the same circumstances, exert the same forces, be brought to a state of apparent rest or motion compared with the ship as a fixed object, whether the ship be at rest or in motion. A game of billiards, which requires considerable practical skill in mechanical science, may be played in the cabin of a ship without the players being aware whether the ship is at rest or in motion. Though, with respect to the earth, the balls, which were apparently at rest while the ship was moving, would be in reality not at rest, but moving with the ship.

MEASURE OF FORCE—DYNAMOMETERS.—We regard all forces as equal which produce the same mechanical effects; and in statics we consider forces as equal, which produce the same effects, when applied in a similar manner, in bringing a body into a state of equilibrium. Instruments, by means of which these effects are estimated, are called dynamometers, or force measurers.

A very simple dynamometer consists of a thin flat bar of steel, A B C, bent into an angle at B, and properly tempered, so that if any force be applied at A and C, to bring the extremities nearer together, the force of elasticity of the steel will cause the extremities, A and C, to resume their position as soon as the forces are removed. The greater the forces applied to A and C, the nearer these extremities of the bar will be brought to one another. To measure this effect, a circular arc of metal, A C D, is fixed perpendicularly to the surface of the steel bar at A, passing freely through an opening in the other extremity of the bar at C. Another arc, C A E, is similarly fixed at C, passing through an opening at A. Rings are fixed at D and E for the convenient application of forces whose effects are to be estimated; and one of the arcs, A D, is graduated by a number of equal divisions.

Fig. 3.



If the extremity E (Fig. 4) of the dynamometer be fixed to a beam, and a weight, P, hung from the ring at D, the graduated arc will show the statical effects of the weight P in bringing the dynamometer to a state of rest, with the extremities of the bent bar nearer to each other than they were before the application of the weight P. If, instead of applying a weight P, we pull with our hand a string attached to D (Fig. 5), till we bring the graduated part of the arc at A to the same division to which the weight P brought it, we produce with our hand a similar statical effect to that produced by the weight. We therefore conclude that the forces exerted by the weight and by the hand are equal to one another, though they are evidently forces of a very different character, the force of the weight being produced by the earth's attraction for the particles of matter of which it is composed, and the force exerted by the arm being derived from the contractions of the muscular fibres of the muscles of the arm, due to some force which we call the muscular force, of the nature of which we are perfectly ignorant.

Fig. 4.

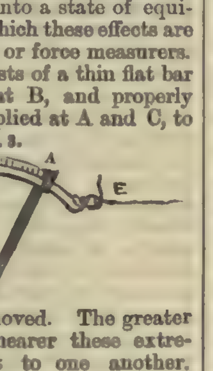


Fig. 5.

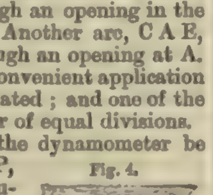
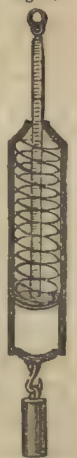


There are many other dynamometers besides that just described, such as one in which the statical effects of a force causing a spiral spring of wire contained in a metal cylinder to be compressed, is measured on a graduated rod, as in the accompanying figure (Fig. 6). The various kinds of balances and steel yards, which will be described hereafter, are all dynamometers.

Fig. 6.



UNIT OF FORCE.—The experiment on the dynamometer, just described, would lead us to infer, what is found to be true in practice, that weight is the most convenient measure of force which we can adopt in statics. We say that a force of ten or twelve pounds is exerted on a body, if the force produce the same statical effect on the body which a weight of ten or twelve pounds applied in a similar way would produce. The unit of force generally adopted in this country is that called a pound weight. But here we may be met with the inquiry, what is a pound weight? This is a very important question, and has been determined by legislative enactment, after careful deliberation, and the report of a scientific commission appointed for the consideration of the difficult subject of standard weights and measures.

POUNDS TROY AND AVOIRDUPOIS.—By the Act of Parliament (5th George IV., c. 74, passed in the year 1824, sections 4 and 5), it is enacted—"That from and after the first day of May, 1825, the standard brass weight of one pound troy weight, made in the year of 1758, now in the custody of the clerk of the House of Commons, shall be, and the same is hereby declared to be, the original and genuine standard of measure of weight, and that such brass weight shall be, and is hereby declared to be, the original and genuine standard measure of weight, and that such brass weight shall be and is hereby denominated the Imperial Standard Troy Pound, and shall be, and is hereby declared to be, the unit or only standard measure of weight from which all other weights shall be derived, computed, and ascertained, and that one twelfth part of the said troy pound shall be an ounce, and that one twentieth part of such ounce shall be a pennyweight, and that one twenty-fourth part of such pennyweight shall be a grain; so that 5,760 such grains shall be a troy pound, and that 7,000 such grains shall be, and they are hereby declared to be, a pound avoirdupois, and that one sixteenth part of the said pound avoirdupois shall be an ounce avoirdupois, and that one sixteenth part of such ounce shall be a dram.

"And whereas it is expedient that the said standard troy pound, if lost, destroyed, defaced, or otherwise injured, should be restored of the same weight by reference to some invariable natural standard; and whereas it has been ascertained by the commissioners appointed by his Majesty to inquire into the subject of weights and measures, that a cubic inch of distilled water, weighed in air by brass weights at the temperature of 62 degrees of Fahrenheit's thermometer, the barometer being at 30 inches, is equal to 252 grains, and 456 thousandth parts of a grain, of which, as aforesaid, the Imperial Standard Troy Pound contains 5760: Be it therefore enacted, that if at any time hereafter the said Imperial Troy Pound shall be lost, or shall in any manner be destroyed, defaced, or otherwise injured, it shall and may be restored by making, under the direction of the Lord High Treasurer, or the Commissioners of His Majesty's Treasury of the United Kingdom of Great Britain and Ireland, or any three of them for the time being, a new standard troy pound, bearing the same proportion to the weight of a cubic inch of distilled water, as the said standard pound, hereby established, bears to such cubic inch of water."

From this Act of Parliament it appears that the troy pound is a certain arbitrary piece of brass, which, weighed in air at a temperature of 62° Fahrenheit, the mercury in the barometer standing at a height of 30 inches, is equal to the weight of 22 cubic inches, and 815 thousand parts of a cubic inch of distilled water. Distilled water is therefore the natural standard to which the unit of weight is ultimately referred. This standard, however, is referred to a cubic inch, or a volume of water an inch in height, an inch in breadth, and an inch in depth.

We must, therefore, have some standard measure of length.

UNIT OF LENGTH.—The Act of Parliament just cited has also determined the standard unit of the measure of length. By the first section of that act, it is enacted—"That from and after the 1st day of May, 1825, the straight line, or distance between the centres of the two points in the gold studs in the straight brass rod, now in the custody of the clerk of the House of Commons, whereon the words and figures, 'Standard yard, 1760,' are engraved, shall be, and the same is hereby declared to be, the original and genuine standard of that measure of length or lineal extension called a yard, and that the same straight line or distance between the centres of the said two points in the said gold studs in the said brass rod, the brass being at the temperature of 62 degrees by Fahrenheit's thermometer, shall be and is hereby denominated the 'Imperial Standard Yard,' and shall be, and is hereby declared to be, the unit or only standard measure of extension, wherefrom or whereby all other measures of extension whatsoever, whether the same be lineal, superficial, or solid, shall be derived, computed, or ascertained; and that all measures of length shall be taken in parts or multiples, or certain proportions of the said standard yard; and that one-third part of the said standard yard shall be a foot, and the twelfth part of such foot shall be an inch, and that the pole or perch in length shall contain 5 such yards and a half, the furlong 220 such yards, and the mile 1,760 such yards.

"And whereas the said standard yard, if lost, destroyed, defaced, or otherwise injured, should be restored of the same length by reference to some invariable natural standard; and whereas it has been ascertained, by the commissioners appointed by his Majesty to inquire into the subject of weights and measures, that the said yard hereby declared to be the Imperial Standard Yard, when compared with a pendulum vibrating seconds of mean time in the latitude of London, in a vacuum, at the level of the sea, is in the proportion of 36 to 39 inches, and 1,393 ten thousandths part of an inch: Be it therefore enacted and declared, That if at any time hereafter the said imperial standard yard shall be in any manner destroyed, defaced, or otherwise injured, it shall and may be restored by making, under the direction of the Lord High Treasurer, or the Commissioners of His Majesty's Treasury of the United Kingdom of Great Britain and Ireland, or any three of them, for the time being, a new standard yard bearing the same proportion to such pendulum as aforesaid, as the said imperial standard yard bears to such pendulum."

UNIT OF TIME.—Time is the ultimate natural standard to which all measures of length, weight, and capacity are referred in this kingdom. Time certainly is one of the most convenient, and perhaps the only natural standard to which we can have recourse, to fix with scientific accuracy our units of measurement. The value of time in this respect depends upon the fact deduced by astronomers, from observations collected and registered for many centuries, that the mean length of day and night is invariable; in other words, that the earth always completes its rotation on its axis in the same period of time. This portion of time is obtained by observing the period which elapses between the passage of a fixed star over a certain imaginary line in the heavens, called the meridian of the place of observation, and its next appearance on this line, and is called a sidereal day. The sidereal day is divided into twenty-four hours, each hour into sixty minutes, and each minute into sixty seconds. A clock is an instrument for measuring time, and is set in motion by a weight; its motion is regulated by the vibrations of a pendulum, and the number of its vibrations are registered by means of a series of wheels, and indicated on the graduated face of the clock by the motion of hands or pointers. The length of the pendulum is so regulated that its time of vibration may be as nearly as possible one second; and these vibrations being registered by the clock, if the clock indicate that 24 hours, or 24 × 60 × 60, or 86,400 seconds have elapsed between one transit of the star over the meridian and another, the clock is said to be correct, and will afford us an accurate measure of sidereal time. Such a clock is called a sidereal clock, and is one of the most valuable and useful instruments in an observatory. Sidereal time is not, however, the time used for the ordinary transactions of life. The true solar day is the interval which elapses between one passage of the sun over the meridian and another, as shown by a dial or other means of astronomical observation; this day is not invariable in length, but changes from day to day, being sometimes longer and sometimes shorter. To avoid this inconvenience, a mean solar day is chosen by the supposed revolution of a fictitious sun, which shall be invariable in length; and this time is divided into 24 hours, and these hours into minutes and seconds, as in the case of the sidereal day. This mean solar day is the time used for the ordinary or civil reckoning of time. What is called the equation of time, is an astronomical calculation, which gives the difference between the time shown by the dial or the true solar time, and that indicated by the ordinary clocks, which show the mean solar or civil measure of time. The sidereal day is 23 hours, 56 minutes, 4 seconds, and nine hundredths of a second of a mean solar day; and the mean solar day is 24 hours, 3 minutes, 56 seconds, and 55 hundredth parts of a second of a sidereal day. The pendulum vibrating seconds, from which, by Act of Parliament, the standard measure of length, if lost, is to be obtained, is to be a pendulum vibrating a second of mean solar time under the conditions specified in the act. So great, however, are the scientific and mechanical difficulties to be overcome in determining accurately the length of this second's pendulum, that though the standard yard was so injured by the fire when the houses of Parliament were burnt down in 1834, and the standard pound troy altogether lost, no attempt has been made to restore the lost standards. The last scientific commission seems to have considered the attempt to do so altogether hopeless. Fortunately, the Royal Astronomical Society had a very beautiful scale constructed about the year 1832, and three feet of this scale were compared many hundreds of times with the Parliamentary standard; and this scale must now be considered the scientific English standard, and the best evidence of the parliamentary standard which exists. There is also great doubt as to the accuracy of Captain Kater's determination of the length of the second's pendulum which is adopted by the Act of Parliament; so that if the standard were to be restored according to that act, it would probably differ from the lost standard (Bailey's Report on a Standard Scale, Astronom. Soc. Mem. vol. ix.) Two Acts of Parliament, 5 and 6 Wm. IV., c. 63, and 16 Vic., c. 29, June, 1853, have been enacted since the fire, on the subject of weights and measures; but neither of them notice the loss of the standards, speaking of them as if they were still in existence.

FRENCH STANDARDS.—The French standards are derived from actual measurements of the earth's surface. From these measurements the length of a line drawn from the pole of the earth to the equator is deduced. The ten-millionth part of this line is called a metre; and this is the French standard of length. The decametre is 10 metres, the hecto-metre is 100 metres, the kilo-metre 1,000 metres, and the myria-metre is 10,000; while the deci-metre is the 10th part of a metre, the centi-metre the 100th part of a metre, and the millimetre the 1,000th part of a metre—Greek prefixes being used for the multiples of the metre, and Latin for its parts. The gramme, which is the standard of weight, is derived from the standard of length, and is equal to the weight of a cubic centi-metre of distilled water, weighed at the freezing point. The same prefixes are used before the gramme, which are added to the metre to express its multiples and parts. Thus a kilo-gramme is a 1,000 grammes, and a milli-gramme the 1,000th part of a gramme.

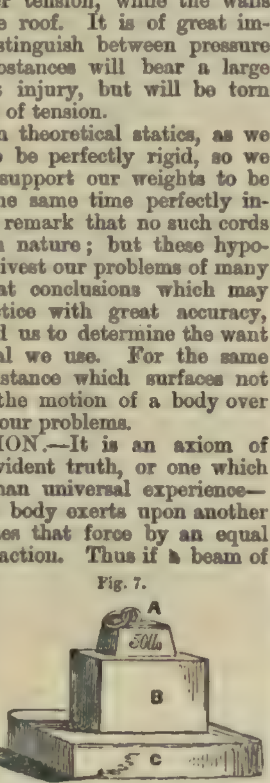
The metre is equal to 3·280899 English feet, and the kilo-gramme is equal to 3·204597 pounds avoirdupois.

PRESSURE AND TENSION.—When a material body is in a state of equilibrium under the influence of forces, the forces applied to the body may either have a tendency to press the particles of the body or to crush it, in which case the forces are called pressures, or they may have a tendency to separate the particles of the body or tear it, in which case they are denominated tensions. A weight placed on a body exerts a pressure on it. Two men pulling a rope, or weights suspended from a rope, exert a tension on the rope throughout its substance; and if one part of the rope be weaker than another, and the weight or force be sufficiently great, the rope will break or be torn asunder at that part. The tie-beams of a roof, which prevent the weight of the roof from thrusting the walls of a building out of the perpendicular, are under tension, while the walls support the pressure of the roof. It is of great importance, practically, to distinguish between pressure and tension; for some substances will bear a large amount of pressure without injury, but will be torn asunder by a far less amount of tension.

FLEXIBLE CORDS.—In theoretical statics, as we conceive our solid bodies to be perfectly rigid, so we conceive the strings which support our weights to be perfectly flexible, and at the same time perfectly inextensible. It is needless to remark that no such cords or strings are to be found in nature; but these hypothetical bodies enable us to divest our problems of many difficulties, and to arrive at conclusions which may afterwards be used in practice with great accuracy, when experiment has enabled us to determine the want of flexibility in the material we use. For the same reason, friction, or the resistance which surfaces not perfectly smooth oppose to the motion of a body over them, is at first neglected in our problems.

ACTION AND REACTION.—It is an axiom of statics—that is, it is a self-evident truth, or one which admits of no other proof than universal experience—that whatever force one rigid body exerts upon another rigid body, the latter opposes that force by an equal force, which is called its reaction. Thus if a beam of wood, B (Fig. 7) standing upright on a floor, C, support on one of its extremities a 50lb. weight, A, the weight A will exert a pressure of 50 lbs., acting downwards, on the beam, and the beam will convey this pressure to the floor. But the rigidity of the beam opposes a force to the weight, which prevents the weight from falling, or crushing the beam; and thus a reaction equal to 50 lbs. is exerted upwards by the beam upon the weight. Again, the beam presses on the floor with its own weight, in addition to that of the 50 lb. weight; and if the floor be strong enough, and of a material sufficiently rigid to prevent B sinking into it, the floor will sustain the pressure of A and B, which acts downwards; but it will react upwards on B with a force equal to the pressure B exerts upon it.

Fig. 7.



EQUILIBRIUM OF A MATERIAL PARTICLE.—If a material particle be acted upon by two forces which are equal to one another, but acting in opposite directions in the same straight line, they will neutralise one another, and the particle will be at rest. This is self-evident, and depends upon our fundamental idea of the equality of forces. Supposing, however, that the two forces do not act on the particle in the same straight line, but in the direction of straight lines inclined to one another at some angle, in what direction must a force be applied to the particle, and of what magnitude must it be, to neutralise the effect of these two forces, both in the case where the two forces are equal, and also where they are unequal? This is one of the most important, and, indeed, the fundamental proposition of statics. Before we can discover it we must adopt some means of representing forces and their directions.

GEOMETRICAL REPRESENTATION OF FORCES.—If we represent the material point by a geometrical point A (Fig. 8), we may draw a line, A P, to represent the direction in which a force, say of P pounds, is acting on the particle,, and A Q to represent the direction in which a force of Q pounds is acting on A; then if we take A P, P inches in length, and A Q, Q, inches in length, the lines A P and A Q will represent the forces P and Q acting on A, both in magnitude and direction. Thus if two forces, one of 4 lbs. and another of 3 lbs., are supposed to act on a particle at right angles, or perpendicular to one another, we should represent them by the lines A B, 3 inches in length, and A C, 4 inches in length, drawn perpendicularly to one another. (Fig. 8).

Fig. 8.

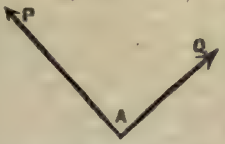


Fig. 9.

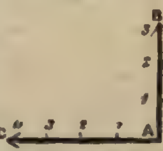
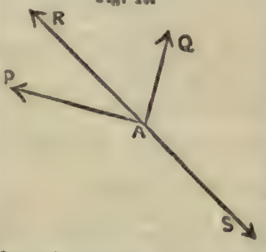


It is not necessary to use an inch as the representative of a pound, or the unit of weight. Any other convenient measure, such as the eighth or tenth of an inch, may be used, if we keep to the same scale throughout. It is usual to indicate the direction in which the force acts by the addition of an arrow-head to the line which represents it.

RESULTANT.—If two forces, P and Q (Fig. 10), represented in magnitude and direction by the lines A P and A Q, act upon the point A, so as to cause it to move, it must begin to move in some direction. Let A R represent that direction. Now we can conceive that some force, S, could be applied to A in the opposite direction to A R, in which A would begin to move, which would stop its motion and keep it at rest. Let A S represent this force in magnitude and direction. Then the particle A would be kept at rest by the three forces, P, Q, and S, acting in the directions A P, A Q, and A S. If, now, the line S A be produced to R, and A R be taken equal to A S, A R will represent in magnitude and direction a force, R, equal to S, which, if P and Q were removed, would counteract the effect of the force represented by A S on A. A R, therefore, represents, in magnitude and direction, a force which would have the same effect on A, when it acted upon it by itself, that the forces represented by A P and A Q would have, if they both acted on A.

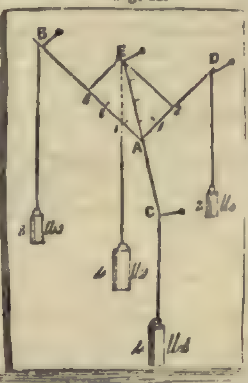
Fig. 10.



The force R, represented by A R, is called the *resultant* of the forces P and Q, represented by A P and A Q; and P and Q are called the *components* of R.

Thus, for example, if three perfectly smooth pegs, B, C, and D (Fig. 11), be inserted in a board standing in a vertical position, and three strings be attached to a point, or simply knotted together at A, and weights of 2 lb., 3 lb., and 4 lb. fixed to their extremities, as in the figure, the weights will balance each other; and, neglecting the friction on the pegs, B, C, and D, and supposing the strings perfectly flexible, the whole will come to rest in the position represented by the diagram. The point or knot A will be kept at rest by the tensions of the weights—that is, by a force of 3 lbs. acting in the direction of A B, 2 lbs. in the direction of A D, and 4 lbs. in that of A C. Let another peg, E, be inserted in the board, somewhere in the straight line C A produced, attach another string to A, and pass it over A E, with a weight of 4 lbs. at its other

Fig. 11.

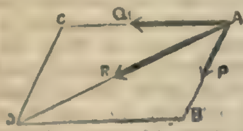


extremity, care being taken to support this latter weight so as not to allow it to act on A till we require it. If, now, the weights of 2 lb. and 3 lb. be supported so as to take off their tensions from A at the same instant that the second 4 lb. weight is allowed to exert its tension on A in the direction A E, the equilibrium of the point A will not be disturbed, since the tension of 4 lbs. acting in the direction A E, will exactly balance the tension of the 4 lb. acting in the direction A C. The tension of 4 lb. acting in the direction A E, produces, therefore, the same effect on the point A that the joint tensions of 3 lb. acting in the direction A B, and of 2 lb. in the direction A D, both together have upon it. The 4 lb. tension, acting in the direction A E, is called the *resultant* of the 3 lb. tension in the direction A B, and the 2 lb. tension in that of A D.

PROPOSITION I.

PARALLELOGRAM OF FORCES.—The proposition which enables us to represent the resultant of any two forces which act upon a material particle in magnitude and direction, when the magnitude and direction of the two forces are given, is called the parallelogram of forces, and is as follows :—

Fig. 12.



Let P and Q be two forces acting upon material point A. (Fig. 12).

Let the line A B represent the force P in magnitude and direction, and A C the force Q in magnitude and direction.

Through B draw B D parallel to A C, and through C, C D parallel to A B.

Let D be the point where the lines B D and C D meet.

Then, by construction, the figure A B D C is a parallelogram.

Join A D, A D is the diagonal of the parallelogram.

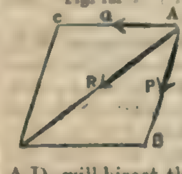
This diagonal A D will represent the resultant R of the two forces P and Q acting in the directions A B and A C, in magnitude and direction.

The parallelogram of forces may therefore be thus enunciated. *If two forces acting upon a material particle be represented in magnitude and direction by two adjacent sides of a parallelogram, the diagonal of the parallelogram, drawn through the point where these sides meet, will represent their resultant both in magnitude and direction.*

We shall first show that this proposition is true for the *direction* of the resultant, and then that it is also true for its *magnitude.*

1st. To prove that the parallelogram of forces is true for the *direction* of the resultant.

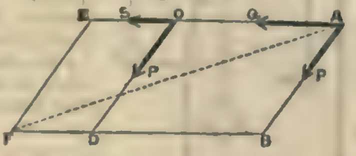
Fig. 13.



When the forces P and Q are equal, the direction of the resultant will manifestly bisect the angle B A C (Fig. 13), since no reason can be alleged why the resultant force R should incline more to one force, P, than to the other, Q. Since A B C D is a parallelogram whose sides A C and A B are equal, its diagonal, A D, will bisect the angle B A C, and therefore A D will represent the *direction* of the resultant when P and Q are equal.

Let us now assume the proposition to be true for two unequal forces P and Q, and also for two unequal forces P and S (Fig. 14), we can then prove that it will be true for the forces P and Q + S.

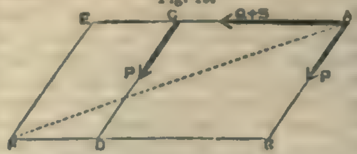
Fig. 14.



Draw a parallelogram A B D C, having one side A B proportional to the force P, and the adjacent side A C to that of Q ; produce A C to E, and make C E in the same proportion to S that the other lines bear to P and Q. Complete the parallelogram E D.

According to our assumption, the resultant of P and Q will act in the direction A D, and that of P and S in the direction C F. Now if all the points in the two parallelograms be supposed to be rigidly connected with one another, a force may be transferred from any point to another, provided the latter be in the same straight line in which the force is acting, without disturbing the equilibrium.

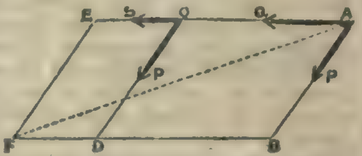
Fig. 15.



Hence the force S acting at C may be transferred to A (Fig. 15), and we shall then have a force Q + S acting on A in the direction A C, a force P acting on A in the direction A B, and a force P acting on C in the direction C D.

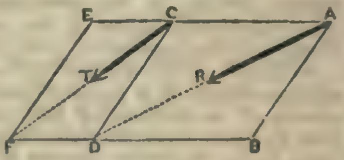
If the proposition be true for P and Q + S, their resultant will act in the direction A F, and these forces may be transferred from A to F. What we have therefore to show is, that the forces P and Q acting at A, and P and S acting at C, may be so transferred, by the principle of transmission of force, without altering the conditions of equilibrium, that we may have the forces Q + S and P acting at F and P at C (Fig. 16).

Fig. 16.



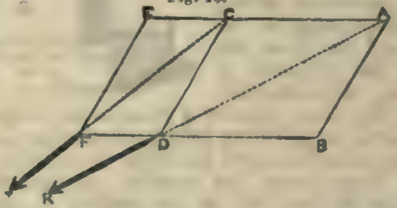
By our assumption, P and Q acting at A may be replaced by their resultant R (Fig. 17) acting in the diagonal A D of the parallelogram C B, and the forces P and S by their resultant T acting in the diagonal C F of the parallelogram E D.

Fig. 17.



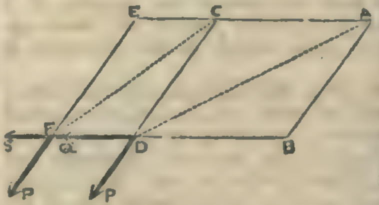
Now, according to the principle of the transmission of force, the force R may be transferred from A to D in the direction A D, and the force T from C to F in the direction C F, as represented in the accompanying diagram (Fig. 18).

Fig. 18.



Upon the same principle that we replaced the forces by their resultants, we may replace these resultants again by the forces from which they were obtained ; and we shall then have R replaced by the force P acting in the direction of C D produced, and Q in that of D F, and T replaced by P acting in E F produced, and S acting in D F produced (Fig. 19).

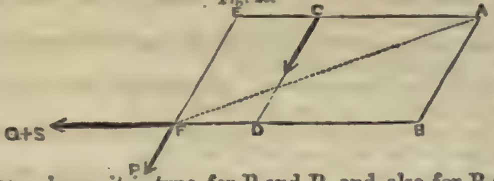
Fig. 19.



Lastly, the force Q may be transferred from D to F in the direction of D F produced (Fig. 20), and the force P from D to C in the direction C D ; so that we ultimately have the forces Q + S and P acting at F, and P at C, without having altered the conditions of equilibrium of any of the points of the parallelograms. Hence, if our proposition be true for two forces P and Q, and also for P and S, as regards the *direction* of the resultant, it is also true for the forces P and Q + S.

Now, we have shown that it is true for two equal forces; hence it is true for P and P, and also for P and P, it must therefore be true for P and P + P, or for P and 2 P. Being true for P and 2 P, and also for P and P, it is true for P and P + 2 P, or for P and 3 P, and so on; it may be shown to be true for P and *m* P, where *m* represents any whole number.

Fig. 20.



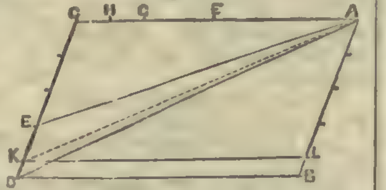
By similar reasoning the proposition may be extended to the forces *n* P and *m* P, where *m* and *n* represent any whole numbers whatever.

Hence the proposition is true, as to the *direction* of the result, for any two forces which are commensurable; or in other words, for any two forces which have a common measure, or can be expressed in terms of a common unit.

The proposition can be extended to the case of incommensurable forces, or forces which have no common measure.

Let the lines A B and A C (Fig. 21) represent two incommensurable forces, in magnitude and direction, of which A C is the greater. Complete the parallelogram A B D C, by drawing B D parallel to A C, and C D parallel to A B. If the resultant do not act in the direction of the diagonal A D of the parallelogram A B D C, let A E represent the direction in which it acts.

Fig. 21.



Divide the line A C in two equal parts in the point F; similarly divide F C in two equal parts in G, and G C in H; continue this subdivision until a part, such as H C, is obtained, which is less than D E.

A C may, therefore, be divided into a number of equal parts, each of which are equal to H C.

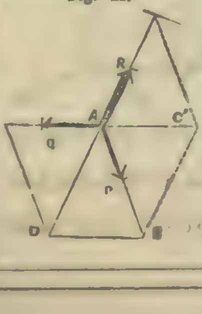
Set off distances each equal to H C along the line C D, commencing from the point C; then one of these divisions, such as K, must fall between E and D, since A C and C D have no common measure, and H C is less than E D.

From A B cut off A L = C K, and join K L and A K.

A C and A L will therefore have a common measure H C, and will consequently represent two commensurable forces; and A K, the diagonal of the parallelogram A L K C, will, by what we have previously proved, represent the direction of their resultant. The resultant A K, therefore, of the forces A L and A C, is further from A C than A E, the resultant of the forces A C and A B; but this cannot be true, since A B, being greater than A L, A E ought to be further from A C, or nearer to A B than A K. Consequently, the supposition that the resultant of A C and A B acts in the *direction* of the line A E, leads to an absurdity; and similarly it may be shown, that if it be supposed to act in any other direction than the line A D, the diagonal of the parallelogram A B D C, we shall be led to a like absurd conclusion.

Hence we infer, that if two forces, acting on a point, whether commensurable or incommensurable, be represented in magnitude and direction by two adjacent sides of a parallelogram, the diagonal of the parallelogram will represent the *direction* in which the resultant of these forces will act. We have next to show, that this diagonal will also represent the *magnitude* as well as the *direction* of the resultant.

Fig. 22.



Let A B, one side of the parallelogram A B C D (Fig. 22), represent a force P, in magnitude and direction, and the side A C, another force Q, in magnitude and direction, these two forces both acting on the point A.

Let R represent the force which is the resultant of the forces P and Q; this force will act, according to what we have already proved, in the *direction* A D, A D being the diagonal of the parallelogram A B C D.

Produce A D to D′, and take A D′ in the same proportion to R that A C bears to Q, or A B to P.

Draw D′ C′ parallel to A B, and B C′ parallel to A D′, meeting in C′, and join A C′, A B C′ D′ will be a parallelogram, A C′ its diagonal, and B C′ will be = A D′.

Since R is the resultant of the forces P and Q, a force R acting on A in the direction A D′, in the same straight line, but in the opposite direction to that in which the resultant of P and Q acts, will keep the point A at rest, when acted on by the forces P and Q.

Hence the forces P Q and R, represented in magnitude and direction by A B, A C and A D′ acting on A, will keep it at rest.

Any one of these three forces will be equal in magnitude to the resultant of the other two, but it will act in an opposite direction to it in the same straight line.

Now A C′, the diagonal of the parallelogram A D′ C′ B is the direction in which the resultant of the forces R and P represented by A D′ and A B acts. Therefore A C′ and A C must be in the same straight line; and since A C is parallel to B D, A C′ will also be parallel to B D; and since B C′ was drawn parallel to A D, A C′ B D must be a parallelogram, and B C′ will = A D.

But B C′ = A D′. Therefore A D = A D′; and since A D′ represents R in *magnitude*, A D will represent R both in *magnitude and direction*.

We are indebted to M. Duchayla, a French mathematician, for this very simple and beautiful demonstration of the parallelogram of forces. It may be proved by other methods, but they either require a knowledge of the higher branches of mathematical analysis, or else assume the principles of Dynamics.

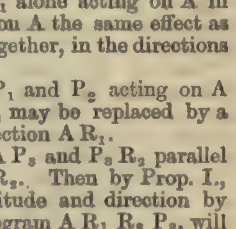
Some writers first demonstrate the properties of the lever, and from these deduce the parallelogram of forces.

PROPOSITION II.

To find the Resultant of any number of Forces acting on a Material Point in the same Plane.

Let P_1 P_2 P_3 and P_4, four forces acting on a point A in the same plane, be represented in *magnitude and direction* by the lines A P_1, A P_2, A P_3, and A P_4, (Fig. 23).

Fig. 23.



Draw P_1 R_1 parallel to A P_2, and P_2 R_1 parallel to A P_1, meeting in R_1; join A R_1. Then A R_1 the diagonal of the parallelogram A P_1 R_1 P_2 will by Prop. I. represent the resultant of the forces P_1 and P_2 acting on A in the directions A P_1 and A P_2.

Let R_1 be this force. Then R_1 alone acting on A in the direction A R_1 will produce on A the same effect as the two forces P_1 and P_2 acting together, in the directions A P_1 and A P_2.

Consequently the two forces P_1 and P_2 acting on A in the directions A P_1 and A P_2 may be replaced by a single force R_1, acting in the direction A R_1.

Again, draw R_1 R_2 parallel to A P_3 and P_3 R_2 parallel to A R_1 meeting in R_2; join A R_2. Then by Prop. I., a force R_2 represented in magnitude and direction by A R_2 the diagonal of the parallelogram A R_1 R_2 P_3, will have the same effect on A as the two forces R_1 and P_3 acting in the direction A R_1 and A P_3.

But R_1 acting on A in the directions A R_1 produces on A the same effect as P_1 and P_2 acting in the directions A P_1 and AP_2.

Hence the force R_2 acting on A in the direction A R_2 produces the same effect as the three forces P_1 P_2 and P_3 acting in the directions A P_1, A P_2, and A P_3.

Lastly, draw $P_4 R_3$ parallel to $A R_2$ and $R_2 R_3$ parallel to $A P_4$, meeting in R_3. Join $A R_3$. Then by Prop. I. a force R_3, represented in magnitude and direction by $A R_3$, will have the same effect on A as the two forces R_2 and P_4 have, acting in the directions $A R_2$ and $A P_4$.

But R_2, acting on A in direction $A R_2$, produces the same effect as P_1 P_2 and P_3 acting in the directions $A P_1$, $A P_2$, and $A P_3$.

Consequently a force R_3, acting in the direction $A R_3$, produces on A the same effect as the four forces P_1, P_2, P_3, and P_4, acting in the directions $A P_1$, $A P_2$, $A P_3$, and $A P_4$; or, in other words, $A R_3$ represents the resultant of these forces *in magnitude and direction.*

The same method may be extended to any number of forces, and affords an easy geometrical construction for finding the single resultant of any number of forces acting upon a material particle.

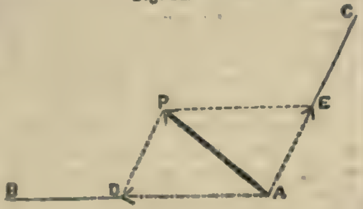
PROPOSITION III.

Resolution of Forces.

By means of the parallelogram of forces we can generally replace a single force by two others acting in any directions we please in the same plane; this is called *resolving* a force, and the forces by which it is replaced are termed its *resolved* parts.

Thus if a force P (Fig. 24) acting on a point A, be represented in magnitude and direction by the straight line A P; and A B, A C drawn through A be the arbitrary directions in which we wish to resolve the force P.

Fig. 24.



Through P draw P D parallel to A C meeting A B in D, and also PE parallel to A D meeting A C in E.

Then, by Prop. I., A E and A D will represent two forces in magnitude acting in the directions A C and A B, which produce on A the same effect as the simple force P acting in the direction A P, and therefore may replace that force without altering the conditions of equilibrium.

A E represents the *resolved* part of P along A C, and A D its *resolved* part in the direction A B.

In resolving forces, it is generally found more convenient to choose the direction A C perpendicular to A B.

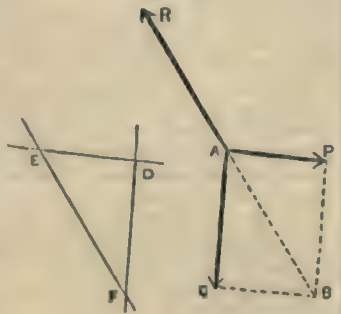
PROPOSITION IV.

Triangle of Forces.

If a material point be kept in equilibrium by the action of three forces acting upon it, in the same plane, the sides of any triangle drawn parallel to the directions of these three forces will be proportional to them; and conversely, three forces, acting on a material particle, will keep it at rest, if these forces be proportional to the sides of a triangle formed by drawing lines parallel to their directions.

Let P and Q (Fig. 25), two forces acting on A, be represented in magnitude and direction by the lines A P and A Q.

Fig. 25.



Through P draw P B parallel to A Q, and through Q, Q B parallel to A P meeting in B; join A B.

Produce A B to R, and make A R equal to A B.

Then Prop. I., a force R acting on A, represented in magnitude and direction by A R, will counteract the forces P and Q acting in the directions A P and A Q.

And A will be kept in equilibrium by the action of the three forces P, Q, and R acting in the directions A P, A Q, and A R.

Take any point E; through E draw E D parallel to A P, and E F parallel to A R.

In E D take any point D, and through D draw D F parallel to A Q, meeting E F in F.

Then by construction the triangle E D F will be equiangular to the triangles A P B or A Q B.

And, by Euc. B. VI., Prop. 4, E D : E F : F D : : A P : A B : B P : : P : R : Q.

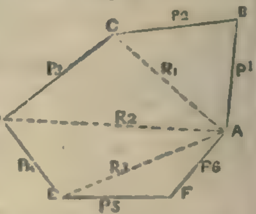
PROPOSITION V.

Polygon of Forces.

If a particle be acted on by any number of forces which are represented in magnitude, or are proportional to the sides of a polygon, it will be at rest, provided each force acts in a direction parallel to the side of the polygon to which it is proportional.

Let A B C D E F (Fig. 26) be a polygon, whose side A B, is proportional to the force P_1, B C to P_2, C D to P_3, D E to P_4, E F to P_5, and F A to P_6.

Fig. 26.



Join A C, A D, and A E.

Let $A C = R_1$, $A D = R_2$, and $A E = R_3$.

Then, by Prop. IV., R_1 will represent the resultant of the forces P_1 and P_2 in magnitude.

R_2 the resultant of R_1 and P_3, or of P_1, P_2, and P_3.

And R_3 the resultant of R_2, and P_4, or of P_1, P_2, P_3, and P_4.

But, by Prop. IV., since R_3, P_5, and P_6 are sides of the triangle A E F, R_3 will represent the resultant of P_5 and P_6.

Hence P_5 and P_6 will counteract the effect of the forces P_1, P_2, P_3, and P_4, provided the conditions of Prop. IV. be fulfilled; *i. e.*, provided these forces act upon a particle, in directions parallel to the sides of the polygon.

Since, in Prop. IV., any side of the triangle may be considered as the resultant of the other two, P_6 may be regarded as the resultant of R_3, and P_5, or of P_1, P_2, P_3, P_4, and P_5. Any one side, therefore, of the polygon may be taken as the resultant of all the others.

In the same manner the proposition may be extended to a polygon of seven, eight, or more sides.

The polygon of forces need not have all its sides in the same plane.

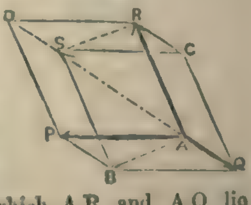
PROPOSITION VI.

Parallelopiped of Forces.

If three forces, whose directions are not in the same plane, act upon a point, and if they be represented in magnitude and direction by three adjacent edges of a parallelopiped, which meet in the point on which the forces act, the resultant of the forces will be represented in magnitude and direction by the diagonal drawn from this point to the opposite solid angle of the parallelopiped.

Let A be the point (Fig. 27), acted on by three forces, represented in magnitude and direction by A P, A Q, and A R, which are not in the same plane.

Fig. 27.



Then, Euc. B. xi. Prop. 2, A Q and A P are in the same plane; complete the parallelogram P A Q B in this plane, by drawing P B parallel to A Q, and Q B parallel to A P.

Similarly in the plane in which A R and A Q lie complete the parallelogram A R C Q.

And in the plane in which A R and A P lie, complete the parallelogram A R D P.

Also complete the parallelograms Q C B S in the plane

QCB, and the parallelogram PBSD in the plane DPB.

We shall then have constructed a parallelopiped, three of whose adjacent edges meeting at A are AP, AQ, and AR.

Join AB, AS, and RS. AB will be the diagonal of the parallelogram APBQ, and AS the diagonal of the parallelogram ARSB.

Hence AB will represent the resultant of the forces represented by AP and AQ in magnitude and direction.

And AS the resultant of the forces represented by AR and AB.

Therefore AS represents the resultants of the forces represented by AR, AP, and AQ, in magnitude and direction.

By the aid of this proposition, any single force acting on a particle may be resolved into three other forces not acting in the same plane. When a force is so resolved, it is generally found convenient to resolve it into three forces acting at right angles or perpendicularly to one another.

PROPOSITION VII.

Condition of equilibrium when a material particle is acted on by any number of forces, whose directions are all in the same straight line.

The condition of equilibrium in this case must evidently be, that the sum of all the forces acting on the particle in one direction must be equal to the sum of all the forces acting in the opposite direction.

It is usual to consider the forces acting in one direction as positive, and those in the opposite as negative. The condition of equilibrium, then, may be thus stated: the algebraical sum of all the forces is zero, or nothing.

Thus, if A be acted on by the positive forces, 4 lbs., 3 lbs., and 5 lbs., in one direction, and the negative forces, 6 lbs, 5 lbs, and 1 lb., in the opposite,

The algebraical sum of these forces will be $4 + 3 + 5 - 6 - 5 - 1 = 12 - 12 = 0$; and A will be at rest under the influence of these forces.

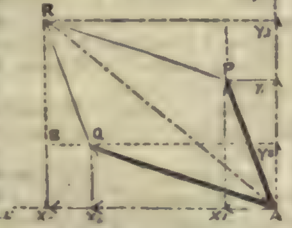
PROPOSITION VIII.

If two straight lines be drawn at right angles to one another through any point, and if two forces act on this point in any direction whatever in the same plane in which these lines are drawn, then the algebraical sum of the resolved parts of the two forces in the direction of each of the lines will be equal to the resolved part of their resultant in the same direction.

Let Ax and Ay (Fig. 29) be the straight lines drawn through the point A perpendicular to one another.

Lines so drawn are called *rectangular axes.*

Fig. 29.



Let two forces, P and Q, acting on A, be represented in magnitude and direction by AP and AQ.

Draw PR parallel to AQ, and QR to AP, meeting in R, and join AR.

Then, Prop. I., AR = R represents the resultant of P and Q in magnitude and direction.

Through the points P, Q, and R, draw PX_1, QX_2, and RX_3, perpendicular to Ax, and through the same points PY_1, QY_2, and RY_3, perpendicular to Ay.

By Prop. III., AX_1 and AY_1 will be the resolved parts of the force P in the directions Ax and Ay.

Similarly, AX_2 and AY_2 will be the resolved parts of Q; and AX_3 and AY_3 the resolved parts of R in the same directions.

Let $AX_1 = X_1$, $AX_2 = X_2$, $AX_3 = X_3$, $AY_1 = Y_1$, $AY_2 = Y_2$, and $AY_3 = Y_3$.

Produce the line Y_2Q to meet the line RX_3 in the point B.

Since APRQ is a parallelogram, AP = RQ; and also because BQ is parallel to Ax, and AP to RQ, the angle RQB = angle PAX.

But the angles RBQ and PX_1A are right angles by construction.

Hence, the triangles RQB and PAX_1 have the side AP = RQ, and the angles $PAX_1 = RQB$, and $PX_1A = RQB$.

Therefore, Euc., B. I., Prop. XXVI., $AX_1 = BQ$, and $PX = RB$.

And $X_1 + X_2 = AX_1 + AX_2 = BQ + AX_2 = X_3X_2 + AX_2 = AX_3 = X_3$, since $BQ = X_3X_2$, because by construction of figure BQX_2X_3 is a parallelogram.

And again $Y_1 + Y_2 = AY_1 + AY_2 = PX_1 + BX_3 = RB + BX_3 = RX_3 = AY_3 = Y_3$.

Since $AY_1 = PX_1$, $AY_2 = BX_3$, and $RX_3 = AY_3$, because AX_1PY_1, AX_3BY_2, and AX_3RY_3, are parallelograms by construction of figure.

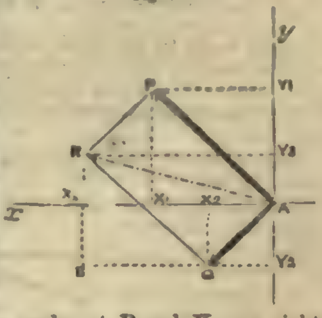
If, therefore, X_1Y_1 be the resolved parts of a force, P, along the rectangular axes, Ax and Ay, X_2Y_2 the resolved parts of Q, and X_3Y_3 the resolved parts of R, the resultant of P and Q in the direction of the same axes

$$X_3 = X_1 + X_2, \text{ and } Y_3 = Y_1 + Y_2.$$

The last figure has been so drawn that the forces P and Q both fall within the axes Ax and Ay; this is not always the case; it may sometimes happen, as in the following figure, that one of the axes may fall between the two forces; in this case it will be seen that the resolved part of the force Q, along the axis Ay, will fall on the opposite side of A, from the resolved forces of P and R along the same line.

The resolved forces which lie on one side of A are called positive, and those on the opposite side negative.

Fig. 30.



Consequently, the resolved parts of P (Fig. 30) will be X_1 and Y_1, of Q, X_2 and $-Y_2$, and of R, X_3 and Y_3. The same construction being made as in the last case, since APRQ is a parallelogram, AP = RQ, and since AX_1 is parallel to BQ, and AP to QR, the angle PAX_1 = angle RQB, also the angles at B and X_1 are right angles.

Hence, in triangles APX_1 and QBR (Euc., B. I., Prop. XXVI.), $RB = PX_1$, and $BQ = AX_1$.

$X_1 + X_2 = AX_1 + AX_2 = BQ + QY_2 = BY_2 = X_3A = X_3$.

$Y_1 - Y_2 = AY_1 - AY_2 = PX_1 - X_3B = RB - X_3B - RX_3 = AY_3 = Y_3$.

And in this case $X_3 = X_1 + X_2$, and $Y_3 = Y_1 - Y_2$.

A similar construction and demonstration will apply to every other position in which the rectangular axes may be placed with respect to the forces, and we may say, generally, that the algebraical sum of the resolved parts of any two forces acting upon a material point in the directions of any two rectangular axes, passing through that point, will be equal to the resolved parts of their resultant, along the same axes.

PROPOSITION IX.

To find the conditions of equilibrium of any number of forces acting upon a material point, the directions of the forces being all in the same plane, but not in the same straight line.

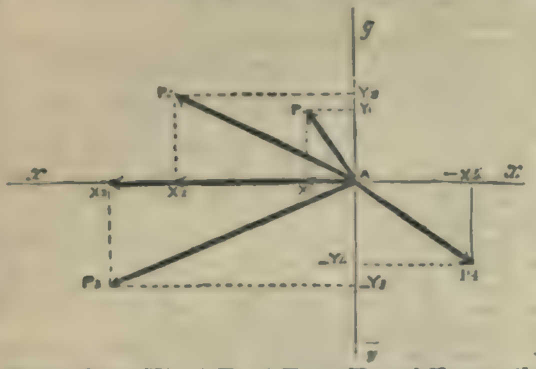
Let P_1, P_2, P_3, and P_4 (Fig. 31), be four forces acting upon A, represented in magnitude and direction by the lines AP_1, AP_2, AP_3, and AP_4.

Through A draw the rectangular axes Ax and Ay.

Through the points P_1, P_2, P_3, and P_4, draw P_1Y_1,

$P_2 Y_2$, $P_3 Y_3$, and $P_4 Y_4$, perpendicular to Ay, and $P_1 X_1$, $P_2 X_2$, $P_3 X_3$, and $P_4 X_4$, perpendicular to Ax.

Fig. 31.



Then, Prop. III., AX_1, AY_1, $= X_1$ and Y_1, are the resolved parts of P_1 in the direction of the axes Ax and Ay.

AX_2 and $AY_2 = X_2$ and Y_2 those of P_2, AX_3 and $-AY_3 = X_3$ and $-Y_3$ those of P_3 and $-AX_4$ and $-AY_4 - X_4$ and $-Y_4$ those of P_4 along the same axes.

Let R_1 be the resultant of the forces P_1 and P_2.

R_2 the resultant of the forces R_1 and P_2, or of P_1, P_2, and P_3.

And R_3 the resultant of the forces R_2 and P_3, or of P_1, P_2, P_3, and P_4.

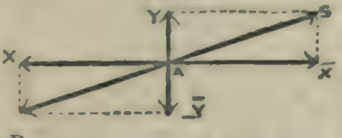
Then Prop. VIII., the resolved part of R_1 along the axis of $Ax = X_1 + X_2$, that of $R_2 = X_1 + X_2 + X_3$, and that of $R_3 = X_1 + X_2 + X_3 - X_4$.

Similarly the resolved part of R_1 along the axis $Ay = Y_1 + Y_2$, that of $R_2 = Y_1 + Y_2 + Y_3$, and that of $R_3 = Y_1 + Y_2 - Y_3 - Y_4$.

Let $X = X_1 + X_2 + X_3 - X_4$, the algebraical sum of the resolved parts of the four forces along the axis Ax, and $-Y = Y_1 + Y_2 - Y_3 - Y_4$, the algebraical sum of the resolved parts of these forces along the axis Ay.

Take $AX = X$ along the axis AX, and $A\bar{Y} = -Y$ along the axis AY.

Fig. 32.



Through X draw XR_3 (Fig. 32) perpendicular to AX, and through $-Y$, $-YR_3$ perpendicular to AY meeting in the point R_3. Join AR_3.

Then, Prop. III., AR_3 will represent the resultant of the forces P_1, P_2, P_3, and P_4, in magnitude and direction.

This single force AR_3, acting alone, will produce on A the same effect as the forces P_1, P_2, P_3, and P_4.

Produce AR_3 to AS, make $AS = AR_3$.

Then, Prop. VII., A force represented in magnitude and direction by AS will exactly counteract the effect of the force represented by AR_1.

Consequently, a force represented in magnitude and direction by AS, will keep the point A in equilibrium when acted on by the forces P_1, P_2, P_3, and P_4.

From S let fall SX perpendicular to AX, and SY perpendicular to AY.

Then, Prop. III., $A\bar{X}$ and AY are the resolved parts of AS along the rectangular axes. Now in the triangles AXR_3 and $AS\bar{X}$, the angle XAR_3 = angle $SA\bar{X}$, and the angles at X and X are right angles, and also $AR_3 = AS$.

Therefore $A\bar{X} = AX = X$, and $S\bar{X} = XR_3$.

$AXR_3\bar{Y}$ and $A\bar{X}SY$ are parallelograms.

Consequently, $S\bar{X} = AY$, and $XR_3 = A\bar{Y}$.

Therefore $AY = A\bar{Y} = -Y$.

The resolved parts of AS are therefore $-X$ and Y.

But $X = X_1 + X_2 + X_3 - X_4$, and $-Y = Y_1 + Y_2 - Y_3 - Y_4$.

Therefore $X_1 + X_2 + X_3 - X_4 - X = 0$, and $Y_1 + Y_2 - Y_3 - Y_4 + Y = 0$.

Or if five forces represented in magnitude and direction by AP_1, AP_2, AP_3, AP_4, and AS keep a point in equilibrium, the algebraical sum of the resolved parts of these forces along the rectangular axes passing through this point, will each be equal to zero.

The same demonstration may be applied to any number of forces. It may also be observed that the position of the rectangular axes is perfectly arbitrary, provided only that they are in the same plane in which the forces are supposed to act.

The conditions of equilibrium when all the forces are not in the same plane, involve the discussion of solid geometry. We shall reserve the consideration of this subject to a more advanced portion of the section.

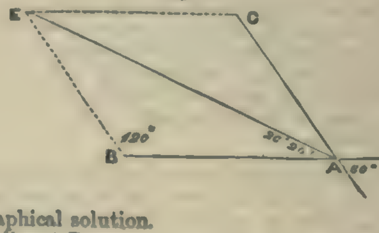
The student will observe that all the conditions of equilibrium, for a material point which we have considered, are geometrical deductions from the parallelogram of forces, and involve no new mechanical principles; and that the parallelogram of forces depends upon one mechanical principle, that of the transmission of a force from any one point to another rigidly connected with it, and in the direction of its action, without altering its effect.

We subjoin two or three examples, to show the method of applying the principles we have determined. Mechanical problems may be solved in two ways—graphically, *i. e.*, by accurately drawing the geometrial figures by mathematical instruments and scales, and obtaining a result, which can be measured by these instruments; or trigonometrically, *i.e.*, by computing the relations of the figures according to the principles of trigonometry, and thus arriving by means of trigonometrical tables at a more accurate result than the former will afford.

We would recommend the student to use both of these methods, as he will by this means obtain a clearer view of the subject than by accustoming himself only to one of them.

PROBLEM I.—*Two forces, represented by 12lbs. and 15lbs., are inclined to each other at an angle of 60°; required the magnitude of the resultant; and its inclination to the greater.*

Fig. 33.



1st, Graphical solution.

Draw a line AB.

Make AB equal to 15 parts of any convenient scale, as the 8th or the 10th of an inch.

Draw AC inclined to AB at an angle of 60°.

Take AC equal to 12 parts of the same scale, that AB is equal to 15 parts.

Through C draw CE parallel to AB, and through B, BE parallel to AC, meeting in the point E.

Join AE.

Then, Prop. I., AE will represent the resultant of the forces represented by AC and AB in magnitude and direction; and if AE be measured by the scale used in drawing AB and AC, it will be found to be $23\frac{4}{10}$ parts of that scale, and the angle EAB will measure very nearly 26° 20′.

The resulting force will therefore be represented by $23\frac{4}{10}$ lbs., and its inclination to the greater force will be 26° 20′ nearly.

The process might have been shortened by the use of Prop. IV., in which case we should have drawn AB = 15 parts of the scale, BE making an angle 180° − 60° or 120° with AB, and BE = 12 parts of the scale, and lastly joined A and E.

2nd. Trigonometrical solution.

$$
\begin{aligned}
AE^2 &= AB^2 + BE^2 - 2\,AB\cdot BE\ \cos.\ 120^\circ.\\
&= AB^2 + BE^2 + 2\,AB\cdot BE\ \cos.\ 60^\circ.\\
&= 12^2 + 15^2 + 2 \times 12 \times 15 \times \cdot 5.\\
&= 144 + 225 + 180 = 549.
\end{aligned}
$$

Hence, $AE = \sqrt{549} = 23\cdot 43$.

Again, $\frac{\sin.\ EAB}{\sin.\ EBA} = \frac{EB}{EA}$, or $\frac{\sin.\ EAB}{\sin.\ 120^\circ} = \frac{12}{23\cdot 43}$.

Hence, $\sin.\ EAB = \frac{12}{23\cdot 43}\sin.\ 120^\circ = \frac{12}{23\cdot 43}\sin.\ 60^\circ$.

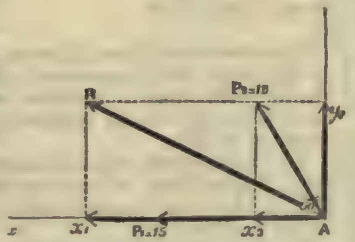
And Log. sin. E A B = Log. 12 + Log. sin. 60° — Log. 23·43.

$$
\begin{aligned}
&= 1\cdot 0791812 + 9\cdot 9375306 - 1\cdot 3697723\\
&= 9\cdot 6469395.\\
&= \text{Log. sin. } 26^\circ\ 20'\ \text{nearly.}
\end{aligned}
$$

Angle E A B = 26° 20′.

When the resultant of more than two forces is to be found, it will be more convenient to resolve the forces as in Prop. IX. We shall therefore work out the above example by that method.

Fig. 34.



Draw two straight lines, A x and A y at right angles to each other (Fig. 34).

Take $AP_1 = 15 =$ force P_1 along A x.

Draw $AP_2 = 12 =$ force P_2, making an angle 60° with AP_1.

Through P_2 draw $P_2\,y_2$ perpendicular to Ay, and $P_2\,x_2$ perpendicular to Ax.

Then Ax_2 Ay_2 are the resolved parts of P_2 along Ax and Ay; AP_1 is the resolved part of P_1 along the axis Ax, and its resolved part along Ay is zero.

Produce AP_1 to x', and make $P_1\,x' = Ax_2$.

Then $Ax' = AP_1 + Ax_2$ is the resolved part of the resultant of P_1 and P_2 along Ax and Ay_2 is the resolved part along Ay.

Through x' draw x' R perpendicular to Ax, and produce $y_2\,P_2$ to meet x' R in R. Join A R.

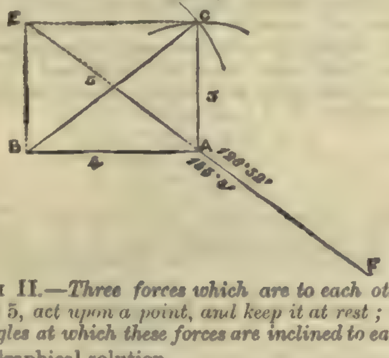
Then A R represents the resultant of P_1 and P_2 in magnitude and direction, $Ay_2 = AP_2 \cos.\ 60^\circ = 12 \times \cdot 5 = 6$, and $Ay_2 = P_2\,X_2 = AP_2 \sin.\ 60^\circ = 12 \times \cdot 866 = 10\cdot 392$.

But $AR^2 = Ay_2{}^2 + Ry_2{}^2 = Ay_2{}^2 + Ax_1{}^2 = (10\cdot 392)^2 + (15+6)^2 = (10\cdot 392)^2 + (21)^2. = 107\cdot 993664 + 441 = 548.993664$.

Therefore $AR = \sqrt{548.993664} = 23\cdot 430$.

Again, $\cos.\ RAx^1 = \frac{Ax^1}{AR} = \frac{21}{23\cdot 43} = \cdot 89628 = \cos.\ 26^\circ\ 20'$ nearly. And therefore angle R A x' = 26° 20′. And this is the inclination of the resultant to the greater force.

Fig. 35.



Problem II.—*Three forces which are to each other as 3, 4, and 5, act upon a point, and keep it at rest; required the angles at which these forces are inclined to each other.*

1st. Graphical solution.

Draw a line A B = 4 parts of some scale, with A as a centre and radius A C = 3 parts of this scale, describe an arc.

Also, with B as centre, and radius B C = 5 parts of the scale, describe another arc.

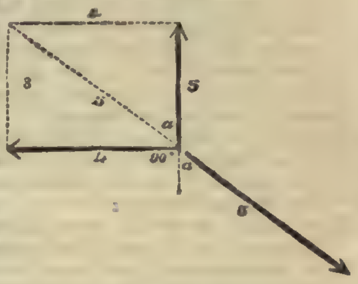
Let C be the point where the two arcs intersect.

Join A C and B C. Through C draw C E parallel to A B and through B, B E parallel to A C, meeting in E. Join A E and produce A E to F, making A F = A E. Then the forces which are to each other as 3, 4 and 5, acting upon the point A, and keeping it at rest, will be represented in magnitude and direction by the lines A C, A B, and A F; and the angles being measured by a protractor, or any other means used for measuring angles, it will be found that the angle B A C = 90°, the angle B A F = 143° 8′, and the angle C A F = 126° 52′, nearly.

2nd. Trigonometrical solution.

Since $3^2 + 4^2 = 9 + 16 = 25 = 5^2$.

Fig. 36.



The forces represented by 3 and 4 must be at right angles to each other, and their resultant 5, will be the diagonal of the rectangular parallelogram whose sides are as 3 and 4.

Let a be the angle between the resultant and the force represented by 3.

Then $\tan.\ a = \frac{4}{3} = 1\cdot 33333 = \tan.\ 53^\circ\ 8'$, nearly.

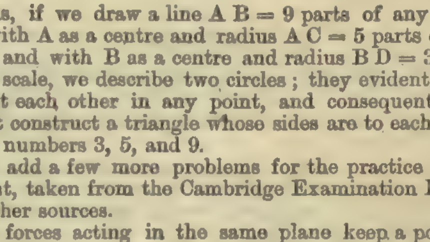
Hence, by a reference to the diagram it will be readily seen that the angle between the forces 3 and 5 is $180^\circ - a = 180^\circ - 53^\circ\ 8' = 126^\circ\ 52'$, while that between the forces 4 and 5 is $90^\circ + a = 90^\circ + 53^\circ\ 8' = 143^\circ\ 8'$.

Problem III.—*Three forces represented by the numbers 3, 5, and 9, cannot under circumstances produce equilibrium on a point.*

This is evidently true, since by Prop. IV., three forces can only produce equilibrium on a point, when a triangle can be described whose sides are respectively proportional to the magnitudes of the forces. Now, the sides of a triangle never can bear to each other the proportion of the numbers 3, 5, and 9, since in every triangle the sum of any two sides must always be greater than the third, and 3 + 5 = 8, a number less than 9.

If we attempt to solve the problem graphically, we shall soon perceive its impossibility.

Fig. 37.



Thus, if we draw a line A B = 9 parts of any scale, and with A as a centre and radius A C = 5 parts of the scale, and with B as a centre and radius B D = 3 parts of the scale, we describe two circles; they evidently will not cut each other in any point, and consequently we cannot construct a triangle whose sides are to each other as the numbers 3, 5, and 9.

We add a few more problems for the practice of the student, taken from the Cambridge Examination Papers and other sources.

Three forces acting in the same plane keep a point at rest; the angles between the directions of the forces are 135°, 120°, and 105°; compare their magnitudes.

Four forces represented by 1, 2, 3 and 4, act in the same plane on a point. The directions of the first and third are at right angles to each other; and so are the directions of the second and fourth; and the second is inclined at an angle of 60° to the first. Find the magnitude and direction of the resultant.

A circular hoop is supported in a horizontal position, and three weights of 4, 5 and 6 lbs. respectively are suspended over its circumference by three strings knotted together at the centre of the hoop. Neglecting the friction of the edge of the hoop, find the angles between the strings when there is an equilibrium.

Three equal forces, each equivalent to 6 lbs., act on a point; the first two are inclined to each other at an angle of 7[illegible]°, and the third is inclined at an angle of 15° to the first. Find the magnitude and direction of the resultant.

The resultant of two forces is 50 lbs., and the angles which it makes with their directions is 20° and 30°; find the component forces.

A boat, fastened to a fixed point by a rope, is acted on at the same time by the wind and the current. Suppose that the wind was S.E., the direction of the current S., and the direction of the boat from the fixed point S. 20° W., and also that the pressure on the point was 150 lbs., it is required to find the forces of the wind and the current.

In pulling a weight along the ground by a rope, inclined to the horizon, at an angle of 45°, a power of 40 lbs. was exerted; required the force with which the body was dragged horizontally.

Four forces are in the same plane, which are to each other as 6, 8, 10, and 12, act upon a given point, and are inclined to a given line at the angles 20°, 40°, 80°, and 150° respectively; find the magnitude and direction of a fifth force which shall balance the others.

EQUILIBRIUM OF A RIGID BODY.—Having considered the conditions of equilibrium of a material particle acted on by any number of forces acting in the same plane, we next proceed to consider the conditions of equilibrium of a rigid body under the same circumstances. Here it may be as well to repeat what has been stated before, that by the term *rigid body*, we understand a body composed of material particles held together by unknown molecular forces of such intensity that the body cannot be altered in shape, or its particles in any way displaced by any forces which can act upon it. This rigid body also possesses the property, that if any force be applied to it, its particles will transmit that force, unimpaired in intensity, to any point in the body, which lies in the line of direction in which the force is acting; consequently, the effect of a force on a rigid body will be the same, if we transfer its point of application from any one point in the rigid body to any other, provided these two points are in the line in which the force is supposed to act.

Unless it is otherwise stated, this *hypothetical rigid body* is also considered as being destitute of weight.

If two or more forces acting on a rigid body are applied to the same point of the body, the conditions of equilibrium will be the same as those for a material point under the same circumstances, for the same force which, when applied to the material point, would counteract the effect of these forces, would also keep the body in equilibrium, when applied to the point in the body upon which the forces act.

PROPOSITION X.

To find the magnitude and direction of the resultant of two forces acting on different points of a rigid body, the directions of the forces being in the same plane, but not parallel to each other.

Let a force P (Fig. 38), represented in magnitude and direction by the line A P, act upon the point A of a rigid body, and another force Q, represented by B Q, act upon the point B of the same body. B Q and A P both being the same plane.

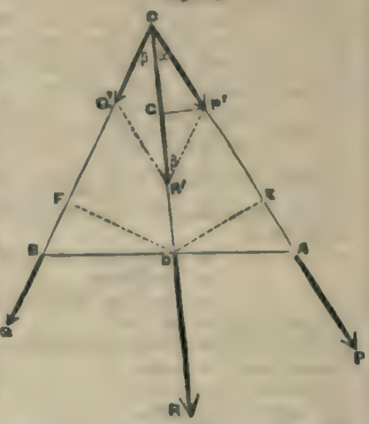
Join A B. Produce P A and Q B to meet in the point C.

Along C B take C Q′ = B Q, and along C A, C P′ = A P.

Draw Q′ R′ parallel to C P′, and P′ R′ parallel to C Q′, meeting in R′.

Join C R′, and produce C R′ to R, cutting A B in D.

Fig. 38.



Make D R = C R′. Then D R will represent the resultant of the forces P and Q in magnitude and direction.

By the principle of the transmission of forces, the points A B and C are supposed to be rigidly connected with each other.

The point of application of the force P may be transferred from A to C, and the force Q from B to C.

Then the forces P and Q acting at C may be replaced by the single force represented in magnitude and direction by C R′, Prop. I., and this force may be transferred from C to D, and be represented in magnitude and direction by D R.

This construction will enable us to represent, graphically, the resultant of any two forces acting on a rigid body in the same plane, but in directions not parallel to one another.

For the purpose of calculation, it will be convenient, however, to determine the geometrical relation of the point D to the forces P and Q, and their directions.

Through D draw D E (Fig. 38), perpendicular to C A, and D F perpendicular to C B; also through P′ draw P′ G perpendicular to C D.

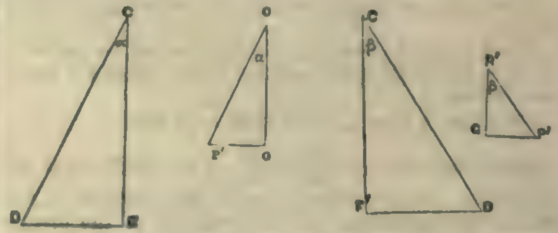
Let α represent the angle A C D, and β the angle B C D.

Then since by construction P′ R′ is parallel to C Q′, therefore (Euc., B. I., Prop. XXVII.), angle C R′ P′ = angle Q′ C R′ = β.

The angles at E, F, and G, are right angles by construction.

Hence the figure will afford us two pairs of similar triangles. (See Fig. 39).

Fig. 39.



Since in the triangles C D E, C G P′ the angles D C E and P′ C G are both = α, and those at E and G′ are right angles (as will probably be more readily perceived in the above figures than in the more complicated figure), it follows that the triangles C D E and C P′ G are equiangular triangles and similar to one another, and therefore (Euc., B. VI., Prop. IV.),

$$CD : DE :: CP' : GP'$$

$$\text{or, } \frac{CD}{DE} = \frac{CP'}{GP'}$$

Similarly, since the angles F C D and G R′ P′ are both equal to β, and the angles at F and G right angles, the triangles C F D and R′ G P′ are similar triangles, and

$$DF : CD :: GP' : P'R'$$

$$\text{or, } \frac{DF}{CD} = \frac{GP'}{P'R'}$$

Multiplying equals together, we have

$$\frac{CD}{DE} \cdot \frac{DF}{CD} = \frac{CP'}{GP'} \cdot \frac{GP'}{P'R'}$$

$$\text{and therefore } \frac{DF}{DE} = \frac{CP'}{P'R'}$$

But C P′ R′ Q′ (Fig. 38) is a parallelogram, and therefore P′ R′ = C Q′.

$$\text{Hence } \frac{DF}{DE} = \frac{CP'}{CQ'} = \frac{P}{Q}.$$

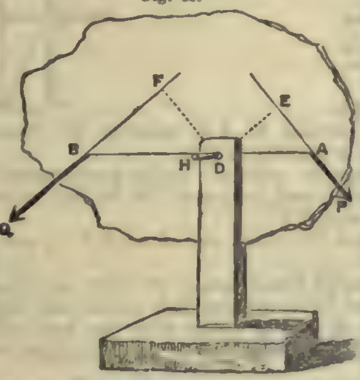
or, The perpendicular

$$\frac{\text{from the point D on the direction of the force Q}}{\text{from the point D on the direction of the force P}} = \frac{P}{Q}$$

Consequently, the perpendicular from the point D on the direction of the force Q multiplied by Q, equals the perpendicular from the point D on the direction of the force P multiplied by P.

MOMENT OF FORCES AND FULCRUM.—If we suppose an axis, H D (Fig. 40), passing through the plane in which the forces act, fixed with perfect rigidity, and perpendicular to that plane at the point D, and then placed on a stand, as in the accompanying figure, so as to allow the plane to move with perfect freedom about the axis H D, then, since the resultant of the forces P and Q acting at A and B passes through the point D, their joint effect will be counteracted by the reaction of the stand on the axis H D. Neglecting the weight of the plane and the friction of the axis, the plane will be in a state of equilibrium, under the influence of the two forces P and Q, acting at A and B in the directions A P and B Q, together with the reaction of the stand acting on the plane at the point D in a direction opposite to the resultant of the forces P and Q. If the rigid body be reduced to the rigid line A B, A B is called a lever, and the point D its fulcrum.

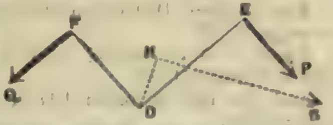
Fig. 40.



Since the conditions of equilibrium, or that the resultant of the forces B and Q should pass through D, are as above stated, that,

The perpendicular from D *on the direction of the force* Q *multiplied by* Q, *equals the perpendicular from* D *on the direction of the force* P, *multiplied by* P; it follows that the force P may be replaced by a force S without altering these conditions, provided that the perpendicular from D, D K on the direction K S of the force S multiplied by S, be equal to the perpendicular from D on the direction of the force P multiplied by P (Fig. 40).

Fig. 41.



The writers on Mechanics have applied the term moment or momentum to this product of the linear units in the length of the perpendicular from a given point on the direction of a force, by the units of force in the given force.

Thus, if the forces P, Q and S be represented in magnitude and direction by E P, F Q, and S K, and D E, D F and D K be the perpendiculars on those directions, P E × D E, Q F × D F, and S K × D K will be the respective moments or moments of the forces P Q and S, about the point D.

These products are not only termed the moments of the forces with respect to the point D, but also the moments of the forces with respect to axis H D, perpendicular to the plane in which they act.

The student must be careful not to confound these *statical moments, or momenta,* with the momenta of dynamics; the momentum of dynamics being the product of the mass of a body by its velocity.

If the force P alone were to act on the plane at the point A, it would evidently twist the plane about the fixed axis H D, and Q acting alone at B, would twist the plane about H D in a direction opposite to that in which P would do so. The tendency of P therefore to twist the plane about the axis H D, or point D, is counteracted by the tendency of Q to twist the plane in the opposite direction, in the case where equilibrium exists.

We have seen, however, that the tendency of Q to twist the body about the axis H D, will be counteracted by any other force whose statical moment, with respect to H D or D, is equal that of the force P.

Hence we may consider the statical moment of a force about a given point or axis, as a measure of its tendency to twist the plane to which it is applied, about that point or axis.

POSITIVE AND NEGATIVE MOMENTS.—The moments of those forces whose tendency is to twist a body about the axis or fulcrum, in the direction in which the hands of a watch move, are termed positive; those whose tendency is in the opposite direction, are called negative.

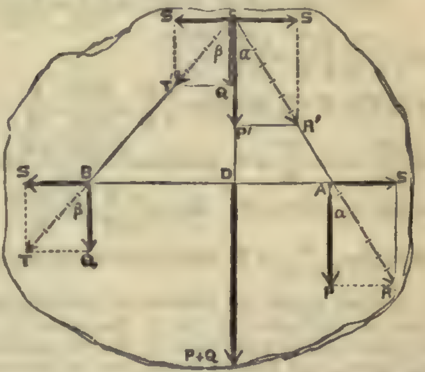
It will readily be seen, that if the directions of the forces P and Q in Proposition X. had been parallel to one another, the demonstration there used could not be applied; as, in that case, the directions of the forces could not be produced till they met.

PROPOSITION XI.

To find the magnitude and direction of the resultant of two forces acting on different points of a rigid body, the directions of the forces being in the same plane, but parallel to each other.

Let P and Q (Fig. 42) be the two forces, A and B the two points in the plane.

Fig. 42.



The force P being represented in magnitude and direction by the line A P, and Q by the line B Q.

Then A P and B Q are parallel to each other.

Join A B.

The conditions of equilibrium will not be altered if any arbitrary force S be applied to A in the direction A S, and to B in the opposite direction B S.

Let these equal and opposite forces be represented in magnitude and direction by A S and B S.

Consequently A S = B S.

Complete the parallelogram S B Q T and the parallelogram S A P R.

Join A R and B T.

Then A R = R represents the resultant of the forces P and S in magnitude and direction, and may be substituted for these forces.

Also B T = T represents the resultant of Q and S in magnitude and direction, and may be substituted for them.

Produce A R and B T to meet in the point C.

Through C draw C D parallel to A P or B Q, meeting A B in D.

The force R acting at A in direction A R may be transferred from R to C in the line R A C, and represented in magnitude and direction by C R′, C R′ being = A R.

Similarly T may be transferred from B to C, and represented in magnitude and direction by C T′, C T′ being equal to B T.

Through C draw the line S C S parallel to A B.

Also through T′ draw T′ Q′ parallel to B A, meeting C D in Q′, and T′ S parallel to D C, meeting S C in S.

Similarly through R′ draw R′ P′ parallel to A B, meeting C D in P′, and R′ S parallel to D C, meeting S C in S.

The parallelogram S C Q′ T′ is similar and equal in all respects to the parallelogram S B Q T, and the parallelogram C P′ R′ S to the parallelogram A P R S.

Hence, Prop. III., the force R acting at C, in the direction C R′, may be replaced by the forces S and P, represented in magnitude and direction by C S and C P′; also the force T acting at C in direction C T′, may be replaced by the forces S and Q′ acting in the directions C S and C Q′.

The equal and opposite forces S and S, acting in the line S C S, will destroy each other.

And the parallel forces P and Q acting at A and B are replaced by the forces P and Q acting at C in the direction C D, and these forces again may be transferred from C to D.

Hence the resultant of the forces P and Q acting at A and B, will be a force P + Q acting at D in a direction parallel to the directions of P and Q.

To determine the position of the point D.

Since P′ R′ is parallel to A D, the triangles C P′ R′, C D A are equiangular, and therefore, Euc., B. VI., P. 4—

$$CD : AD :: CP' : R'P', \text{ or } \frac{CD}{AD} = \frac{CP'}{R'P'}$$

Similarly because Q′ T′ is parallel to D B, the triangles C T′ Q′, C B D are equiangular, and

$$BD : CD :: T'Q' : CQ', \text{ or } \frac{BD}{CD} = \frac{T'Q'}{CQ'}$$

$$\text{Hence } \frac{CD}{AD} \cdot \frac{BD}{CD} = \frac{CP'}{R'P'} \cdot \frac{T'Q'}{CQ'}$$

$$\text{But } R'P' = T'Q', \text{ therefore } \frac{BD}{AD} = \frac{CP'}{CQ'} = \frac{P}{Q}$$

$$\text{And } \frac{BD}{AD} + 1 = \frac{P}{Q} + 1, \text{ therefore } \frac{BD + AD}{AD} = \frac{P + Q}{Q}$$

$$\text{But } BD + AD = AB. \quad \text{Hence } \frac{AB}{AD} = \frac{P + Q}{Q}$$

$$\text{And } AD = \frac{Q}{P + Q} AB, \text{ which determines the point D.}$$

Or, in other words, the distance of the fulcrum from the point of application of one of the forces P, is equal to the other force Q multiplied by the distance between the two forces, and divided by the sum of the two forces.

When A B is perpendicular to A P or B Q, we have, since—

$$\frac{BD}{AD} = \frac{P}{Q}$$

$$Q \times BD = P \times AD;$$

but in this case Q × B D is the moment of Q with respect to D, and P × A D the moment of P with respect to D. Hence in this case, as in the last proposition, the moments of P and Q with respect to D, are equal to each other.

In the case we have just considered, we supposed the two forces P and Q to be acting in the same direction; when they act in the opposite directions, our construction will be modified as represented by the accompanying diagram. (Fig. 43).

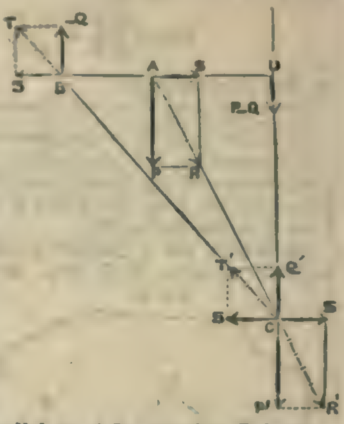
To A and B, as before, apply two equal and opposite forces represented in magnitude and direction by A S and B S.

Complete the parallelograms A P R S and B Q T S.

Join B T and A R, and produce them till they meet at C.

Through C draw C D parallel to A P or B Q, meeting B A produced in D.

Fig. 43.



The resultant of the forces S and Q acting at B will be represented in magnitude and direction by B T, and this force may be transferred from B to C, and represented by C T′ = B T.

The resultant of the forces P and S acting at A will also be represented by A R, and this may be transferred from A to C, and represented by C R′ = A R.

Through C draw S C S parallel to B A, through T′, T′ Q′ parallel to A B, T′ S parallel to D C, and through R′, R′ P′ parallel to A B, meeting D C produced in P′, and R′ S parallel to D C.

The force C T′ may be replaced by the forces represented by C Q′ and C S, and the force C R′ by the forces represented by C S and C P′.

But C S = B S, and C S = A S, and A S = B S by construction.

Hence the two equal forces acting on C in opposite directions in the line S C S destroy each other, and the forces P acting at A, and Q acting at B, are replaced by the two forces C Q′ and C P′ acting on C in opposite directions.

But C Q′ = B Q = Q, and C P′ = A P = P.

Hence these two forces may be represented by a single force P − Q acting at C in the direction C P′, and this force may be transferred from C to D in the line C D.

The resultant of the two parallel forces, P and Q, acting in opposite directions at the points A and B, will be a force P − Q acting at D in B A produced.

To determine the position of the point D.

Since A P is parallel to D C, the angle A R S = angle A C D, and the angles at C and D are common to the two triangles A R S, A C D.

Therefore the triangles A R S, A C D are equiangular and similar.

$$\text{And } AS : SR :: AD : DC, \text{ or } \frac{AS}{SR} = \frac{AD}{DC}$$

Also because B Q is parallel to C D, the angle T B Q = angle B C D.

Again, T Q is parallel to B D, therefore the angle Q T B = angle D B C.

And the two triangles T Q B, B D C are equiangular and similar.

$$\text{And } BQ : QT :: DC : BD, \text{ or } \frac{BQ}{QT} = \frac{DC}{BD}.$$

Multiplying the equal fractions together, we have

$$\frac{AS}{SR} \cdot \frac{BQ}{QT} = \frac{AD}{DC} \cdot \frac{DC}{BD}.$$

$$\text{But } QT = BS = AS, \text{ and } SR = AP$$

$$\text{Hence } \frac{BQ}{AP} = \frac{AD}{BD}, \text{ or } \frac{Q}{P} = \frac{AD}{BD}.$$

$$\text{Now } BD = AB + AD, \text{ therefore } \frac{Q}{P} = \frac{AD}{AB + AD}.$$

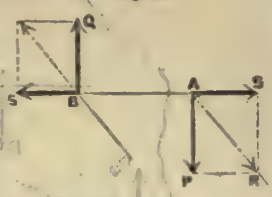
And Q. A B + Q. A D = P. A D, or Q. A B = (P − Q) A D.

$$\text{Therefore } AD = \frac{Q.\,AB}{P - Q}.$$

This result might have been obtained from the previous case by substituting − Q for Q, which would give P − Q for the resultant, but the expression for A D would be $-\frac{Q.\,AB}{P - Q}$, the negative sign signifying that the point D in this case would lie on a different side of A from what it would when the force Q was positive, or when both forces acted in the same direction.

In the last case, that is, when P and Q act in opposite directions, if P and Q are equal, we cannot represent their resultant by any single force.

Fig. 44.



For if we pursue the mode of construction adopted before, we shall find the line B T (Fig. 44), in this case parallel to the line A R; and consequently these lines, if produced, will never meet.

This admits of an easy proof, because B Q is parallel and equal to A P, and B S and A S are equal to each other, and are in the same line.

Therefore the parallelogram A P R S is similar and equal to the parallelogram B Q T S, and the angle P A R = the angle T B Q.

Also because A P is parallel to B Q, the angle P A B = angle Q B A.

And by addition, angle P A R + angle P A B = angle T B Q + angle Q B A.

Or the angle R A B = the angle T B A.

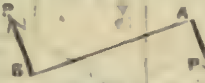
And, by Euc., B. I., P. XXVII., R A must be parallel to T B.

Our method in this case fails to discover a point D anywhere in the line A B produced, to which a single resultant can be applied.

This is indicated by the formulæ which we have already obtained of P − Q for the magnitude of the resultant, and $\frac{Q.\ AB}{P-Q}$ for A D, the distance of its point of application from A, since when Q = P, they give us P − P or 0 for the magnitude of the resultant, and $\frac{P.\ AB}{P-P}$ or $\frac{P\ \ AB}{0}$ the algebraical sign of infinity for A D; a result which shows that our problem in this case is impossible.

COUPLE.—When two equal and opposite parallel forces act at different points of a rigid body in the same plane, their effect, as we have seen, cannot be counteracted by any single force applied to the body, and their tendency will evidently be to twist the body in the direction of the plane in which they act. Thus P (Fig. 45) acting on A in the direction A P, and P acting on B in the direction B P will twist the body round in the direction B A P or A B P.

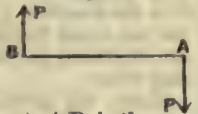
Fig. 45.



The term couple is applied to such a system of forces.

ARM OF A COUPLE.—The perpendicular distance between the directions in which the forces producing a couple act, is called the arm of that couple. Thus if the line A B (Fig. 46) is perpendicular to A P and B P, which represent the directions in which the forces producing a couple act, A B is the arm of that couple.

Fig. 46.



MOMENT OF A COUPLE.—The product of the arm of a couple and one of the forces producing it, is called the moment of that couple.

Thus if P be the force acting in the direction A P or B P, then P × A B is the *moment* of the couple produced by the couple whose *arm* is A B.

This moment is a measure of the tendency of the couple to twist the body on which it acts, and it is customary to indicate a couple by its moment.

EQUILIBRIUM OF A COUPLE.—Though no single force can be found which can counteract the effect of a couple on a rigid body, yet a couple may be found to neutralise the influence of another. Thus if a force Q (Fig. 47—1), equal and opposite to the force P represented by A Q be applied to A in the direction A Q of the line P A produced, and a similar and equal force at B in the line B P produced to Q, then the force Q at A being equal and opposite to that of P at A, but in the same straight line, will neutralise it.

Fig. 47—(1).

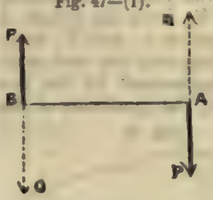


Fig. 47—(2).

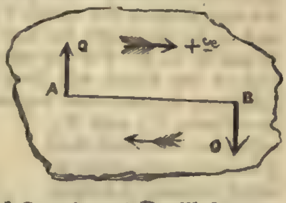
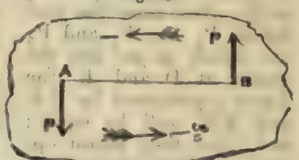


Similarly, the forces P and Q acting at B will destroy each other, and the body will be in a state of equilibrium under the influence of two couples whose moments are P × A B and Q × A B, but which tend to twist the body in opposite directions. (Fig. 47—2).

A couple whose tendency is to twist the body in the direction in which the hands of a watch move is called a positive couple, such as Q × A B in the accompanying diagram (Fig. 47—2), while the couple which would cause the body to move in the opposite direction, such as P × A B, is called a negative couple. (Fig. 48).

Fig. 48.



It is also convenient to designate a couple by its moments; thus, when we speak of the couple P × A B, we mean the couple whose moment is P × A B, A B representing its arm, and P one of the equal forces acting at its extremity.

It is more convenient generally to represent the product of P and A B, by the symbol P · A B instead of P × A B.

AXIS OF A COUPLE.—The *axis* of a couple is a straight line, which is supposed to be drawn perpendicular to its plane, and proportional in length to its *moment.*

Thus, if the arm of a couple be 4 inches in length, and the forces acting at its extremities be both 5 pounds, and the arm of another couple be 6 inches, and the forces at its extremities be both 8 pounds, the *moments* of these couples will be represented by the numbers 20 and 48; and a line 20 inches in length, perpendicular to the plane of the first, and another of 48 inches, perpendicular to that of the second, will represent their respective axes.

PROPOSITION XII.

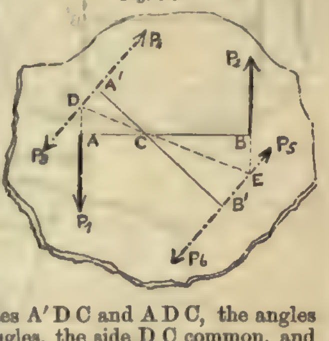
The arm of a couple may be turned round any point in that arm, in the plane of the couple, without altering the conditions of equilibrium.

Let A B represent the arm of the couple, P_1 and P_2, the forces acting at A and B. (Fig. 49).

In A B take any point C, turn A B round C into the new position A′ C B′.

Now at the points A′ and B′ we may apply equal and opposite forces, P_3, P_4, P_5, and P_6, perpendicular to the line A B′, and each equal to the force P_1 or P_2, without disturbing the conditions of equilibrium of the body on which the couple P·A B is supposed to act.

Fig. 49.



Produce the line A P_1 to meet A′P_3 in the point D, and P_2B to meet B′P_5 in E. Join C D and C E.

Because in the triangles A′ D C and A D C, the angles at A and A′ are right angles, the side D C common, and A′ C = A C.

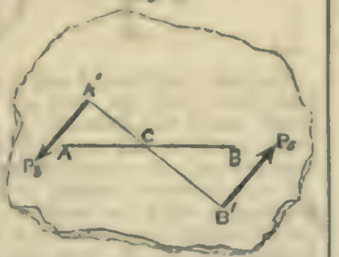
Therefore A′ D = A D, and the angles at D and C are bisected by C D.

Similarly, it may be shown that the angles at C and E are bisected by C E.

Hence C D and C E are both in the same straight line.

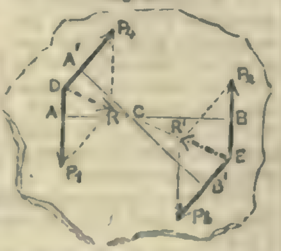
Since any force may be transferred from its point of application to any other point in the line of its action, we may remove the forces P_1 and P_4 from the points A and A′ to the point D, and the forces P_2 and P_6 from B and B′ to E. For the sake of clearness, the new position of the forces will then be represented by the two following figures—one representing the positions of the two forces P_3 and P_5, which have not had their points of application altered, forming a couple, and acting at the extremities of the arm A′ B′ (Fig. 50); and the other, the positions of the forces whose points of application have been changed. (Fig. 51).

Fig. 50.



Now, completing the parallelograms P_1 D P_4 R and E P_2 R′ P_6; D R and E R′ their diagonals will represent the resultants of the forces P_1 and P_3 acting at D, and P_2 and P_6 acting at E. And since the four forces P_1 P_4, P_2 and P_6 are equal, as are also the angles at D and E, the forces represented by D R and E R′ will be equal; and since they attain opposite directions in the same straight line D C E, they will counteract each other.

Fig. 51.



Hence on the whole we have replaced the couple P · A B by the couple P · A′ B′, without altering the conditions of equilibrium.

PROPOSITION XIII.

The effect of a couple will not be altered if its arm be removed to any position parallel to itself, either in its own plane or else in one parallel to it.

Firstly, let the arm A B of the couple P · A B be removed to the new position A′ B′ (Fig. 52—1), A′ B′ being parallel and equal to A B and in the same plane.

The conditions of equilibrium will not be altered if we apply to A′ two forces P_3 and P_4, acting in opposite directions perpendicularly to A′ B′, and both equal to P_1 or P_2.

Similarly we may apply at B′ the forces P_5 and P_6, each equal to the former, and perpendicular to A′ B′.

Fig. 52—(1).

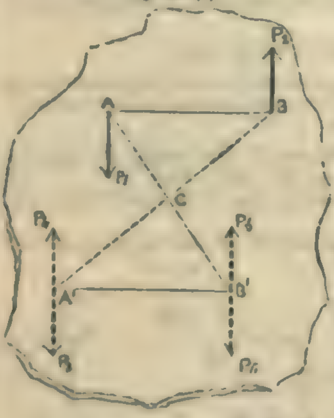


Fig. 52—(2).

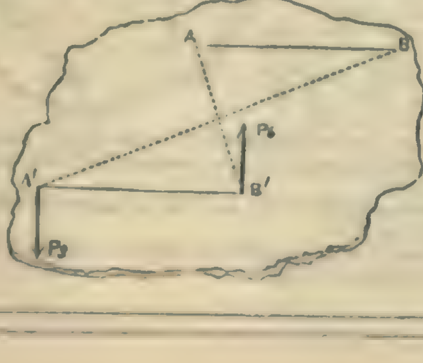
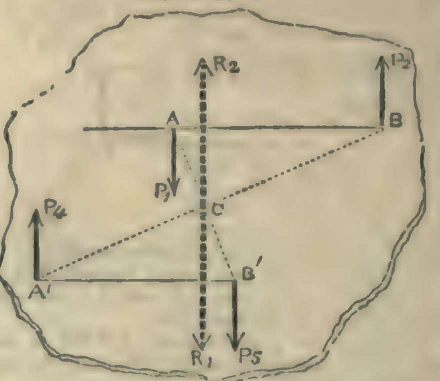


Join A′ B, A B′ meeting in C. Then since A B is parallel and equal to A′ B′, we have in the triangles A B C, A′ B′ C, the angles at A and B equal to the angles at B′ and A′, and also A B = A′ B′. Hence A C = B′ C and B C = A′ C.

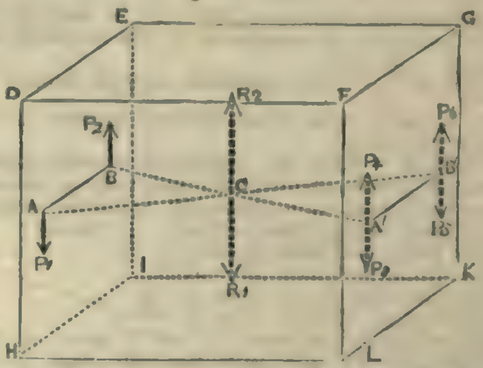
Fig. 52—(3).



Now for the sake of clearness we may suppose the six forces represented above divided into two groups, as in Nos. 2 and 3, one (2) consisting of the arm A′ B′ acted on by the equal and opposite forces P_3 and P_6, forming a couple P · A′ B′; and the other (3) of the four equal and parallel forces; P_1 and P_5 acting at A and B′ in one direction, and P_4 and P_2 at A′ and B in the opposite direction.

Now by Prop. XI., since A C = B′ C and $P_1 = P_5$, P_1 and P_5 acting at A and B′ will be equivalent to a single force C R_1 = 2 P acting at C in the direction C R_1 parallel to A P_1 or B′ P_5. Similarly P_4 and P_2 acting at A′ and B will be equivalent to C R_2 = 2 P acting at C in the direction C R_2 parallel to A′ P_4 or B P_2. But the two equal forces C R_1 and C R_2 acting on C in opposite directions in the same straight line will counteract each other.

Fig. 52—(4).



Hence the group of forces P_1, P_2, P_4, and P_5 will neutralise each other, and we shall only have the effect of the couple P · A′ B′ left, as represented in the other group (4).

On the whole, therefore, we have replaced P · A B by the couple P · A′ B′, the arm A′ B′ being parallel and equal to the arm A B and in the same plane with it.

Secondly, let the arm A B be removed to the position A′ B′ parallel to A B, in a plane parallel to the plane of the couple P · A B (4).

Let D E H I represent the plane of the couple P · A B F G K L a plane parallel to D E H I, the plane to which the arm A B is supposed to be removed.

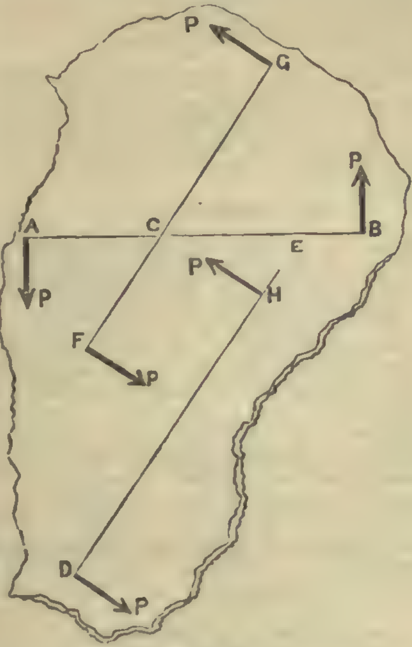
For the sake of clearness we may consider these planes as opposite faces of the parallelopiped D E F G H I K L.

Then A′ B′, the new position of the arm, will be drawn in the plane F G K L, parallel and equal to A B in the plane D E I H.

Join A B′, B A′ meeting in C, and apply, as in the preceding case, equal and opposite forces P_3, P_4, P_5, P_6

at A′ and B′, each equal and parallel to P_1 or P_2. Then Euc., B. XI., Prop. II., the triangles A B C, A′ B′ C are in the same plane, and as in the preceding case A C = B′ C′ and A′ C = B C. (Fig. 52—5).

Fig. 52—(5).



The parallel forces P_1 and P_5 acting at A and B′ are equivalent to C R_1 = 2 P acting at C parallel to P_1 or P_5; and the parallel forces P_2 and P_4 acting at B and A′ are equivalent to C R_2 = 2 P acting at C parallel to P_2 or P_4. The forces C R_1 and C R_2 neutralise each other, leaving, as in the previous case, the forces P_3 and P_6 acting at A′ and B′ as a couple P·A′ B′.

Combining the two last proportions, we see that the arm of a couple may be transferred from any position in its own plane, to any other position in that plane, or to any plane parallel to it.

Thus, if we wish to transfer the couple P· A B (5) to the position, in which one extremity of its arm shall correspond to the point D, and the arm itself be in the direction D E, all we have to do is to take any point C in A B, and through C draw F G parallel to D E. Then by Prop. XII., P · A B may be transferred to the position P · F G, and from that, by Prop. XIII., to the position P · D H. F G and D H being both equal to A B.

PROPOSITION XIV.

Couples acting in the same plane or in planes parallel to each other, will be equal if their moments be equal.

Let P· A B (Fig. 53—1) be a positive couple, and Q · D E (2) a negative one, either acting in the same plane with P · A B or else in one parallel to it. P being greater than Q, and D E greater than A B.

Then the couple Q · D E can be transferred so as to have its arm in such a position that one extremity D shall coincide with A (1), and its arm be the same line as A B. This is represented in (3), A F being equal to D E. Now, the opposite forces P and Q acting at A, are equivalent to a single force P—Q acting at A in the direction A P, as shown in (4).

Hence the effect of the two opposite couples P · A B and Q · D E on the rigid body, on which they are supposed to act, will be equivalent to the three parallel forces P—Q, P and Q acting at the points A, B and F in the same straight line A B F.

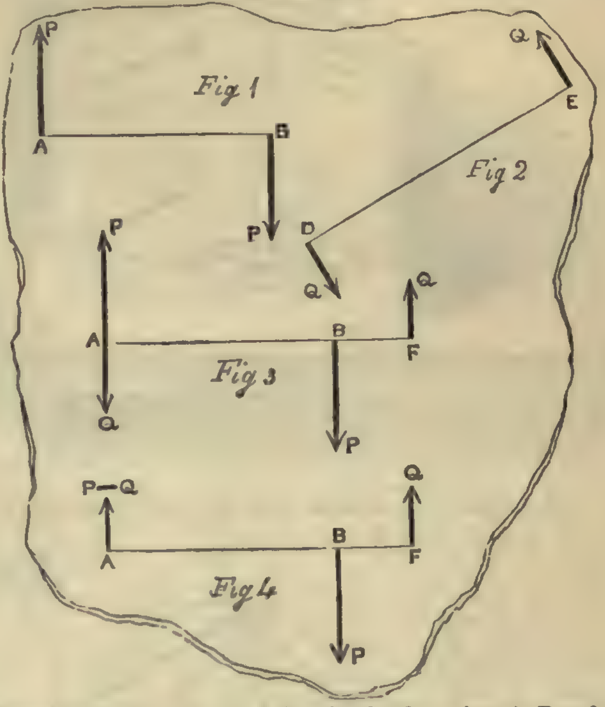
Now, if these couples P·A B and Q·D E, are such as to neutralise each other or produce equilibrium, the equilibrium will not be disturbed by the alteration we have made in the position of their arms. Hence, the parallel forces P — Q, P and Q acting in the points A, B and F in the line A B F, must in this case produce equilibrium, and by Prop. XI. we shall have

$$(P - Q)\ A B = Q \cdot B F$$

$$\text{or } P \cdot A B = Q \cdot A B + Q \cdot B F = Q\ (A B + B F)$$
$$= Q \cdot A\ F = Q \cdot D\ E\ ;$$

which shows that the moments of the two couples are equal. But a negative couple P A B would counteract the positive couple P·A B if their arms were in the same position.

Fig. 53.



Hence, two negative couples will be equivalent to each other, if their moments be equal, provided only that they act in the same plane or in planes which are parallel to each other.

The same reasoning will apply to positive couples.

PROPOSITION XV.

To find the resultant couple of two couples, which do not act in the same plane on a rigid body.

For the sake of clearness, we shall suppose the planes in which the two couples act, represented by the open pages of a book E F·G H K L, standing upon a table (Fig. 54—1), and inclined to each other at an angle θ. E H will be the intersection of the two pages or planes, which are both supposed to be perpendicular to the surface plane of the table.

Let P·A B be the couple acting in the plane L E H K, Q·C D that acting in the plane E F G H.

By the previous proposition the couple P·A B may be replaced by the couple P′· E H acting in the same plane L E H K, provided P′· E H = P·A B,

$$\text{or, } P' = P \cdot \frac{A B}{E H}$$

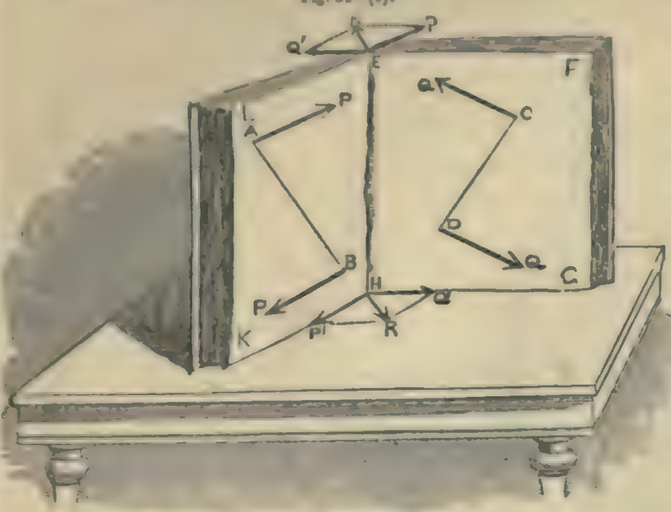
$$\text{In H K take H } P' = P \cdot \frac{A B.}{E H}$$

Produce L E to P′ and make E P′ = H P′.

Then P′ E H P′ will represent in magnitude and direction the couple P′· E H, which replaces P·A B

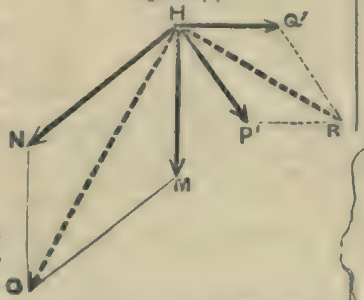
In a similar manner Q′ E H Q′ will represent in magnitude and direction the couple $Q' \cdot E \cdot H$, which will replace $Q \cdot DC$ provided $Q'H$ or $Q' = Q \cdot \frac{CD}{EH}$.

Fig. 54—(1).



Completing the parallelogram P′ H Q′ R on the plane of the table, and joining H R, H R its diagonal will represent a force R in magnitude and direction, which will replace the forces P′ and Q′.

Fig. 54—(2).



Since the plane of the table is at right angles to the planes E F G H, and L E H K, and consequently Euc., B. XI., Prop. XIX., to their intersection E H. Therefore H R in the plane of the table will be at right angles to E H.

Similarly, P′ and Q′ acting at E will be replaced by a force R, represented by E R acting at right angles to E H.

Hence, on the whole, we have replaced the couples P·A B and Q·C D, by a single couple R·E H, whose arm lies in the intersection of the planes in which the couples P·A B and Q·C D act.

Let us now suppose the parallelogram H Q′ R P′, which we have previously drawn on the plane of the table, to be drawn as in (2), on the plane of the paper.

Draw H M perpendicular to H Q′, H O perpendicular to H R, and H N perpendicular to H P′.

Then if θ = angle Q H P′, M H N will = θ, the angle M H O will = Q′ H R, and N H O = P′ H R.

Take H M = Q′·H E, H O = R·H E, and H N = P′·H E. Join M O and N O.

Then H M, H O, and H N will be the axes of the couples Q′. H E, R·H E, and P′·H E.

Because H P′ R Q′ is a parallelogram; therefore, the angle H P′ R = 180° $-\theta$ and by Trigonometry,

$$HR^2 = HP'^2 + P'R^2 - 2\,HP' \cdot P'R \cos.\ HP'R = HP'^2 + P'R^2 + 2\,HP' \cdot P'R \cdot \cos\theta$$

or $R^2 = P'^2 + Q'^2 + 2\,P' \cdot Q' \cdot \cos.\ \theta$

Multiplying both sides of the above equation by HE^2, we have

$$R^2\,HE^2 = P^2 \cdot HE^2 + Q^2 \cdot HE^2 + 2 \cdot P \cdot HE \cdot Q \cdot HE \cos.\ \theta$$

but H M = Q·H E, H O = R·H E, and H N = P′ H E by construction.

Hence, substituting these values in the equation, we have

$$HO^2 = HN^2 + HM^2 + 2\,HN \cdot HM \cdot \cos.\ \theta = HN^2 + HM^2 - 2\,HN \cdot HM \cos.\ NHM.$$

This is an equation identically the same as that we should arrive at if we suppose H M O N a parallelogram whose diagonal is H O.

Hence, if two sides of a parallelogram represent the axes of two component couples, its diagonal represents the axes of the resultant couple.

Similarly it may be shown that if the three edges of a parallelopiped represent the axes of three component couples, the diagonal of the parallelopiped will give the magnitude and direction of the axis of the resultant couple.

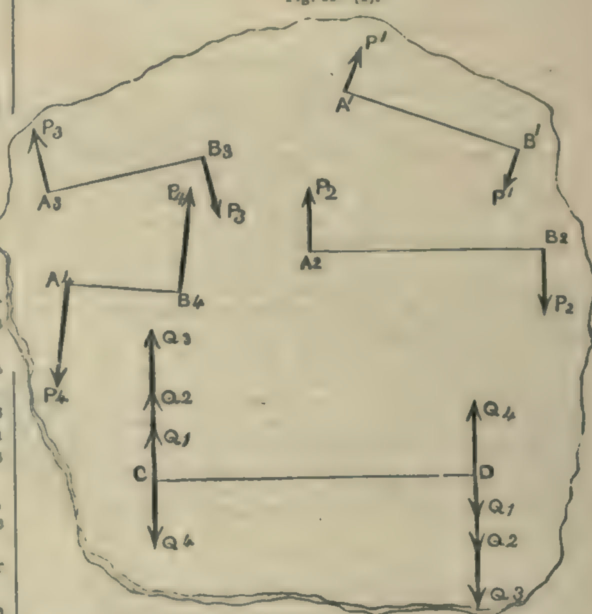
PROPOSITION XVI.

When any number of couples act in the same, or in parallel planes; the moment of the resultant couple is the algebraical sum of the moments of the component couples.

Let $P_1 \cdot A_1 B_1$, $P_2 \cdot A_2 B_2$, $P_3 \cdot A_3 B_3$ be three positive, and $P_4 \cdot A_4 B_4$ a negative couple acting in the same plane (Fig. 55—1).

Draw any arbitrary line C D, and apply at opposite extremities of it, two equal and opposite forces Q_1, such that $Q_1 \cdot CD = P_1 \cdot A_1 B_1$ or $Q_1 = P_1 \cdot \frac{A_1 B_1}{CD}$. Then Prop. XIV., the couple $P_1 \cdot A_1 B_1$ may be replaced by the couple $Q_1 \cdot CD$.

Fig. 55—(1).



Similarly apply at C and D two additional equal and opposite forces Q_2 such that $Q_2 = P_2 \cdot \frac{A_2 B^2}{CD}$

The couple $P_2 \cdot A_2 B_2$ may be replaced by the couple $Q_2 \cdot CD$.

Also the couple $P_3 \cdot A_3 B_3$ may be replaced by the couple $Q_3 \cdot CD$, provided $Q_3 = P_3 \cdot \frac{A_3 B_2}{CD}$

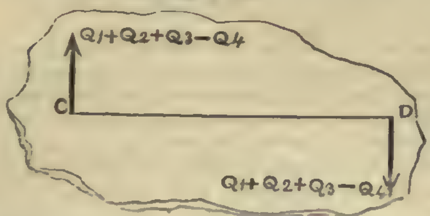
If one of the couples as $P_4 \cdot A_4 B_4$ act in the opposite direction to the others, it will be replaced by the couple $Q_4 \cdot CD$, where $Q_4 = P_4 \cdot \frac{A_4 B_4}{CD}$

The force Q_4 acting in the opposite direction to the forces Q_1, Q_2 and Q_3.

Hence, on the whole, we have replaced the four couples $P_1 \cdot A_1 B_1$, $P_2 \cdot A_2 B_2$, $P_3 \cdot A_3 B_3$, $P_4 \cdot A_4 B_4$, acting in any direction on a rigid body in the same plane by four couples, acting at the extremities of the same arm.

This is evidently equal to a single couple whose arm is C D, with equal and opposite forces $Q_1 + Q_2 + Q_3 - Q_4$ acting at each extremity. (Fig. 55—2).

Fig. 55—(2).



Hence we have
$(Q_1 + Q_2 + Q_3 - Q_4) \cdot C\,D = Q_1 \cdot C\,D + Q_2 \cdot C\,D + Q_3 \cdot C\,D - Q_4 \cdot C\,D$
$= P_1 \cdot A_1\,B_1 + P_2 \cdot A_2\,B_2 + P_3 \cdot A_3\,B_3 - P_4 \cdot A_4\,B_4$, or the resultant couple is the algebraical sum of the moments of the component couples.

The same reasoning may be extended from four to any number of couples, and, by Prop. XIII., to couples acting in parallel planes.

THEORY OF COUPLES.—The propositions from 12 to 16 contain the fundamental principles of what has been called the *theory of couples.* For this beautiful theory, which was introduced into the science of Mechanics about forty years since, we are indebted to the distinguished mathematician, M. Poinsot. After we have extended our 11th proposition from two to any number of parallel forces, we shall again return to the theory of couples, and determine, by its aid, the conditions of equilibrium for any number of forces acting on a rigid body.

PROPOSITION XVII.

To find the magnitude and direction of the resultant of any number of parallel forces acting on a rigid body in the same plane.

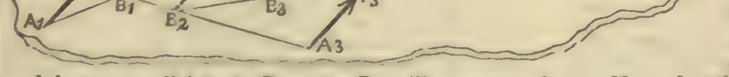
Let four parallel forces, P_1, P_2, P_3, and P_4 (Fig. 56), acting in the same plane on the points A_1, A_2, A_3, and A_4, be represented in magnitude and direction by $A_1\,P_1$, $A_2\,P_2$, $A_3\,P_3$, and $A_4\,P_4$.

Join $A_1\,A_2$; then by Prop. XI., $B_1\,Q_1 = P_1 + P_2$ applied at a point B_1 in $A_1\,A_2$ such that

$$A_1\,B_1 = \frac{P_2}{P_1 + P_2} A_1\,A_2$$

and drawn parallel to $A_1\,P_1$ or $A_2\,P_2$ will represent Q_1 the resultant of the parallel forces P_1 and P_2 in magnitude and direction.

Fig. 56.



Then join $B_1\,A_3$, in $B_1\,A_3$ take a point B_2 such that

$$B_1\,B_2 = \frac{P_3}{Q_1 + P_3} . B_1\,A_3 = \frac{P_3}{P_1 + P_2 + P_3} B_1\,A_3$$

Through B_2 draw $B_2\,Q_2$ parallel to $A_3\,P_3$ and $= P_1 + P_2 + P_3$.

$B_2\,Q_2$ will represent Q_2 the resultant of P_3 and Q_1, or of P_3, P_2, and P_1 in magnitude and direction.

Again, join $B_2\,A_4$ in $B_2\,A_4$, take a point B_3 such that

$$B_2\,B_3 = \frac{P_4}{Q_2 + P_4} B^2\,A_4 = \frac{P_4}{P_1 + P_2 + P_3 + P_4} B_2 A_4$$

Through B_3 draw $P_3\,Q_3 = Q_2 + P_4 = P_1 + P_2 + P_3 + P_4$ parallel to $A_4\,P_4$.

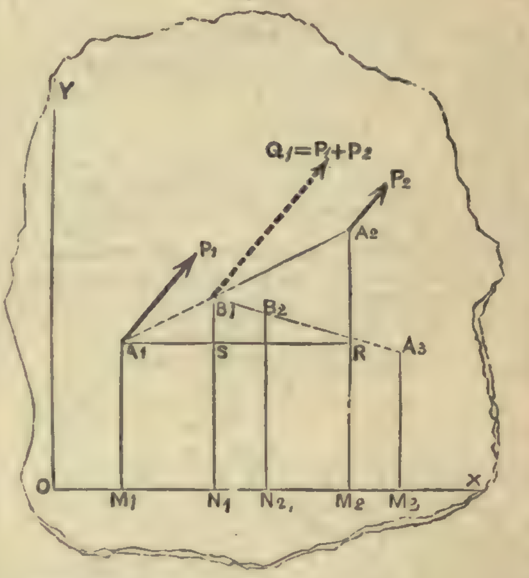
Then $B_3\,Q_3$ will represent Q_3 the resultant of the forces Q_2 and P_4, or of the four parallel forces P_1, P_2, P_3, and P_4 in magnitude and direction.

The same reasoning may be extended to any number of parallel forces.

It is sometimes far more convenient to refer these various points, A_1, A_2, A_3, A_4, B_1, B_2, B_3, &c., to two fixed arbitrary lines or axes drawn at right angles to each other, as in Props. VIII. and IX.

Let O X and O Y (Fig. 57), drawn through the point O at right angles to each other, be chosen as arbitrary *rectangular axes,* to which the points A_1, A_2, &c., B_1, B_2, &c., are to be referred.

Fig. 57.



Through A_1, B_1, and A_2 draw $A_1\,M_1$, $B_1\,N_1$, and $A_2\,M_2$ perpendicular to O X.

Then the lines $O\,M_1$ and $M_1\,A_1$, which determine the position of the point A_1 with respect to the axes O X and O Y, are called the *rectangular co-ordinates of the point* A_1.

Similarly, $O\,N_1$ and $N_1\,B_1$ are the *rectangular co-ordinates* of B_1; and $O\,M_2$ and $M_2\,A_2$ are those of the point A_2.

Let $O\,M_1$ be represented by the symbol x_1, $O\,M_2$ by x_2, $A_1\,M_1$ by y_1, and $A_2\,M_2$ by y_2.

Through A_1 draw $A_1\,R$ parallel to O X, cutting $B_1 N_1$ in S and $A_2\,M_2$ in R.

Then from the construction of the figure, it is evident that the angles at S, R, M_1, N_1 and M_2 are right angles; consequently $A_1\,S = M_1\,N_1$, $A_1\,R = M_1\,M_2$, and also $A_1\,M_1$, $S\,N_1$, and $R\,M_2$ are equal to each other.

Now, by the previous part of the proposition, the point B_1, was so taken in $A_1\,A_2$ that

$$A_1\,B_1 = \frac{P_2}{P_1 + P_2} A_1\,A_2, \text{ or } \frac{A_1\,B_1}{A_1\,A_2} = \frac{P_2}{P_1 + P_2}$$

Again, because $A_2\,R$ is parallel to $B_1\,S$, therefore Euc., B. VI., P. II.

$$\frac{A_1\,B_1}{A_1\,A_2} = \frac{A_1\,S}{A_1\,R} = \frac{B_1\,S}{A_2\,R}.$$

$$\text{But } \frac{A_1\,S}{A_1\,R} = \frac{M_1\,N_1}{M_1\,M_2} = \frac{O\,N_1 - O\,M_1}{O\,M_2 - O\,M_1} = \frac{O\,N_1 - x_1}{x_2 - x_1}$$

Hence since $\frac{A_1 S}{A_1 R} = \frac{A_1 B_1}{A_1 A_2} = \frac{P_2}{P_1 + P_2}$,

we have $\frac{O N_1 - x_1}{x_2 - x_1} = \frac{P_2}{P_1 + P_2}$.

Or $(O N_1 - x_1)(P_1 + P_2) = P_2 x_2 - P_2 x_1$.
And $O N_1 (P_1 + P_2) - P_1 x_1 - P_2 x_1 = P_2 x_2 - P_2 x_1$.
Hence $O N_1 (P_1 + P_2) = P_1 x_1 + P_2 x_2$.

And $O N_1 = \frac{P_1 x_1 + P_2 x_2}{P_1 + P_2}$.

Again, $\frac{B_1 S}{A_2 R} = \frac{B_1 N_1 - S N_1}{A_2 M_2 - R M_2} = \frac{B_1 N_1 - A_1 M_1}{A_2 M_2 - A_1 M_1}$
$= \frac{B_1 N_1 - y_1}{y_2 - y_1}$.

But $\frac{B_1 S}{A_1 R} = \frac{A_1 B_1}{A_1 A_2} = \frac{P_2}{P_1 + P_2}$.

Hence $\frac{B_1 N_1 - y_1}{y_2 - y_1} = \frac{P_2}{P_1 + P_2}$.

And $(B_1 N_1 - y_1)(P_1 + P_2) = P_2 y_2 - P_2 y_1$.
Or $B_1 N (P_1 + P_2) - P_1 y_1 - P_2 y_1 = P_2 y_2$ $P_2 y_1$.

And $B_1 N_1 = \frac{P_1 y_1 + P_2 y_2}{P_1 + P_2}$.

If, now, from B_2 and A_3 we draw $B_2 N_2$ and $A_3 M_3$ perpendicular to O X, and represent $O M_3$ by x_3 and $A_3 M_3$ by y_3.

Then, by a similar construction and demonstration to that used for the points A_1, B_1 and B_2, we can show that

$\frac{B_1 B_2}{B_1 A_3} = \frac{B_1 N_1 - B_2 N_2}{B_1 N_1 - A_3 M_3} = \frac{B_1 N_1 - B_2 N_2}{B_1 N_1 - y_3}$.

But it has been shown that $\frac{B_1 B_2}{B_1 A_3} = \frac{P_3}{P_1 + P_2 + P_3}$

Hence $\frac{P_3}{P_1 + P_2 + P_3} = \frac{B_1 N_1 - B_2 N_2}{B_1 N_1 - y_3}$.

Or $P_3 \cdot B_1 N_1 - P_3 y_3 = B_1 N_1 (P_1 + P_2) + P_3 \cdot B_1 N_1 - B_2 N_2 (P_1 + P_2 + P_3)$.

But $B_1 N_1 = \frac{P_1 y_1 + P_2 y_2}{P_1 + P_2}$, or $B_1 N_1 (P_1 + P_2) = P_1 y_1 + P_2 y_2$, and substituting this value in the above equation, and transposing, we have $B_2 N_2 (P_1 + P_2 + P_3) = P_1 y_1 + P_2 y_2 + P_3 y_3$.

Or $B_2 N_2 = \frac{P_1 y_1 + P_2 y_2 + P_3 y_3}{P_1 + P_2 + P_3}$.

In a similar manner it may be shown that

$$O N_2 = \frac{P_1 x_1 + P_2 x_2 + P_3 x_3}{P_1 + P_2 + P_3}.$$

If, now, perpendiculars $B_3 N_3$ and $A_4 M_4$ are supposed to be drawn from B_3 and A_4 to O X,

And $O M_4 = x_4$, and $M_4 A_4 = y_4$, we shall have by the carrying out the same method of demonstration

$$B_3 N_3 = \frac{P_1 y_1 + P_2 y_2 + P_3 y_3 + P_4 y_4}{P_1 + P_2 + P_3 + P_4}.$$

$$\text{And } O N_3 = \frac{P_1 x_1 + P_2 x_2 + P_3 x_3 + P_4 x_4}{P_1 + P_2 + P_3 + P_4}.$$

We might proceed from the case of four forces to five, from five to six, and so on; so that, assuming the symbols $\bar{x}$ and $\bar{y}$ to represent the rectangular co-ordinates of the point of application of the resultant of n parallel forces P_1, P_2, P_3, &c., P_n referred to the arbitrary axes O X and O Y; we shall have

$$\bar{x} = \frac{P_1 x_1 + P_2 x_2 + P_3 x_3 + \&c., + P_n x_n}{P_1 + P_2 + P_3 + \&c., + P_n}.$$

$$\text{And } \bar{y} = \frac{P_1 y_1 + P_2 y_2 + P_3 y_3 + \&c., + P_n y_n}{P_1 + P_2 + P_3 + \&c., + P_n}.$$

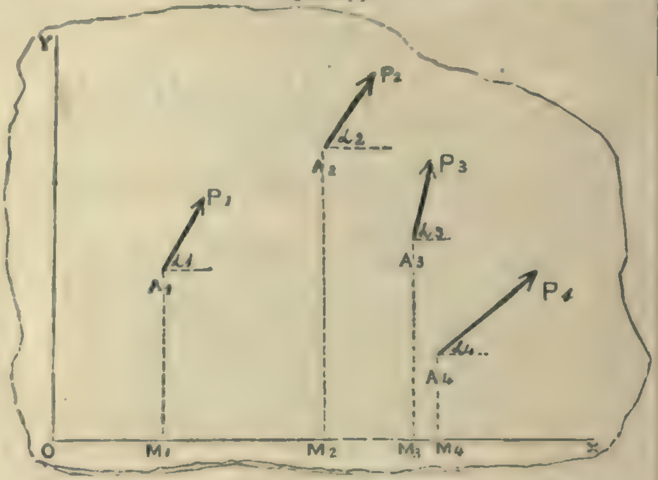
If any of the forces act in an opposite direction to the others, they must be taken with the negative sign; the co-ordinates of the various points of application of the forces must also be taken with the proper signs, determined by their position with regard to the axes.

PROPOSITION XVIII.

To find the magnitude and direction of the resultant force and resultant couple of any number of forces acting on a rigid body in the same plane, and the conditions under which there will be equilibrium.

Let P_1, P_2, P_3, and P_4 (Fig. 58—1), be four forces represented in magnitude and direction by $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_4 P_4$; acting on a rigid body in the same plane. A_1, A_2, A_3, and A_4, being the points of application of these forces to the rigid body. In the plane in which the forces act, take any two straight lines O X, O Y, at right angles to each other as rectangular axes.

Fig. 58—(1).



Let $O M_1 = x_1$, $A_1 M_1 = y_1$, be the rectangular co-ordinates of A_1, referred to the axes O X and O Y.

$O M_2 = x_2$, $A_2 M_2 = y_2$, those of A_2; $O M_3 = x_3$, $A_3 M_3 = y_3$ those of A_3; and $O M_4 = x_4$, $A_4 M_4 = y_4$, those of A_4.

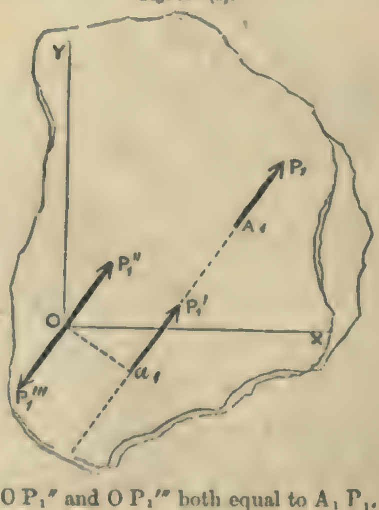
Also let a_1, a_2, a_3, and a_4 be the angles that $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_4 P_4$, make with lines drawn through A_1, A_2, A_3, and A_4 parallel to O X.

For the sake of clearness we will first confine our attention to the force P_1, acting at the point A_1.

Through O (2) draw $O a_1$ at right angles to $P_1 A_1$ produced.

Also through O draw $P_1'' P_1'''$ parallel to $A_1 P_1$.

Fig. 58—(2).



Make $O P_1''$ and $O P_1'''$ both equal to $A_1 P_1$.

Then without disturbing the equilibrium of the body, we may introduce two equal and opposite forces P_1, represented in magnitude and direction by $O P_1''$ and $O P_1'''$, acting at O, and also transfer the point of application of P_1 from A_1 to a_1.

Hence, on the whole, the effect of the force P_1 acting at A_1, is equivalent to a force P_1 acting at O in the direction $O P_1''$ parallel to $A_1 P_1$, and two equal and opposite forces represented in magnitude and direction by $O P_1'''$, $a_1 P_1'$ acting at right angles to $O a_1$ and forming a couple $P_1\ O a_1$, or a couple whose moment is P_1 multiplied by the perpendicular from O on the line $A_1 P_1$ produced.

In a similar manner the force P_2 (1) acting at A_2 may be replaced by a force P_2 acting at O, parallel in direction to $A_2 P_2$ and a couple whose moment is P_2 multiplied by the perpendicular from O on $A_2 P_2$ produced.

The force P_3 acting at A_3 (1), may be replaced by a force P_3 acting at O parallel to $A_3 P_3$, and a couple whose moment is P_3 multiplied by the perpendicular from O on $A_3 P_3$ produced.

And, lastly, P_4 acting at A_4 (1) may be replaced by a force P_4 acting at O parallel to $A_4 P_4$, and a couple whose moment is P_4 multiplied by the perpendicular from O on $A_4 P_4$ produced.

On the whole, therefore, the forces P_1, P_2, P_3, and P_4 acting at the points A_1, A_2, A_3, and A_4, may be replaced by forces P_1, P_2, P_3, and P_4, all acting at O in directions parallel to $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_4 P_4$, whose resultant will be a single force whose magnitude and direction may be found by Prop. II.; and four couples whose arms will have a common extremity O, and whose moments will be equal to P^1, P_2, P_3, and P_4, each respectively multiplied by the perpendicular from O on the original direction of the force; or on $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_4 P_4$ produced.

By Prop. XVI., these four couples will be equivalent to a single couple, whose moment is equal to the algebraical sum of their moments.

The single resultant force acting at O shows the tendency of the four forces P_1, P_2, P_3, and P_4, acting at O to move O in some rectilinear direction, while the resultant couple gives their tendency to twist the body in some direction round the point O.

In order, therefore, that the rigid body should be in equilibrium, when acted on by these forces, these resultants must each be equal to nothing, since if the resultant force alone were equal to nothing, the resultant couple would twist the body round O, as a fixed point; or if the moment of the resultant couple alone were equal to nothing, the body would move so as to keep O in a straight line.

Hence the *conditions of equilibrium* of four forces P_1, P_2, P_3, and P_4, acting on a rigid body in the same plane at the points A_1, A_2, A_3, and A_4 in the directions $P_1 A_1$, $P_2 A_2$, $P_3 A_3$, and $P_4 A_4$ are two.

First.—The resultant of four forces, respectively equal to P_1, P_2, P_3, and P_4, acting on any point O of the body, in directions respectively parallel to $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_4 P_4$, must be equal to zero.

Second.—The algebraical sum of the moments of the four couples, whose arms are the perpendiculars drawn from O on $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_4 P_4$ produced, and whose forces are respectively equal to P_1, P_2, P_3, and P_4, must likewise be equal to zero.

This latter condition is technically called taking the moments about the point O.

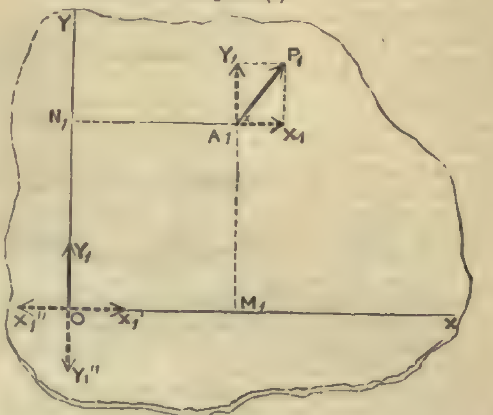
The reasoning above used for four forces may readily be extended to any number; it must also be observed that the position of the point O is perfectly arbitrary in the solution of problems. It is generally so chosen as to facilitate the solution, and to avoid unnecessary labour.

Instead of pursuing the preceding method, it is frequently advisable to resolve each of the forces P_1, P_2, P_3, and P_4 into two, acting in directions parallel to the arbitrary axes O X and O Y (1), as in Props. VIII. and XI.

Confining, as before, our attention first to the force P_1, acting at A_1 in the direction $A_1 P_1$.

Through A_1 (3) draw $A_1 X_1$ and $A_1 Y_1$ parallel to O X and O Y respectively; and through P_1, $P_1 X_1$, and $P_1 Y_1$ perpendicular to $A_1 X_1$, and $A_1 Y_1$. Again through A_1 draw $A_1 N_1$ perpendicular to O Y, and $A_1 M_1$ perpendicular to O X.

Fig. 58—(3).

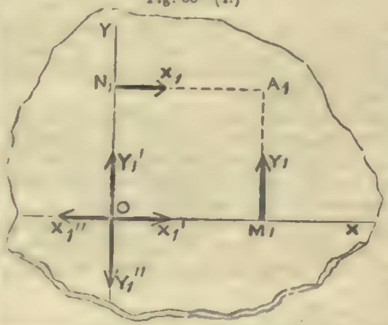


The force P_1 acting at A_1 may be replaced by two forces X_1 and Y_1 at right angles to each other, represented in magnitude and direction by $A_1 X_1$ and $A_1 Y_1$ (Prop. III.)

Without disturbing the conditions of equilibrium, two equal and opposite forces represented in magnitude and direction by $O X_1'$ and $O X_1''$, each equal to $A_1 X_1$, may be applied to O in the direction O X.

And two equal and opposite forces $O Y_1'$, $O Y_1''$, each equal to $A_1 Y_1$ may be applied to O in the direction O Y.

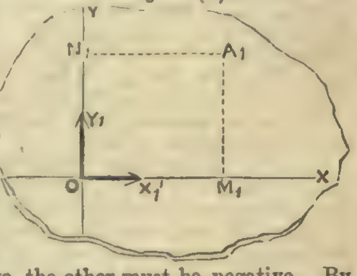
Fig. 58—(4.)



Also (4) the force X_1 may be transferred from A_1 to N_1, and the force Y_1 from A_1 to M_1.

The forces now acting on the body as in (4), may be divided into two groups, one as in (5), consisting of the forces X_1 and Y_1 acting at O, and represented in magnitude and direction by $O X_1'$ and $O Y_1'$; and the other as in (6), of the couples whose moments are X_1 multiplied by $O N_1$, and Y_1 multiplied by $O M_1$.

Fig. 58—(5.)



The tendency of the couple $X_1 \cdot O N_1$ is evidently to twist the body in the opposite direction to that in which the couple $Y_1 \cdot O N_1$ has a tendency to twist it. Hence, if one be considered positive, the other must be negative. By construction $A_1 M_1 = y_1$, and $A_1 N_1 = M_1 O = x_1$.

Hence the resultant moment of these two couples, Prop. XVI., will be

$$Y_1 \cdot x_1 - X_1 \cdot y_1.$$

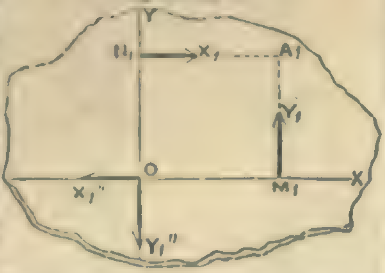
On the whole, therefore, we have replaced the force P_1 acting at A_1 by the forces X_1 and Y_1 acting on O in the direction of the axes O X and O Y, and a couple whose moment is equal to $Y_1 \cdot x_1 - X_1\, y_1$.

Referring to (3), we see that $A_1 X_1 = A_1 P_1 \cos. a_1$, and $A_1 Y_1 = A_1 P_1 \sin. a_1$.

Hence $X_1 = P_1$ cos. a_1 and $Y_1 = P_1$ sin. a_1.

In a similar manner it may be shown the force P_2 acting at A_2 may be replaced by the forces X_2 and Y_2 acting at O in the directions O X and O Y, and the couple whose moment is $Y_2 x_2 - X_2 y_2$, where $X^2 = P_2$ cos. a_2 and $Y_2 = P_2$ sin. a_2.

Fig. 58 b.



Likewise P_3 acting at A_3 may be replaced by X_3 and Y_3 acting at O in the directions O X and O Y and the couple whose moment is $Y_3 x_3 - X_3 y_3$, where $X_3 = P_3$ cos. a_3 and $Y_3 = P_3$ sin. a_3.

Lastly, P_4 acting at A_4 may be replaced by X_4 and Y_4 acting at O in the directions O X and O Y and the couple whose moment is $Y_4 x_4 - X_4 y_4$, where $X_4 = P_4$ cos. a_4 and $Y_4 = P_4$ sin. a_4.

On the whole, therefore, the four forces P_1, P_2, P_3, and P_4, acting at A_1, A_2, A_3, and A_4, in the directions $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_4 P_4$, have been replaced by four forces X_1, X_2, X_3, and X_4, acting at O in the direction O X, whose resultant is a single force equal to $X_1 + X_2 + X_3 + X_4$, acting at O in the direction O X; by four forces Y_1, Y_2, Y_3, and Y_4, acting at O in the direction O Y, whose resultant is a single force equal to $Y_1 + Y_2 + Y_3 + Y_4$ acting at O in the direction O Y; together with four couples, whose resultant couple, Prop. XVI., will be one whose moment is equal to

$$(Y_1 x_1 - X_1 y_1) + (Y_2 x_2 - X_2 y_2)$$
$$+ (Y_3 x_3 - X_3 y_3) + (Y_4 x_4 - X_4 y_4).$$

The two forces $(X_1 + X_2 + X_3 + X_4)$ acting at O in the direction O X, and $(Y_1 + Y_2 + Y_3 + Y_4)$ acting at O in the direction O Y, will have a single resultant, which may be found by Prop. I.

In order that the body may be in a position of equilibrium when acted on by the forces P_1, P_2, P_3, and P_4, applied at A_1, A_2, A_3, and A_4, in the directions $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_4 P_4$, this resultant must be zero, and so must the moment of the resultant couple.

In this case, excluding those conditions which belong to the couples, referring to Prop. IX., we shall have two conditions for the forces acting at O in the directions O X and O Y.

$$X_1 + X_2 + X_3 + X_4 = o$$
$$\text{And } Y_1 + Y_2 + Y_3 + Y_4 = o$$

The moment of the resulting couple being also zero, gives us a third condition.

$$(Y_1 x_1 + X_1 y_1) + (Y_2 x_2 - X_2 y_2) + (Y_3 x_3 - X_3 x_3) + (Y_4 x_4 - X_4 y_4) = 0.$$

Where $X_1 = P_1$ cos. a_1, $X_2 = P_2$ cos. a_2, $X_3 = P_3$ cos. a_3, $X_4 = P_4$ cos. a_4 · $Y_1 = P_1$ sin. a_1, $Y = P_2$ sin. a_2, $Y_3 = P_3$ sin. a_3, and $Y_4 = P_4$ sin. a_4.

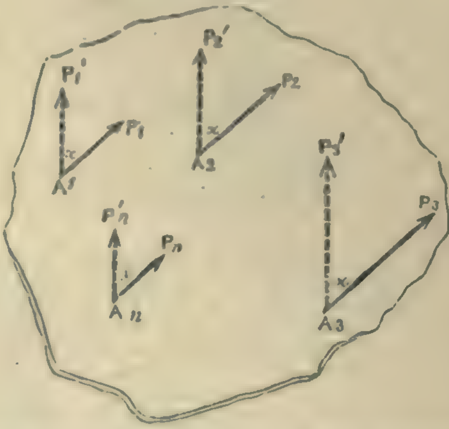
The above reasoning may readily be extended from four to any number of forces.

We have, for the sake of simplicity, drawn the directions of the forces P_1, P_2, P_3, and P_4, in such a manner that their co-ordinates and resolved portions should be positive. In other cases we must remember that if the resolved part of any force act in an opposite direction to that we have drawn, it must be considered negative;* and if one or both of the co-ordinates of the points of application of the force be negative, we have only to use the negative sign. Substituting these signs carefully in the above formulæ, we may extend them so as to include every possible case of any number of forces acting on a rigid body in the same place.

CENTRE OF GRAVITY.—By Prop. XVII. we found that if any number of parallel forces represented in magnitude and direction by P_1, P_2, P_3, &c., P_n (Fig. 59), acting on a rigid body in the same plane, at points A, A^2, A , &c., A_n, be referred to rectangular axes, and x_1, y_1; x_2, y_2; x_3, y_3; &c., x_n, y_n, be the rectangular co-ordinates of A_1, A_2, A_3, &c., A_n referred to these axes, the resultant force will be equal to $P_1' + P_2' + P_3' + P_n'$, acting in a direction parallel to P_1, P_2, &c., and applied at a point whose co-ordinates $\bar{x}$ and $\bar{y}$ may be found by the formulæ.

$$\bar{x} = \frac{P_1 x_1 + P_2 x_2 + P_3 x_3 + \&c., + P_n x_n}{P_1 + P_2 + P_3 + \&c., + P_n}$$
$$\bar{y} = \frac{P_1 y_1 + P_2 y + P_3 y_3 + \&c., + P_n y_n}{P_1 + P_2 + P_3 + \&c., + P_n}.$$

Fig. 50.



From these formulæ it is obvious that the position of the point of application of the resultant of the parallel forces is independent of their direction. Hence, if each of the forces represented in magnitude and direction by $A_1 P_1$, $A_2 P_2$, $A_3 P_3$, and $A_n P_n$, be turned through the same angle a, about the points A_1, A_2, A_3, &c., A_n, into the position shown by the dotted lines, the point of application of the resultant will not move.

For this reason this point is called the *centre of the parallel forces.*

We have seen that the weight of a heavy body is produced by the earth's attraction on each of the material particles of which it is composed, and that this attraction is the same for all kinds of matter. Hence, a cubic inch of iron weighs more than a cubic inch of wood; not because the earth's attraction is greater for particles of iron than for those of wood, but because a cubic inch of the former contains a greater number of gravitating particles than the latter.

The attraction which the earth exerts on all masses near its surface, on account of its larger relative mass, is so great, that for all masses which are not very large, we may neglect the attraction which the particles of these masses or those in their neighbourhood exert on one another. We can, on this account, rapidly determine, with considerable accuracy, the direction of the earth's attraction, or *gravity.*

Fig. 60.

Let a small weight of lead or brass P (Fig. 60), be fixed to one extremity of a thin flexible string A P, and suspended from a fixed point A. The weight P, after oscillating for some little time, will, if undisturbed, rest in such a position that the string A P shall point to the earth's centre. Such an instrument is called a *plummet* or a *plumb-line,* and the line in which it rests, the *vertical.* If two plumb-lines be suspended from points situated at different parts of the earth's surface, they cannot be exactly parallel, but must make a certain angle with each other, unless the one point lie in the antipodes of the other, in which case the directions will be in the same straight line.

For all practical purposes, on account of the comparative greatness of the earth's radius, we may say that two plumb-lines of any ordinary length, suspended within any apartment, however large, will be parallel to each other; since if in still water, at a distance of 200 yards from each other, we were to sink two plummets a mile and a-half in length, they would not deviate further than 3 inches from perfect parallelism. It is true that a large mass of matter, such as a mountain, will slightly deflect, as according to the theory of gravitation it ought, the plumb-line from the true vertical; but in ordinary cases this source of error may be neglected. Again, the attraction of the earth will vary according to the distance from its centre of the particle or body attracted; but this variation may also be neglected for bodies which are small when compared with the magnitude of the earth.

---

* See ante, p. 708

Hence, in most cases, even such, for instance, as the largest line-of-battle ship, without introducing any sensible error, we may regard the attraction of the earth, on any mass of matter, as acting on every material particle composing that mass, in directions parallel to the plumb-line suspended near it.

The *centre of the parallel forces*, produced by the weights of the material particles of which any heavy body is composed, is called the *centre of gravity of that body.*

Hence, Prop. XVII. enables us to find the position of the centre of gravity of any number of heavy particles whose weights and positions are known.

From the properties of the *centre of parallel forces* we have already demonstrated, it follows that the *centre of gravity* of a heavy body *is that point within or without the body at which the whole of its weight may be conceived to act; and the body will produce the same mechanical effect, as if we were to suppose the whole of its weight concentrated in that point.* This enables us to extend Prop. XVII., to find the common centre of gravity of several bodies, whose weights and the position of whose respective centres of gravity are known.

Again, because the parallel forces exerted by the weights of the material particles of a body will have the same direction in whatever position it is placed, its centre of gravity will not change its position with respect to the body for any change in the position of the body. Hence, if the centre of gravity be fixed, the body will balance about it in every position, because the resultant of the weights of every one of its elementary particles will pass through the fixed point (the centre of gravity) in every position in which the body can be placed.

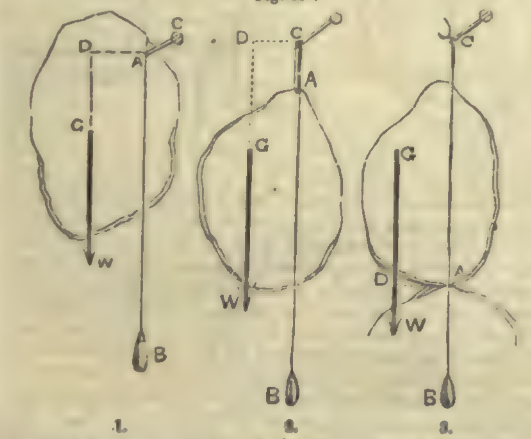
PROPOSITION XIX.

If a heavy body be in equilibrium when suspended from a point, or when resting on a point in contact with another body, its centre of gravity will be in the vertical line passing through the point of suspension or contact.

Let (Fig. 60*,) 1, 2, and 3 represent a section of the heavy body, taken through the plane passing through its centre of gravity G, and its point of suspension or contact A.

In (1) we suppose the body supported by a pin A C, passing through a hole at A, about which it can move freely; in (2) it is suspended from a point at A, by a string fixed at C; and in (3) it is supported by another body with which it is in contact at A.

Fig. 60*.



In all three cases let the vertical be represented by the plumb-line AB; the centre of gravity must lie in that line. If it do not, let it have some other position, as G.

From our definition of the centre of gravity, the weight of the body will produce the same effect upon the body as if, being destitute of weight, a force equal to its weight, acting vertically downwards, were applied to its centre of gravity.

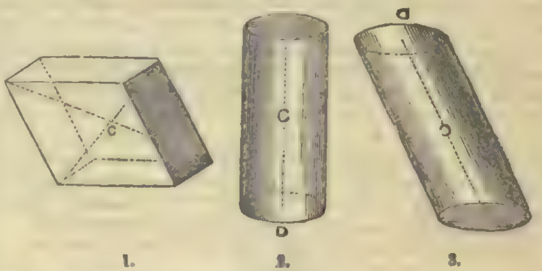
Let G W = W represent this force, the weight of the body, in magnitude and direction, and we then have the case of a rigid body without weight in equilibrium when acted on by the force W acting at G, and the reaction or tension at the point A.

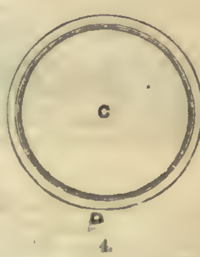
Through A draw A D perpendicular to G W or G W produced. Then by the principle of the transmission of force, W may be transferred from G to D, and W · A D will be the moment of a force tending to twist the body round the point A, which is counteracted by no other force. Consequently, equilibrium can only exist if W or A D be equal to nothing. But by the terms of the proposition, W cannot be equal to nothing. Hence, there can only be equilibrium where A D is nothing, in which case G must lie in the line A B.

In the same manner it can be shown that if a heavy body balance on a given straight line—as, for instance, the sharp edge of another body which is a straight line—its centre of gravity will lie in a straight line.

If any homogeneous heavy body be of a form which is symmetrical with respect to a certain point or line, the centre of gravity will be in that point or line; for the very idea of symmetry requires, that if any point be taken in the body, there must be another point in that body equidistant from the point or line about which it is symmetrical. Hence, since the centre of gravity is the centre of the parallel forces produced by the weights of the material particles composing the body; if it be homogeneous, that is, composed of particles of the same weight, and distributed uniformly throughout its substance, any one particle in the body will be balanced about the point or line around which its form is symmetrical, by another particle equal to it in weight, and equidistant from that point or line.

Fig. 61.





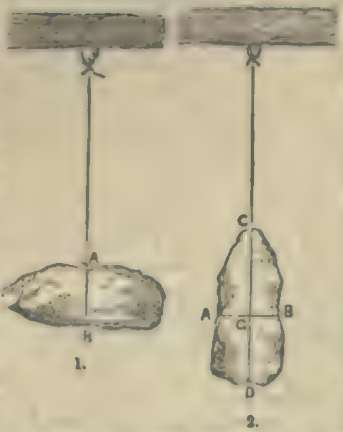
The centre of gravity, therefore, of a sphere, will be the centre of the sphere; that of a cube or oblique parallelopiped (Fig. 61—1), the point where two diagonals intersect each other. The centre of gravity of a right (2) or oblique (3) cylinder will be in the middle of its axis; and that of a ring (4) will be the centre of the ring.

The centre of gravity of a hollow sphere or cylinder will be the same as if it were solid, provided it be of the same thickness throughout. From this it follows that the centre of gravity of a body need not necessarily be a point within it.

EXPERIMENTAL DETERMINATION OF THE CENTRE OF GRAVITY.—The preceding proposition affords a means, in many instances, of determining the position of the centre of gravity of a body experimentally.

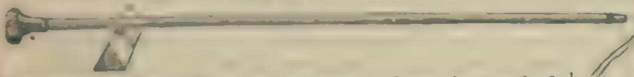
Thus, if a body be suspended by a string, attached to the point A (Fig. 62—1), the centre of gravity will lie in the vertical line A B passing through the body when it has attained a position in which it is perfectly at rest. We now suspend it (2) from another point C; let C D be the position of the vertical when it is at rest, this line will intersect the previous line A B in the point G, which will be the centre of gravity of the body. In many cases we shall thus be enabled to estimate the position of the centre of gravity. If the body A C B D (2) be bounded by plane surfaces, and be of uniform thickness throughout, we know that if the lines A B and C D be traced on both parallel surfaces, the centre of gravity will lie in the middle of the straight line joining the two points of intersection of these lines.

Fig. 62.



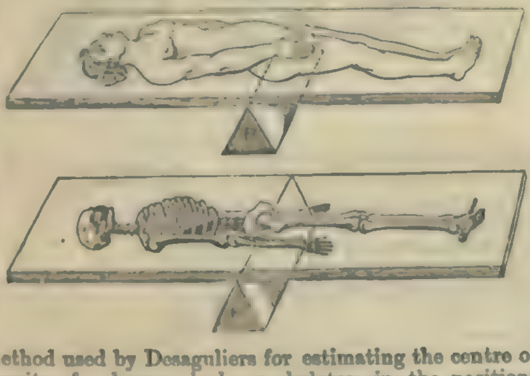
To find the centre of gravity of a walking-stick, which is supposed to be symmetrical with respect to an axis passing through its centre, and has a heavy head or handle, we have only to balance it on the sharp edge of a body, as indicated in Fig. 63, and we know the centre of gravity will lie in the point where the vertical plane passing through the edge intersects the axis of the stick.

Fig. 63.



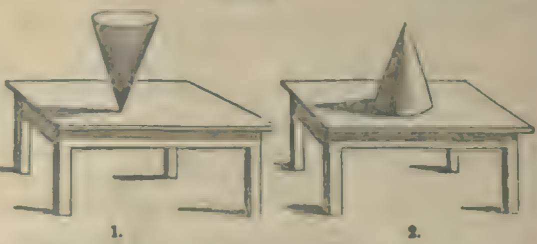
In these experimental determinations of the centre of gravity it does not signify whether the body be homogeneous or not: thus, the adjacent figures show the method used by Desaguliers for estimating the centre of gravity of a human body or skeleton, in the positions there indicated. (Fig. 64).

Fig. 64.



STABLE AND UNSTABLE EQUILIBRIUM.—Theoretically we say that a heavy body under the action of gravity, may be in equilibrium in a certain position, though we may not be able practically or experimentally to demonstrate it, because the slightest disturbance of the position of the body may destroy the conditions of its equilibrium. Thus, theoretically, a cone will be in a position of equilibrium whether it rest on a table (Fig. 65—1) on its apex, or (2) on its base. In the former case, however, the slightest possible movement to the one side or the other will destroy the equilibrium. The equilibrium which is theoretically but not practically possible, is called *unstable*, while that which is practicable is called *stable*. An egg will rest on its side in a position of *stable equilibrium*, while the attempt to balance it on one of its extremities will only be successful by imitating the well-known method Columbus used, to destroy its *unstable equilibrium*. A body may be said to be in *stable equilibrium* if after a slight disturbance it recovers its position of equilibrium; and in *unstable equilibrium* if after a slight disturbance it does not recover it. When a body is supported by its centre of gravity, it will rest in every position about that point; this has been called *indifferent equilibrium*.* Thus, a circle or any plane figure, of uniform thickness, will rest in every position, on an axis passing through its centre of gravity.

Fig. 65.

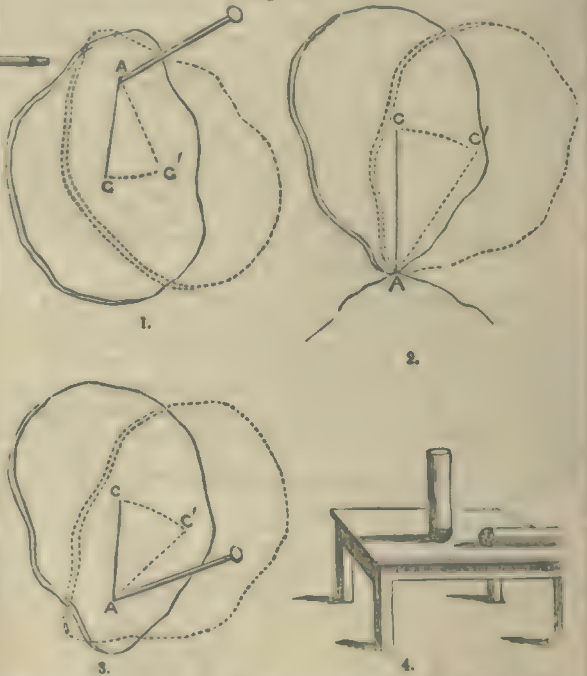


PROPOSITION XX.

The equilibrium of a body will be stable or unstable according as its centre of gravity is in the lowest or highest position possible.

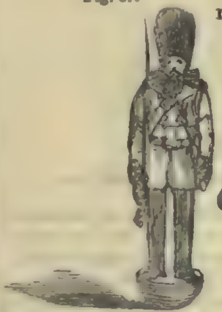
If a body be in a state of equilibrium, suspended by an axis at A (Fig. 66—1), about which it is capable of moving freely, or resting on a point A (2), any slight disturbance will cause the body to move to the right or left, as shown by the dotted lines, and the centre of gravity, to describe a small arc G G′; but the centre of gravity, having moved, however slightly, below the point G, the tendency of the weight of the body will evidently be to remove the centre of gravity further from the original position G. But if the centre of gravity be in its lowest position G (3) after any disturbance which should remove the point G to G′, the tendency of the weight will be to restore the body to its original position, and the point G′ to G.

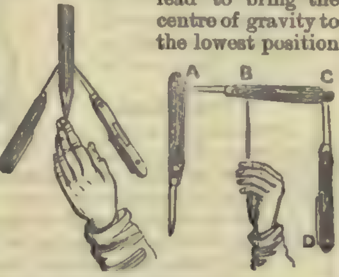
Fig. 66.



The tendency of the centre of gravity to recover its place if removed from its lowest to a higher position is well illustrated by fixing the half of a bullet (4), or any hemispherical heavy metallic body, to a cylinder of elder-pith, cork, or any other light substance. The centre of gravity of the whole, will lie somewhere in the heavy hemisphere; and if the cylinder be removed to any position, except it be laid almost absolutely on its side, it will speedily recover its upright position, as shown in the figure. Toys are constructed on this principle, the cylinder being cut into the form of a soldier; a regiment of such mimic troops being pressed nearly to the ground by passing a stick over them, seem immediately to spring up and recover their position as if by magic. (Fig. 67). The toys called *tumblers*, made of plaster of Paris, with a hemispherical bottom loaded with iron or lead to bring the centre of gravity to the lowest position possible, also owe their amusing properties to the same principle. Screens have been invented which, by this contrivance, right themselves after being pressed down. The preceding illustrations show how a pointed stick may be easily balanced on the tip of the finger by fixing two pen-knives in its side, thus converting an unstable into stable equilibrium; and how three pen-knives, placed in the position A, B, C, and D, may be kept in equilibrium on the point of a needle held in the hand. In both cases the centre of gravity must fall below the point on which the bodies are balanced.

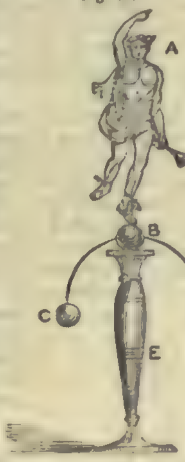
Fig. 67.





A small figure A (Fig. 68) with its foot fixed to a sphere B, through which passes a bent wire, having two leaden balls C and D attached to its extremities, if placed loosely on a stand E, will speedily recover its upright position after being moved from it; the figure being so constructed, that the centre of gravity of the three bodies A, C, and D, falls below the point of support; that is, where the sphere B rests on the stand E.

Fig. 68.

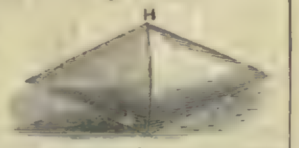


The apparent paradox of a double cone ascending an inclined plane by its own weight, is produced by the construction of the cone and plane being such that the centre of gravity of the cone really descends, and by its descent causes the cone to ascend the plane.

Construct an inclined plane of two equal pieces of straight wire A C and B C (Fig. 69—2), fixed at their extremities to three upright pieces A E, B F, and C D, standing perpendicular to the horizontal stand D E F: A E and B F being equal to each other, and C D less than A E or B F.

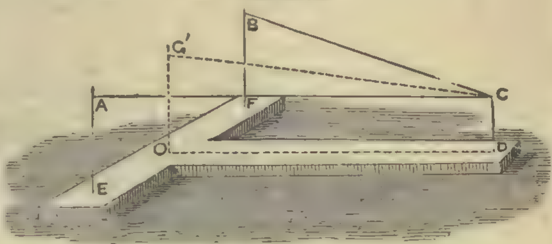
Let H be a double cone consisting of two right cones united together by their circular bases.

Fig. 69—(1).



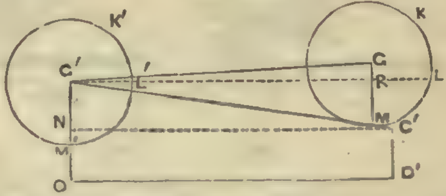
If the distance A B or E F be equal to or less than that between the two vertices of the cone, and the difference between A E and C D less than the radius of the circular base of the double cone, upon placing the cone near C with its circular base between the wires A C and B C, it will roll up the inclined plane till its extremities are stopped by the upright supports at A and B.

Fig. 69—(2).



That the centre of gravity really descends in this case will be readily seen by the diagram (3), which represents an imaginary section of the inclined plane through C D, perpendicular to E F, represented by the lines G′ O, O D, C D, G′ C (2).

Fig. 69—(3).



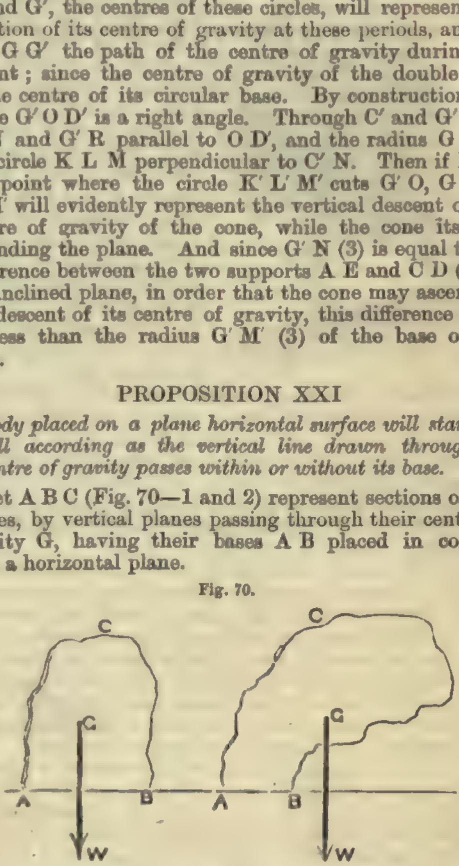
Let the circles K L M, K′ L′ M′ (3) represent the two positions of the circular base of the cone at the commencement and end of its ascent up the inclined plane; G and G′, the centres of these circles, will represent the position of its centre of gravity at these periods, and the line G G′ the path of the centre of gravity during the ascent; since the centre of gravity of the double cone is the centre of its circular base. By construction, the angle G′ O D′ is a right angle. Through C′ and G′ draw C′ N and G′ R parallel to O D′, and the radius G M of the circle K L M perpendicular to C′ N. Then if M′ be the point where the circle K′ L′ M′ cuts G′ O, G R or N M′ will evidently represent the vertical descent of the centre of gravity of the cone, while the cone itself is ascending the plane. And since G′ N (3) is equal to the difference between the two supports A E and C D (2) of the inclined plane, in order that the cone may ascend by the descent of its centre of gravity, this difference must be less than the radius G′ M′ (3) of the base of the cone.

PROPOSITION XXI

A body placed on a plane horizontal surface will stand or fall according as the vertical line drawn through its centre of gravity passes within or without its base.

Let A B C (Fig. 70—1 and 2) represent sections of two bodies, by vertical planes passing through their centre of gravity G, having their bases A B placed in contact with a horizontal plane.

Fig. 70.



1. 2.

In (1) the vertical G W passing through G falls within A B, and in (2) without A B.

The whole effect of the weight of the body is equivalent in both cases to a single force equal to that weight applied at G in the direction G W.

In (1) this force is evidently destroyed by the reaction of the plane, and the body will stand. In (2) this force has a moment about the point B, which is not counteracted by the resistance of the plane; and consequently the body will turn round B till it falls in such a position that G W will lie within the base on which it rests. This property is readily shown, experimentally, by taking two oblique cylinders (Fig. 71—1 and 2) of such lengths that the vertical passing through the centre of gravity of the one, when placed on a table, shall fall within its circular base, and the other without. The former will stand and the latter will fall when placed with their circular bases in contact with the table.

If the surface on which the body rests be inclined instead of horizontal, the same effect will be produced, provided the body be prevented from sliding down the inclined plane by friction or some other force.

Fig. 71.

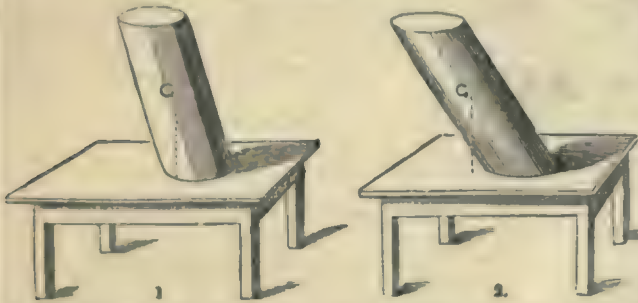


Fig. 72.

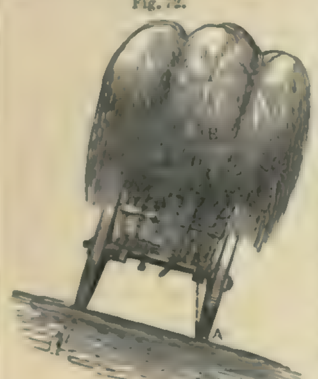


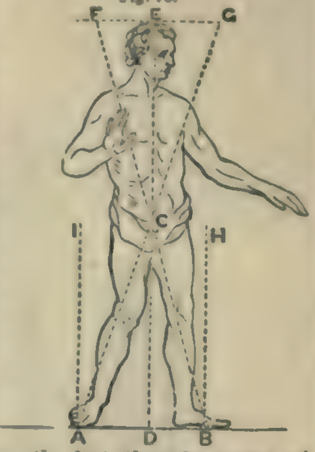
Thus, a loaded waggon passing along an inclined road will not be overturned so long as the vertical G A (Fig. 72) passing through the centre of gravity G of the load and waggon falls within the points where the wheels touch the road. As soon as the inclination of the road becomes so great, or the position of the centre of gravity of the load be such, that the vertical falls without these points, the waggon will be overturned.

The broader the base, and the lower the centre of gravity of the body, the firmer will be its stability. A waggon carrying a load of straw is more likely to be overturned than if it were laden with an equal weight of iron or some other heavy material; because, in the first instance, the distance of the centre of gravity of the load and waggon from the ground is much higher than in the latter.

The round tower which is the belfry of the cathedral at Pisa, is 190 feet high, and deviates from the perpendicular about 14 feet. At Bologna there is a square tower called Garisenda, 134 feet high, and deviating 9 feet from the perpendicular. Both these buildings are supposed to owe their inclination from the depression of the ground under their foundations; and they have not been overthrown, because the vertical, passing through their centre of gravity, still falls within their base.

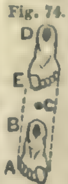
Desaguliers, in his *Course of Experimental Philosophy*, has the following interesting observations on the position of the centre of gravity in animal bodies when at rest, or in motion, in various positions. "When we stand upright, with our feet as represented in Fig. 73, the line of direction (*i. e., the vertical passing through the centre of gravity*) goes through the point C, and passes between our feet to D, and we may move our heads from E to F or G, and our bodies forwards, backwards, or sideways, as far as I or H, without danger of falling, or stirring our feet, as long as the line of direction traverses no farther than I A or H B, and falls anywhere within the space A B, which in this situation of our feet makes a pretty large base. But if we set one foot before the other, as in Fig. 74, a little push sideways will make the line of direction (which went through C) fall out of the base to the right or left towards E or B; in which case a man must fall if he do not quickly remove his feet to the position of Fig. 73.

Fig. 73.



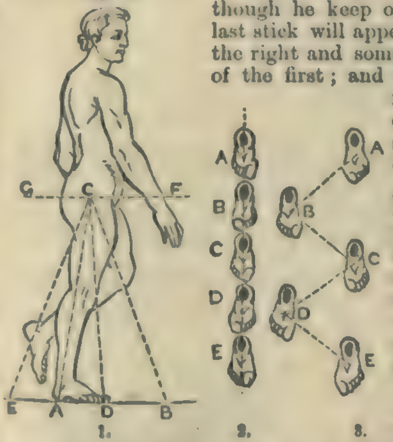
"When we stand upon either leg, we must bring our body so much over the foot, that the centre of gravity being directly over it, the line of direction may go through the sole of it; and in walking, the line of direction must travel through every place where each foot is set down, going successively through the points E, A, D, B (Fig. 75), while the centre of gravity goes through the points G, C, F, &c.; so that unless a man in walking straight forward, sets one foot directly before the other, the line of direction will not describe a straight line upon the plane where the man walks, but an indented line; that is, angles to the right and left, whilst the body of the man goes on in a waddling motion. This we see in the walking of fat people, and all others that straddle in their gait. The line of direction going through the points A, B, C, D, E, describes a straight line in Fig. 75 (2), where the feet are set before one another; but when the motion of one foot is in a parallel line with the motion of the other, an indented line is described by the motion of the centre of gravity above, and the line of direction as it cuts the ground at A, B, C, D, E (3).

Fig. 74.



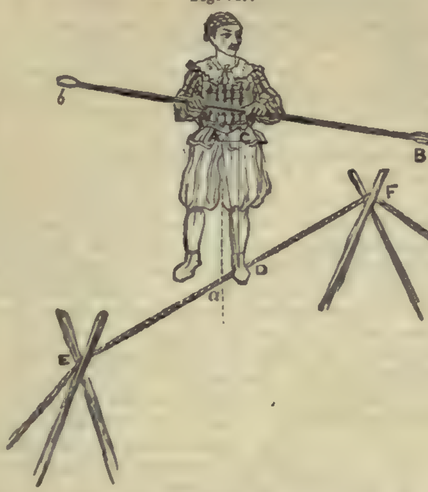
"It is not strictly true that any man in his common walk sets one foot so exactly before the other as to carry on the bottom of his line of direction in a straight line, as represented in (3); because if a straight line be drawn with chalk, it is difficult to walk straight along it: but the plainest proof is the observation of two upright sticks, of about the height of a man, the one painted white and the other black, and set up about ten yards beyond one another, in the same line that a man walks towards them; for in such a case, though he keep one eye shut, the last stick will appear sometimes on the right and sometimes on the left of the first; and the more so the nearer the man comes to the sticks. Rope-dancers, indeed, go in a straight line; but it is what they have learned by art, and inured themselves to by long practice; yet they must, even after all, have helps to keep their centre of gravity over the rope. They generally keep their eyes on some distant point in the same plane as the rope. They have commonly a long pole loaded at the ends with the balls of lead B *b* (Fig. 76), by the motion of which they can alter the position

Fig. 75.



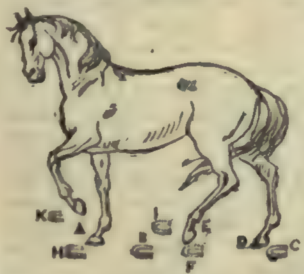
of the common centre of gravity of their body and the pole; as, for example, the centre of gravity of the rope-dancer C A being at A, his line of direction should go through *a*, off from the rope; but by moving the pole towards B, the common centre of gravity of the man and pole is brought to C, and the line of direction C D goes through the rope. Those that are well skilled in this art will sometimes use their arms only instead of a pole; and it is very common for several of them to dance with a flag, with which they strike the air the same way that the centre of gravity goes when the line of direction does not go through the rope; and by the reaction of the air the centre of gravity is brought back to its proper place.

Fig. 76.



"The ancients observing that horses and other quadrupeds, in galloping, lift up their two fore feet, and then their hind feet as soon as the fore feet are set down, did imagine that in walking, as well as pacing and trotting, a horse has two feet off of the ground at one time; and accordingly, in their brass or marble statues, they have represented their horses with two legs off of the ground diagonally opposite—as the right before and the left behind, or left before and right behind. The modern statuaries have also fallen into the same error, because in the quick walking of a horse, the eye cannot well distinguish; and therefore Borelli (*De motu animalium*) has shown from mechanical principles, that the motion of raising two feet at once in walking cannot be consistent with the wisdom and simplicity of nature.

Fig. 77.



"Let us consider a horse as an oblong machine sustained by the four legs, as four props or columns, resting on the points A, B, C, D, (Fig. 77), which make a rectangular quadrilateral figure; then the line of direction will fall perpendicularly on E, a point in or near the centre of the quadrilateral figure, which will make the station or standing of the horse the most firm. The progressive motion begins by one of the hind feet—as, for example, the left hind foot C, which, by strongly pressing back the ground, moves forward the centre of gravity, and consequently carries on the line of direction from E to G as itself moves from C to F. This done, the foot B is raised and carried forward as far as H, which motion of the foot is easy, because the line of direction first falls within the triangle A B D; secondly, within the trapezium A B F D—that is, the body of the horse is sustained by three or by four columns. Lastly, the three feet A, D, F, remaining firm, and taking the line of direction at G, immediately the left fore foot B is carried forward to H; and by the impulse already made, the centre of gravity is also carried over I—namely, the central point of the rhomb A H F D. The motion of the two left feet being completed, the impulse and motion of the right hind foot D begins, and then that of the right fore foot, and so on in the manner above described, as the animal moves forward.

"Ducks, geese, and the greatest part of the water-fowl, whose legs are set wide asunder for the convenience of their swimming, and turning quick in the water, have always a waddling motion upon land; but a cock, a stork, an ostrich, and most other birds that are not web-footed, walk almost directly forward without waddling (especially when they walk slowly), having their legs so placed as to put one foot before the other with greater ease. Thus quadrupeds seldom or never waddle, because they have commonly three feet upon the ground at a time; so that, however the base receiving the line of direction alters from a quadrangular to a triangular figure, that part of it, in which the line of direction falls, is always in or near the same line.

"When a man stands in a firm posture (Fig. 73) A B, the distance of his feet is the length of a quadrilateral figure, whose breadth is nearly the length of the feet, and D is the point under the centre of gravity C, where the line of direction falls. Let the lines A C and B C be drawn, then let these two lines and D C be continued to the points E F G so as to make the triangles E C G and A C B equal and similar; as long as the line F D (or a plane going through it) cuts the whole body of the man into two equal parts, the centre of gravity will be at C, and C D will be the line of direction. But if the body be inclined towards the left hand H, the centre of gravity will move from C to H, the line of direction will become H B, and the right foot being easily removed from A, may be carried on beyond B, by which means the man will go on towards the left. In like manner, by inclining towards I, the line of direction will be removed to I A, and the man go to the right. When a man stands upon one foot it is with some difficulty. For example, let the line of direction be C D (Fig. 75—1); by the motion of the blood and lungs, and other animal motions, the centre of gravity will be apt to vacillate or totter towards F or G on either side about the centre of motion D, where now the base is but small. If the line of direction come to B, the man must fall forwards, backwards if to E; and though A be under the heel of the foot, yet in the motion of the said line of direction from D to A, the body will be apt to go towards E, and so bring the line of direction beyond the base. This will more probably happen in the side motion of the body; so that the body will be in danger of falling, unless the right foot be put down towards that side where the body inclines. Birds stand upon one foot much more easily than men, because their line of direction being much shorter, and the base of one foot a large rhomboidal figure made by the four claws, the line of direction cannot go out of that base, unless the centre of gravity rises, which is impossible without a violent motion."

When a porter carries a burden upon his shoulders, he must stoop, because, if he should stand upright, the common centre of gravity of the man and burden would be so far brought back, that the line of direction would fall behind the feet.

PROPOSITION XXII.

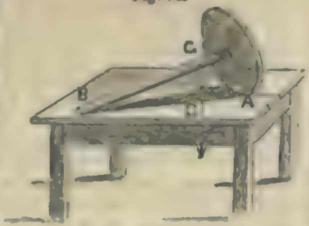
A heavy body rests upon a horizontal plane, to find the pressures produced by its weight upon the points of contact by which it is supported.

When a heavy body rests upon a horizontal plane, the pressures produced by its weight on the points on which it is in contact with the plane can be determined, if these points do not exceed three in number. When the points of contact are more than three, the pressure upon each is indeterminate.

If the body rest upon a single point, it is evident that the pressure on this point is equal to the weight of the body.

When the body rests upon two points A and B, as in Fig. 78, where the body is supposed to consist of a circular disc and a cylindrical stick, fixed perpendicularly to its centre, the pressures on these points may readily be determined.

Fig. 78.



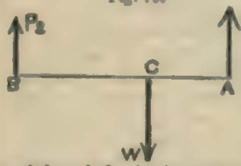
Let G be the centre of gravity of the body resting on the plane.

This body is evidently kept in equilibrium by its weight, and the equal and opposite reactions produced by the two pressures on the points A and B.

The vertical passing through G must therefore pass through the line adjoining A and B.

Let C be the point where the vertical cuts A B; the weight of the body acting at G may be transferred from G to C.

Fig. 79.



Then (Fig. 79) we have two reactions, P_1 and P_2, acting upwards, perpendicular to the plane at A and B; and a weight W equal to the weight of the body acting downwards, and also perpendicular to the plane.

Hence, Prop. XI., $P_1 + P_2 = W$, and $P_2 \cdot BC = P_1 \cdot AC$.

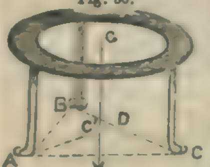
Two equations are thus obtained from which P_1 and P_2 may readily be determined, when the position of the centre of gravity G of the body is known.

The reactions P_1 and P_2 will be equal and opposite to the pressures produced by the body at A and B.

When the body rests upon three points A, B and C (Fig. 80), we may still find the pressures produced by its weight on these points.

Join the points A, B and C. In order that there may be equilibrium, the vertical passing through G, the centre of gravity of the body, must fall within the triangle A B C. (Prop. XXI.)

Fig. 80.



Let C' be the point where the vertical passing through C cuts the triangle A B C.

Join A C; and produce A C' to meet B C in D.

If W be the weight of the heavy body, we may transfer the force W from G to C. This force, acting perpendicular downwards at C, may be resolved into two forces, W_1 acting at A, and W_2 acting at D, both perpendicular to the plane of the triangle A B C.

Where $W_1 + W_2 = W$, and $W_1 \cdot AC = W_2 \cdot CD$.

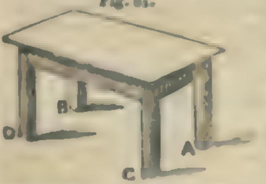
The force W_2 acting at D may again be resolved into two others, W_3 acting at B and W_4 at C, both perpendicular to the triangle A B C.

Where $W_3 + W_4 = W_2$, and $W_3 \cdot BD = W_4 \cdot CD$.

From these equations the forces W_1, W_3, and W_4, which will be the pressures exerted by the heavy body on the points A, B and C, may be readily determined.

If the heavy body rest on the plane by four points of support, as a table on its four legs, A, B, C, D, (Fig. 81), the pressures upon these points will be indeterminate if we consider the body perfectly rigid.

Fig. 81.



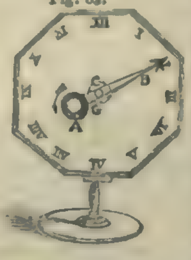
For since it may be supported by any three of the points of contact, the pressure on the fourth may be either nothing or some finite proportion of the weight of the body. The method used in the two preceding cases to determine the pressures will fail in this. The only condition we have is, that the sum of the pressures on the points A, B, C and D must be equal to the weight of the body; and if we consider them as weights acting perpendicularly to the plane on which the table rests, the centre of gravity of these weights will lie in the vertical, passing through the centre of gravity of the table.

The same reasoning may be extended to the cases where the points of contact are more than four.

THE MAGIC CLOCK.—The influence of the centre of gravity on the position of equilibrium of a heavy body, which can only turn round a fixed horizontal axis, is well illustrated by an ingenious contrivance called the *magic clock*.

A transparent glass dial-face has a hole pierced through its centre at C (Fig. 82); in this is a fixed horizontal axis; on this axis is placed the hour-hand of the clock, which can move freely round it to the right or left. The extremity of the hand opposite the pointer B is terminated by a hollow ring; in this ring there is a heavy spherical ball A, capable of moving freely round it. This ball is made to move uniformly round the interior of the ring, by a watch-movement concealed in the hand, once in twelve hours, in the direction indicated by the arrow in Fig. 82. The weight of the ball A is so proportioned to that of the hand with its concealed watch-work, that as A moves round the interior of the ring G, the common centre of gravity of the ball and hand would describe a circle round the centre of the axis C, if the hand were fixed in one position. Since the hand can move freely round C, for every new position of A the hand will assume that position which shall make C G vertical (Prop. XIX.) As A, therefore, is carried round the ring uniformly once in twelve hours, the pointer of the hand B moves with the same uniformity round the dial in the opposite direction, and indicates the hour.

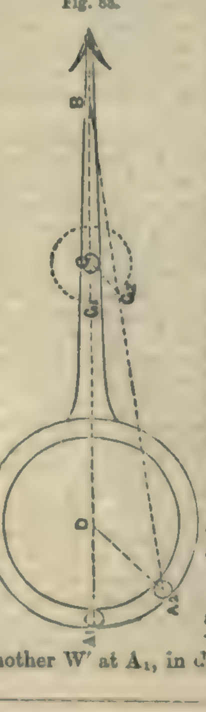
Fig. 82.



The ball A, and the watch-movement which causes it to turn round the ring, being both concealed, the hand seems to move by itself, as if by magic. The remarkable property that the hour-hand being made to move by your finger backwards or forwards, when left to itself, will, after a few oscillations, resume its position, and point to the correct hour, adds considerably to the illusion.

Let D (Fig. 83) represent the centre of the ring round which the spherical body circulates; A_2, the centre of the spherical body; C, the centre of the axis round which the hand moves; B, the centre of gravity of the hand and its concealed watch-work, exclusive of the movable spherical body; G_2, the common centre of gravity of the hand and spherical body. Also let W represent the weight of the hand and works exclusive of the sphere, whose weight is represented by W'.

Fig. 83.



Then, if W and W' be so chosen that $W \cdot BC = W' \cdot CD$, the common centre of gravity G_2 of the hand and movable sphere will describe a circle round C, if the hand be supposed to be fixed while A_2 describes a circle round D.

Let A_1 represent the position of the centre of the sphere, when it lies in B C D produced; G_1 the centre of gravity of the hand and sphere for this position.

Join D A_2, C G_2, and B G_2 A_2.

When the centre of the movable sphere is in the position A_1, we have a weight W acting at B, and another W' at A_1, in directions parallel to each other;

and since G_1 is the position of their resultant, we have (Prop. XI.)

$$W \cdot BG = W' \cdot A_1 G_1;$$

but by the construction of the instrument,

$$W \cdot BC = W' \cdot CD.$$

Hence $\frac{BG_1}{BC} = \frac{A_1 G_1}{CD}$, or $\frac{BC + CG_1}{BC} = \frac{A_1 C - CG_1}{CD}$.

Therefore $CD \cdot BC + CD \cdot CG_1 = A_1 C \cdot BC - BC \cdot CG_1$.

Or $CG_1 \cdot (CD + BC) = (A_1 C - CD) BC \cdot$

And $CG_1 \cdot BD = A_1 D \cdot BC$.

Or $CG_1 = \frac{A_1 D \cdot BC}{BD}$.

When the centre of the sphere is in the position A_2, we have a weight W acting at B, and a weight W′ at A_2, in parallel directions. Hence (Prop. XI.) he have

$$W \cdot BG_2 = W' \cdot A_2 G_2.$$

But $W \cdot BC = W' \cdot CD$.

Hence $\frac{BG_2}{BC} = \frac{A_2 G_2}{CD}$.

Therefore (Euc., B. VI., P. II.), the line CG_2 is parallel to $A_2 D$, and BCG_2 and BDA_2 are similar triangles; and consequently

$$\frac{CG_2}{A_2 D} = \frac{BC}{BD}, \text{ or } CG_2 = \frac{BC}{BD} \cdot A_2 D.$$

But $A_2 D = A_1 D$. Hence $CG = \frac{A_1 D \cdot BC}{BD}$. The same value which we have before obtained for CG_1.

Hence for every position A_2 of the centre of the movable sphere out of the line BCD, we shall have CG_2 parallel to DA_2, and equal to CG_1.

Fig. 84.

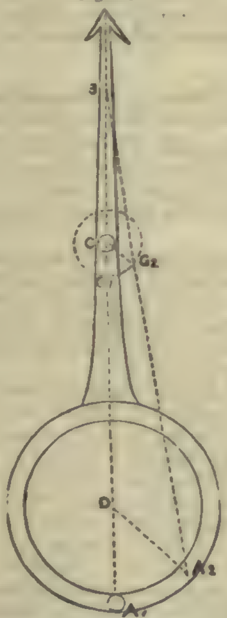


Fig. 85.

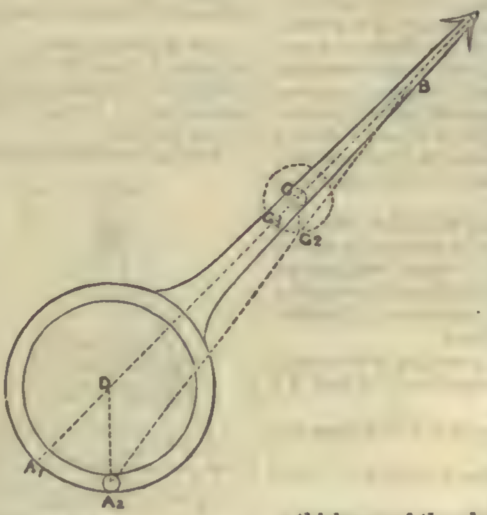
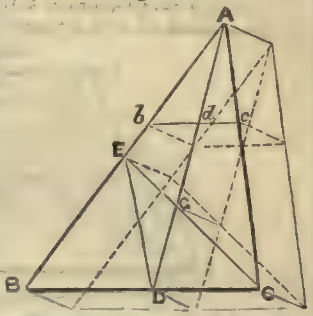


As A_1 therefore describes a circle round D, G_1 will describe a circle round C in the same direction, and uniformly with it; the radius of this circle being equal to the product of the radius of the circle described by the centre of the sphere, and the distance of B from C divided by BD.

When the centre of the sphere is in the position A_1, the hand will rest in such a position that CG_1 shall be vertical (Prop. XIX.), as shown in Fig. 84. When A_2 represents the position of the centre of the sphere, CG_2 will be vertical, and the hand will rest in the position shown by Fig. 85. Hence it is evident that, as the watch-movement concealed in the hand causes the centre of the sphere to move from A_1 to A_2, the extremity of the pointer of the hand will move through a similar arc in the opposite direction round C as its centre.

MATHEMATICAL DETERMINATION OF THE CENTRE OF GRAVITY OF A HEAVY BODY.—The application of Prop. XVII. to find the centre of gravity of a body of uniform or variable density, in most instances requires the aid of the differential and integral calculus before we can arrive at a solution. As this would lead us beyond the limits proposed for the mathematical department of our work, we give some instances of the determination of the centre of gravity of a few geometrical forms and solids of uniform density, depending upon the properties of the centre of gravity demonstrated in Prop. XIX.

Fig. 86.



EXAMPLE I.—*To find the centre of gravity of a triangular plate of uniform thickness and density.*

Let ABC (Fig. 86) be the surface of the triangular plate, bounded by two parallel triangular faces, and by parallelograms perpendicular to these faces.

Bisect BC in D. Join AD.

Through *b* any point in AB draw *bdc* parallel to BC, and cutting AD in *d*.

Then the triangle A*bd*, by construction, is similar to the triangle ABD, and the triangle A*dc* to the triangle ADC.

Hence (Euc., B. VI., P. IV.), $\frac{Ad}{AD} = \frac{bd}{BD}$, and $\frac{Ad}{AD} = \frac{dc}{DC}$.

Therefore $\frac{db}{BD} = \frac{dc}{DC}$, but $BD = DC$.

Hence $bd = dc$; and so it may be shown that every line drawn through any point in AB parallel to BC will be bisected by AD.

Now we may conceive the triangular plate, whose thickness is uniform, to be made up of a number of extremely thin slices, cut perpendicular to the surface, and parallel to BC.

Each of these slices, being symmetrical, will balance about its centre, and therefore every one of them will balance about a line drawn parallel to AD, and passing through the centre of the thickness of the plate.

The whole triangular plate will therefore balance about this line.

Next bisect AB in E, join EC cutting CD in G.

It may be shown, as before, that the triangular plate ABC will balance about a line parallel to EC, passing through the centre of the thickness of the plate.

Since the centre of gravity of the plate lies in both the lines passing through the centre of the thickness parallel to CE and AD, the intersection of these two lines must be the centre of gravity.

Hence a point in the middle of the thickness of the plate below G will be the centre of gravity of the plate, provided its thickness and density be uniform throughout.

To find G, join DE.

Then because AB is bisected in E, and BC in D,

Therefore (Euc., B. VI., Props. II. and IV.), ED is parallel to AC, and $ED = \frac{1}{2} AC$.

Hence the angle EDG = angle GCA, the angle at G is common, and therefore the triangle EGD is similar to the triangle AGC.

Therefore (Euc., B. VI., P. IV.), $\frac{DG}{DE} = \frac{AG}{AC}$.

Or $DG = \frac{AG \cdot DE}{AC} = \frac{1}{2} \cdot \frac{AG \cdot AC}{AC} = \frac{1}{2} AG$.

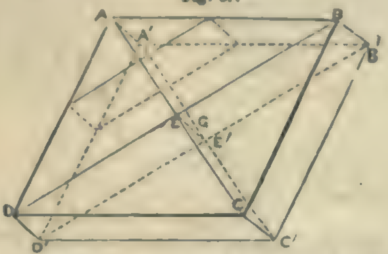
And $A D = A G + D G = 2 D G + D G = 3 D G$.

Or $D G = \frac{1}{3} A D$.

EXAMPLE II.—*To find the centre of gravity of a plate of uniform thickness and density bounded by parallel planes, whose upper and lower surfaces are parallelograms.*

Let the parallelogram A B C D (Fig. 87) represent the upper surface of the plate, A′ B′ C′ D′ the lower; the other boundary planes, such as B C C′ B′, being perpendicular to A B C D.

Fig. 87.



Join B D and A C meeting in E, B′ D and A′ C′ meeting in E′. A C will bisect all lines drawn through the parallelogram parallel to B D, and B D will bisect all similar lines drawn parallel to A C.

Then we may conceive, as in the last example, the plate as made up of a number of parallel plates, each parallel to the plane B D D′ B′, each of which will balance about a line drawn through the centres of A A and C C′.

Again, we may conceive the plate as composed of a number of parallel plates parallel to A A′ C′ C, which will each balance about a line drawn through the centre of D D and B B′.

G, the intersection of these lines, or the centre of E E′, will therefore be the centre of gravity of the plate.

To find the centre of gravity of the surface of any rectilineal figure, we have only to divide it into triangles, find the centre of gravity of each triangle, suppose weights acting at each of these centres of gravity proportional to the surface of the triangle at whose centre of gravity it is supposed to act, and then find the centre of gravity of these weights, which will be the centre of gravity of the figure.

It will be found, on calculation, that the centre of gravity of any triangular surface is the same as that of three spheres, or any other body, whose weights are equal, placed with their centres of gravity in the angular points of the triangle. This also applies to a parallelogram, but not to all four-sided figures.

EXAMPLE III.—*To find the centre of gravity of a homogeneous solid of uniform density, whose form is that of a pyramid on a triangular base.*

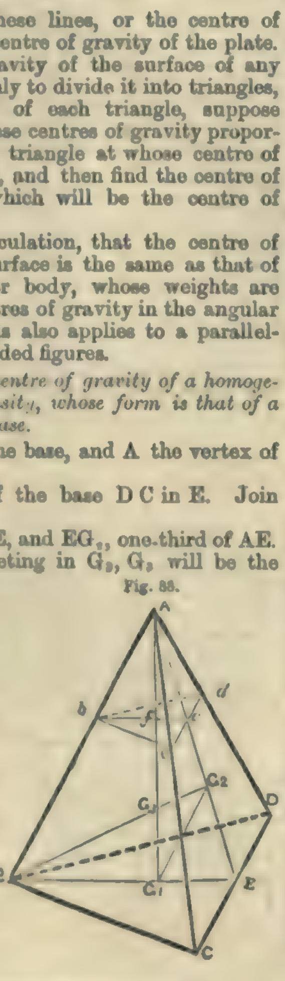
Let B C D (Fig. 88) be the base, and A the vertex of the pyramid.

Bisect one of the sides of the base D C in E. Join A E, B E.

Take EG_1, one-third of BE, and EG_2, one-third of AE.

Join $A G_1$ and $B G_2$ meeting in G_3, G_3 will be the centre of gravity of the pyramid.

Fig. 88.



In A C take any point *c*, through *c* draw *c d* parallel to C D cutting A E in *e*, and *b c* parallel to B C. Join *b d* and *b e* cutting $A G_1$ in *f*.

Then the plane *b c d* is evidently parallel to the plane B C D, and the line *b e* parallel to the line B E.

Hence by similar triangles $A E G_1$, $A e f$, $\frac{e f}{E G_1} = \frac{A e}{A E}$ and by similar triangles $A e b$ $A E B$, $\frac{b e}{B E} = \frac{A e}{A E}$

Therefore $\frac{e f}{E G_1} = \frac{b e}{B E}$ but $E G_1 = \frac{1}{3} B E$

Hence $e f = \frac{1}{3}$ of $b e$.

Again, because *c d* is parallel to C D, and C D is bisected in E, *c d* is also bisected by A E.

f therefore is the centre of gravity of the triangle *b c d*.

In a similar manner it may be shown that the centre of gravity of any triangular slice of the pyramid parallel to B C D must lie in the line $A G_1$; and since we may conceive the pyramid made up of an infinite number of such parallel slices, the centre of gravity of the whole pyramid must lie in $A G_1$.

By similar reasoning it may be shown that the centre of gravity of the pyramid lies in the line $B G_2$.

Consequently, G_3, the intersection of the lines $A G_1$ and $B G_2$, will be the centre of gravity of the pyramid.

Join $G_1 G_2$, then since $E G_2 = \frac{1}{3} A E$, and $E G_1 = \frac{1}{3} B E$, $G_1 G_2$ is parallel to A B. Consequently the triangle $G_3 G_1 G_2$ is similar to the triangle $G_3 A B$, and the triangle $E G_1 G_2$ to the triangle E B A.

Hence $\frac{G_1 G_3}{A G_3} = \frac{G_1 G_2}{A B}$ and $\frac{G_1 G_2}{A B} = \frac{E G_1}{B E} = \frac{1}{3}$.

Therefore $\frac{G_1 G_3}{A G} = \frac{1}{3}$ and $G_1 G_3 = \frac{1}{3} A G_3$

Or $G_1 G_3 = \frac{1}{4} A G_1$.

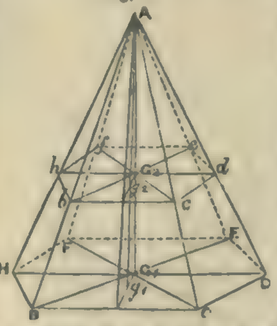
Hence the centre of gravity of the pyramid is found to be in the line joining the vertex and the centre of gravity of the base, at a distance of a fourth of its length.

EXAMPLE IV.—*To find the Centre of Gravity of any Pyramid of uniform density, whose base is any Polygon.*

Let A be the vertex of the pyramid, B C D E F H its polygonal base (Fig. 89). Let G_1 be the centre of gravity of this base; join $A G_1$, and in $A G_1$ take G_2 so that $G_1 G_2 = \frac{1}{4} A G_1$. G_2 will be the centre of gravity of the pyramid.

Join G_1 with each of the angular points of the base, through G draw the plane *b c d e f h* parallel to the base, and cutting A B in *b*, A C in *c*, &c., and join G_2 *c*, G_2 *d*, &c.

Fig. 89.



Let g_1 be the centre of gravity of the triangle $B G_1 C$, join $A g_1$ cutting the triangle $b G_2 c$ in g_2.

Then since the triangle $b G_2 c$ is parallel to the triangle B G C and $G_1 G_2 = \frac{1}{4} A G_1$; hence $g_1 g_2 = \frac{1}{4} A g_1$ and g_2, is the centre of gravity of the pyramid $A B C G_1$ on a triangular base G_1 B C, and it lies in the plane *b c d e f h*. In a similar manner it may be shown that the centres of gravity of every one of the triangular pyramids $A G_1$ C D, $A G_1$ D E. &c., into which the whole pyramid may be divided, all lie in the plane *b c d e f h*.

It follows, therefore, that the centre of gravity of the whole pyramid must lie in this plane.

Again the plane *b c d e f h* is in every respect similar to the base, and G_2 its centre of gravity will therefore lie in the line $A G_1$. In like manner it may be shown that the centre of gravity of every section of the pyramid parallel to the base will lie in $A G_1$; hence the centre of gravity of the whole pyramid must lie in $A G_1$.

We have shown, therefore, that the centre of gravity of the whole pyramid must be in the plane *b c d e f h*, and also in the line $A G_1$. Hence the centre of gravity must be their intersection G_2.

The centre of gravity of any pyramid of uniform density on a polygonal base, will lie in the line joining its vertex and the centre of gravity of the base, at a distance equal to three-fourths of its length from the former, or one-fourth of its length from the latter.

The above reasoning is altogether independent of the number of the sides of the polygon, and since we may conceive a curve to be made up of an infinite number of straight lines, or a polygon bounded by an infinite number of small sides, the above solution enables us to determine the centre of gravity of a cone with a curvilinear base.

Hence the centre of gravity of a right or oblique cone on any curvilinear base is found by joining the centre of gravity of the base with the apex of the cone, and taking a point in this line, equal to one-fourth of its length, measuring this point from the centre of gravity of the base.

CHAPTER II.

THE MECHANICAL POWERS.

Any instrument by means of which a force is communicated from one point to another, so as to keep at rest or set in motion a body acted on by another force, is called a machine. The simplest of these instruments are *cords*, *rods*, and *hard planes*; and these, by their combinations, form all complex machines, however various their forms and actions.

In statics, we only consider machines when the forces acting upon them are in a state of equilibrium; motion will be produced by an addition to some of the forces which produce equilibrium. But the discussion of this branch of the subject belongs to Dynamics, which will be investigated in the following chapter.

For the sake of simplicity, and to enable us to apply the theoretical principles we have already proved, we consider *cords* as being destitute of weight and perfectly flexible, *rods* and *planes* as perfectly rigid, inflexible, and without weight. When necessary, we can take the weights of the elementary parts of our machines into consideration, by considering their weights as a force proportional to their weight applied to the centre of gravity, in a vertical direction.

We also neglect the friction of all surfaces in contact with each other. It is evident, therefore, that our machines will be theoretical ones, which cannot exist in nature, and whose properties cannot be strictly proved by experiment. But if we determine the rigidity, flexibility, and friction of the substances composing our machine by experiment, and compare the force exerted by a real machine with the force it ought to exert by theory, we may arrive at a knowledge of the retarding forces produced by friction or want of flexibility; and thus by our theoretical knowledge of the combination of machines, estimate the forces produced by any actual complex machine, the friction or flexibility of whose elements we have determined.[*]

MECHANICAL POWERS.—The simplest combinations of these machines are called the *mechanical powers.* They are usually regarded as seven in number:—1, the lever; 2, the wheel and axle; 3, the toothed wheel; 4, the pulley; 5, the inclined plane; 6, the wedge; 7, the screw.

The wheel and axle, toothed wheel and pulley, may be regarded as modifications of the lever, and the wedge and screw as particular cases of the inclined plane.

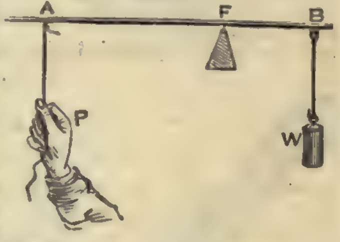
THE LEVER.—The simplest form of a lever is a straight rod, supposed to be inflexible and without weight, resting on a fixed point, somewhere in its length, about which it can turn freely, and having two forces applied at two other points of the rod.

The fixed point on which it rests, and about which it can turn, is called the *fulcrum;* one of the forces applied to it is called the *power*, and the other the *weight.* The distances of the points of application of the power and weight, from the fulcrum, are called the *arms* of the lever.

There are three kinds of levers, distinguished by the relative position of the *power*, *weight*, and *fulcrum*.

Lever of the first kind. — In the lever of the first kind the power P (Fig. 90) and the weight W act in the same direction on opposite sides of the fulcrum F. A crow-bar (Fig. 91), by means of which a man raises a heavy body W by placing one extremity B under W, and resting it on any body C while he presses the extremity B′, is an instance of a lever of the first kind.

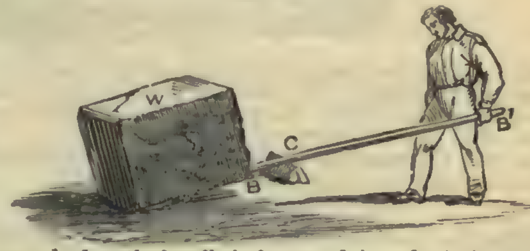
Fig. 90.



A poker is another. In this case the coals form the weight, the bar of the grate the fulcrum, and the hand the power.

The spade is a lever; the ground against which it is pressed when the handle is depressed, in order to turn up the earth in front of it, being the fulcrum.

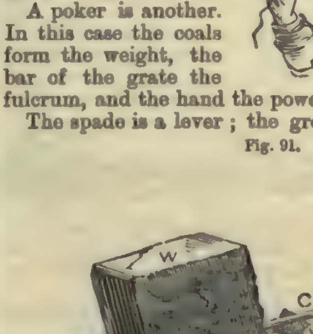
Fig. 91.



Scissors and carpenters' pincers are examples of double levers of the first kind.

Lever of the second kind.—In the lever of the second kind the power P (Fig. 92) and the weight W act in opposite directions on the same side of the fulcrum F, the weight being nearer to the fulcrum than the power.

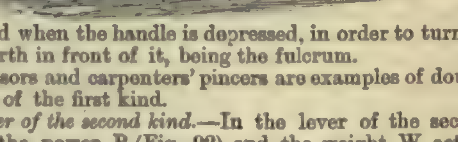
Fig. 92.



A cutting-knife (Fig. 93) and an oar are instances of levers of the second kind. In the case of the oar, the arm of the rower is the power, the pressure of the oar on the side of the boat is the weight, and the point of the blade of the oar, which is for a moment stationary in the water, forms the fulcrum.

Nutcrackers give a good illustration of a double lever of the second kind.

Fig. 93.

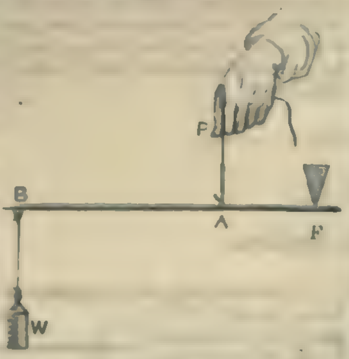


---

[*] See *Pressure, Tension,* and *Flexible Cords,* p. 693.

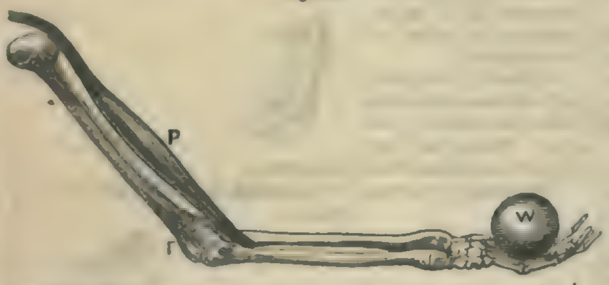
Lever of the third kind.—In the lever of the third kind the power P (Fig. 94) and the weight W act as in the second kind, in opposite directions on the same side of the fulcrum; but in the third species of lever, the power is nearer the fulcrum than the weight.

Fig. 94.



Most muscles in animals are generally inserted near the joint, as in Fig. 95, and act as levers of the third kind; the joint forms the fulcrum; the limb which the muscle moves, together with any resistance opposed to its motion, represents the weight; while the force exerted by the contraction of the muscle is the power. The treadle of a turning-lathe, or razor-grinder's machine, where the foot of the operator acts as the power, is a lever of the third kind.

Fig. 95.



A pair of tongs, and a pair of sheep-shears, afford familiar instances of double levers of the third kind.

PROPOSITION XXIII.

To find the Conditions of Equilibrium and the Pressure on the Fulcrum when two Parallel Forces act in the same plane on a straight lever.

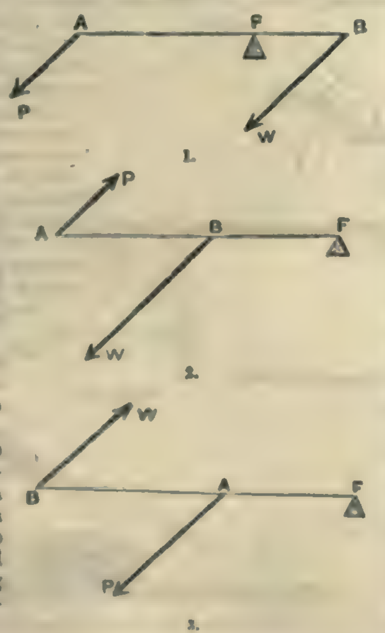
Let P and W be two parallel forces acting at A and B, on the straight lever A B whose fulcrum is F in each of the three kinds of levers.

And let A P and W B (Fig. 96—1, 2, and 3) represent these forces in magnitude and direction.

In order that there may be equilibrium, the resultant of the two parallel forces must pass through F, and the pressure on that point will be equal to their resultant, and this will be destroyed by the resistance of the fulcrum.

The proposition is therefore reduced to the case of Prop. XI., which we have already demonstrated; and from this we may learn that the pressure on F will be equal to P + W acting in a direction parallel to P or W.

Fig. 96.



And also that $P \cdot AF = W \cdot BF$ or $\frac{P}{W} = \frac{BF}{AF}$ in every case.

From this we find that in the lever of the first kind, the power may be less than, equal to, or greater than, the weight; in the second kind the power is always less; and in the third kind always greater than the weight.

In the preceding cases we have supposed the lever to be without weight; we shall show how to take the weight of lever into consideration, in the cases of the balance and steelyard.

PROPOSITION XXIV.

To find the Conditions of Equilibrium of two Forces acting in the same plane on a Bent Lever, when the directions of the Forces are not Parallel.

Let A C B (Fig. 97) be a bent lever consisting of a portion of a plane rigid body, supposed to be destitute of weight. C the fulcrum about which the lever turns. A and B the points of application of the two forces represented in magnitude and direction by A P and B W.

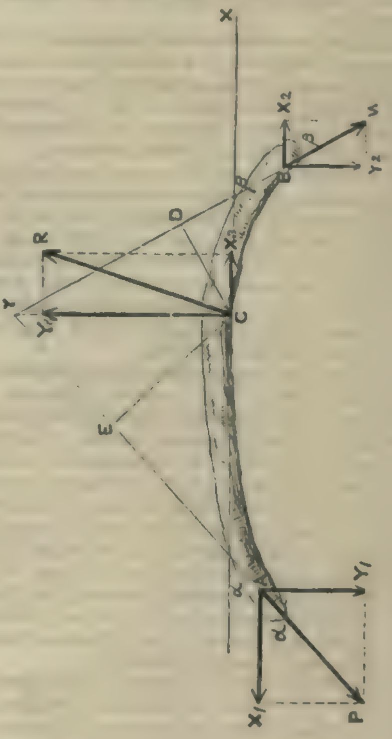


Fig. 97.

The effect of these forces will be to produce a pressure on C; and when there is equilibrium, this pressure must be destroyed by the reaction R of the fulcrum C, represented in magnitude and direction by C R.

Let α and β be the angles which A P and B W produced, make with a line C X drawn through C at right angles to the vertical C Y passing through C, and θ the angle C R makes with C X.

R and θ are two unknown quantities which we have to determine: through C draw C E and C D perpendicular to A P and B W produced.

We may regard our lever as a rigid body kept in equilibrium by the three forces P, W, and R. Resolving these forces into forces parallel to C X and C Y, X_1 and Y_1 being the resolved parts of P, X_2 and Y_2, those of W, and X_3 and Y_3 those of R; and taking moments about C, we have by Prop. XVIII., the following conditions of equilibrium.

(1.) $X_3 + X_2 - X_1 = 0$, or $R \cos. \theta + W \cos. \beta - P \cos. \alpha = 0$.

(2). $Y_2 - Y_3 - Y_1 = 0$, or $R \sin. \theta - W \sin. \beta - P \sin. a = 0$.

And (3). $P \cdot CE - W \cdot CD = 0$.

From this last equation we obtain $P \cdot CE = W \cdot CD$, or

$$\frac{P}{W} = \frac{CD}{CE} = \frac{\text{Perpendicular on direction of W.}}{\text{Perpendicular on direction of P.}}$$

From equations (1) and (2) we can determine R and θ, and consequently the magnitude and direction of the pressure on the fulcrum, which will be equal to R, and act in the direction opposite to C R.

Transposing equation

$$(1).\ R \cos. \theta = P \cos. a - W \cos. \beta$$
$$(2).\ R \sin. \theta = P \sin. a + W \sin. \beta$$

Dividing one of these equations by the other, we have

$$\tan. \theta = \frac{P \sin. a + W \sin. \beta}{P \cos. a - W \cos. \beta}, \text{ which determines } \theta.$$

Or, adding their squares, we have

$$R^2 (\cos.^2 \theta + \sin.^2 \theta) = P^2 (\cos.^2 a + \sin.^2 a) + W^2 (\cos.^2 \beta + \sin.^2 \beta) - 2\,P\,W (\cos. a \cos. \beta - \sin. a \sin. \beta).$$

Hence, by Trigonometry,

$$R^2 = P^2 + W^2 - 2\,P\,W \cos. (a + \beta),$$

which determines the magnitude of R.

If we had supposed B instead of C as the point of application of the fulcrum, and taken our moments about B, we should have had

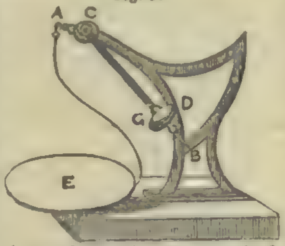
$$\frac{P}{R} = \frac{\text{Perpendicular on direction of R}}{\text{Perpendicular on direction of P}}.$$

Hence the condition of equilibrium in a lever of any kind, *is that the power must be to the weight, inversely as the perpendiculars drawn from the fulcrum on their directions.*

The bent lever evidently includes the straight one, as in the latter case A, B, and C are in the same straight line.

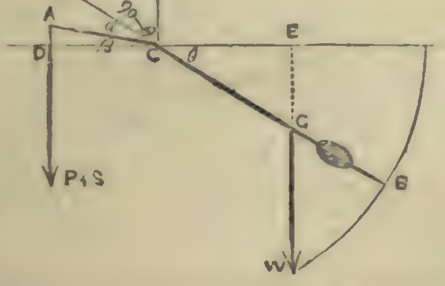
THE BENT-LEVER BALANCE.—The bent-lever balance (Fig. 98) is a machine which, within certain limits, enables us to weigh substances without the use of weights; it consists of a bent lever whose two arms are A C and B C, movable about a fulcrum C. The fulcrum C is fixed to a stand which carries a graduated arc; over this arc the extremity B of the lever moves as C B turns round the fulcrum C. From the other extremity A, a scale-pan E is so suspended as to have its centre in all positions of the lever in the vertical passing through A.

Fig. 98.



A weight D, is fixed to the arm C D so as to bring the centre of gravity of the whole lever and scale-pan to some point below the fulcrum C: the magnitude of this weight is so arranged that the extremity B of the lever shall point to zero on the graduated arc, when the scale-pan is empty, and the lever is in a state of equilibrium.

Fig. 99.



To graduate the arc, weights of 1, 2, 3, &c., pounds or ounces, or whatever denomination of weight the instrument is intended to indicate, are placed successively in the scale-pan; and the corresponding points of the arc over which B rests, are marked on the scale as 1, 2, 3, &c.

This balance is of great use for determining quickly the weights of bodies where extreme nicety is not essential.

To explain the graduation of this balance mathematically,

Let C (Fig. 99) be the fulcrum of the lever, A C and B C its arms; let G in B C be the centre of gravity of the whole lever, exclusive of the scale-pan and wire by which it is suspended. Let W represent this weight, and let $CA = a$ and $CG = b$. Also let S represent the weight of the scale-pan and wire by which it is suspended, P that of a body placed in the scale-pan.

Let θ be the angle C B makes with a line D C E drawn through C perpendicular to C F, the vertical passing through C; β the angle A C makes with D C E.

Also let $a = BCA$ be the angle the arms of the lever make with each other, and let $\acute{a} = 180 - a$, and let D and E be the points where the vertical lines passing through A and B cut the line D C E.

Then Prop. XXIV. $(P+S) \cdot CD = W \cdot CE$,

or $(P+S)\, a \cos. \beta = W \cdot b \cos. \theta$.

but $\beta = 90 - \theta + \acute{a} = 90 - (\theta - \acute{a})$; hence $\cos. \beta = \sin. (\theta - \acute{a})$.

Therefore $(P+S) a \sin. (\theta - \acute{a}) = Wb \cos. \theta$,

or $(P+S) a \{\sin. \theta \cos. \acute{a} - \cos. \theta \sin \acute{a}\} = Wb \cos. \theta$,

$$\text{and } \tan. \theta \cos. \acute{a} - \sin. \acute{a} = \frac{Wb}{(P+S)a}$$

$$\text{or } \tan. \theta = \frac{W \cdot b}{(P+S) a \cos. \acute{a}} + \tan. \acute{a}.$$

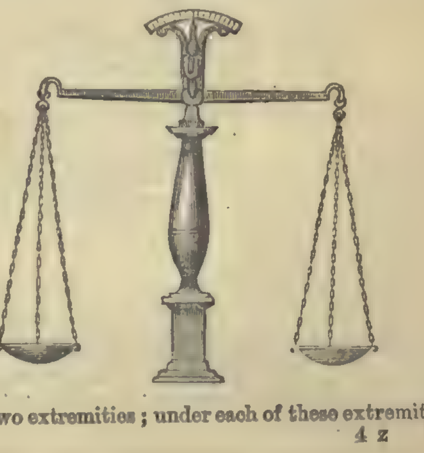
Hence if we wish to graduate the arc for pounds, we must take P successively equal to 0, 1, 2, 3, &c., pounds, in which case tan. θ will be successively equal to

$$\frac{W \cdot b}{Sa. \cos. \acute{a}} + \tan \acute{a},\ \frac{Wb}{(S+1)a. \cos. \acute{a}} + \tan. \acute{a},$$
$$\frac{Wb}{(S+2)a. \cos. \acute{a}} + \tan \acute{a},\ \frac{Wb}{(S+3)a. \cos. \acute{a}} + \tan a, \text{ \&c.},$$

where W and S represent the weight of the lever and scale-pan in pounds.

THE COMMON BALANCE.—This instrument is popularly called the *scales*, or a *pair of scales*, and is perhaps more frequently used than any other for determining the weights of substances or goods. It consists of a lever supported on an axis or fulcrum equally distant from its two extremities; under each of these extremities

Fig. 100.



a dish is suspended, in one of which the substance to be weighed is placed, and in the other the weights by which its value is determined.

The lever is so constructed as to be capable of moving on its axis in a vertical plane; and when a given weight is placed in one dish, and a substance equal in weight to it in the other, after vibrating some little time, it assumes a horizontal position. When a slight excess of weight is added to either dish, the lever again vibrates and assumes such a position of rest, that the extremity above the dish containing an excess of weight over the other, lies below the horizontal line. The lever is called the *beam*; and the two dishes, *scale-pans*.

There are three requisites in a balance:—

First.—When equal weights are placed in the scale-pans, the two extremities of the beam should rest in a perfectly horizontal line. This is called its *horizontality*.

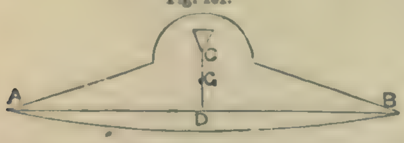
Second.—On the slightest addition of weight to either scale, the beam should lose its horizontal position. This is called its *sensibility*, and is measured by the smallest weight which causes the beam to depart from its *horizontality*.

Third.—After any disturbance the beam should assume a state of rest as speedily as possible: this is called its *stability*.

We shall now proceed to consider the mathematical conditions which must be satisfied, in order to obtain these requisites; for this purpose we must first confine our attention to the construction of the *beam*.

Let A B (Fig. 101) represent the beam, G its centre of gravity, and C the point on which its axis or fulcrum is supported.

Fig. 101.



Join A B, and produce C G to meet A B in the point D.

To secure the *horizontality* of the beam, the points C and G must not coincide, for if they did, from the properties of the centre of gravity, we should have indifferent equilibrium, and the beam, either by itself or when loaded at its extremities with equal weights, would rest in every position in which the line A B might be placed.

When C does not coincide with G, by Prop. XIX., and the beam is at rest, C G will assume a vertical position; hence in order that A B may be horizontal, C D must be perpendicular to A B. In order that this horizontal position may be that of equilibrum when equal weights are suspended from A and B, we must also have A D = B D.

The axis C is generally a prismatic piece of metal, which pierces and also is firmly fixed at right angles to the beam. This prism rests on one of its edges, technically called the *knife-edge*, on a plane or curved surface, so placed as a support on each side of the beam, that the edge or line of support about which the beam oscillates is horizontal and perpendicular to the plane in which it oscillates. The axis might be a cylinder or cone working in a socket, but the *knife-edge* is generally preferred, in order to avoid friction as much as possible.

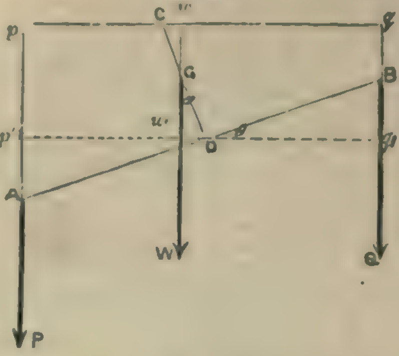
The conditions of *horizontality* given above require, therefore, that the plane passing through the line of support and the centre of gravity of the beam shall be at right angles to, and also bisect, the line passing through its extremities, or the points from which the scale-pans are suspended.

To determine the other two conditions, retaining the same letters as before, let two unequal weights P and Q (Fig 102), represented in magnitude and direction by A P and B Q, be suspended from A and B.

Let θ be the angle A B makes with the horizontal line p' q' drawn through the point D, and let p q cut A P in p and B Q in q.

Through C draw p q parallel to p' q', and cutting A P

Fig. 102.



in p, and B Q in q. Let W, represented in magnitude and direction by G W, be the weight of the beam and its axis, and let the line G W cut p q in w, p' q' in w'.

Also let A D = D B = a, C G = b, and C D = c.

Since C D is at right angles to A B, and θ is the angle A B makes with the horizontal line p' q', it will also make the angle θ with the vertical line w G w'.

Also because p q is parallel to p' q' and P p', w w' and q q' are parallel to each other, p w = p' w', and q w = q' w'.

Taking the moments of the three forces P, Q, and W, about the point C, we shall have, as a condition of equilibrium,

$$W \cdot Cw + Q \cdot Cq = P \cdot Cp.$$

$$\begin{aligned}
\text{But } Cq &= Cw + wq = Cw + w'q' \\
&= Cw + w'D + Dq' \\
&= CG \sin.\theta + GD \sin.\theta + DB \cos.\theta \\
&= b \sin.\theta + (c - b) \sin.\theta + a \cos.\theta \\
&= c \sin.\theta + a \cos.\theta.
\end{aligned}$$

$$\begin{aligned}
\text{Again } Cp &= pw - Cw = p'w' - Cw \\
&= p'D - w'D - Cw \\
&= a \cos.\theta - (c - b) \sin.\theta - b \sin.\theta \\
&= a \cos.\theta - c \sin.\theta.
\end{aligned}$$

Also $Cw = b \sin.\theta$.

Substituting these values of Cq, Cp, and Cw in the equation $W \cdot Cw + Q \cdot Cq = P \cdot Cp$, we have

$$W \cdot b \sin.\theta + Q(c \sin.\theta + a \cos.\theta) = P(a \cos.\theta - c \sin.\theta).$$

Dividing both sides by $\cos.\theta$

$$W \cdot b \tan.\theta + Q(c \tan.\theta + a) = P(a - c \tan.\theta);$$

$$\text{Or} \quad (Wb + Qc + Pc) \tan.\theta = (P - Q)a;$$

$$\text{And} \quad \frac{\tan.\theta}{P - Q} = \frac{a}{W \cdot b + (P + Q)c}.$$

Now the *sensibility* of the balance for a given difference of P and Q will be greater, the greater the angle θ; also for a given value of θ, the sensibility will be greater the smaller the difference between P and Q. Since $\tan.\theta$ is greater, the greater the angle θ, it follows that $\frac{\tan.\theta}{P - Q}$ is a measure of the sensibility of the balance.

Hence the greatest sensibility will be attained when $\frac{a}{Wb + (P + Q)c}$ is as great, or $\frac{Wb + (P + Q)c}{a}$ as small as possible.

In making this calculation we have neglected the friction of the edge of the fulcrum on its supports, which will have a tendency to diminish the sensibility.

In instruments where great accuracy is required, such as chemical, philosophical, and assay balances, this friction is diminished as much as possible by making the knife-edge of the fulcrum of hard polished steel, and the support on which it rests a plane of polished agate. Having thus obviated the diminution of sensibility due to the friction, it appears from the above expression for the sensibility of the balance, that it will be greater, the greater a is, and the less W, b, and c are.

We must, therefore, make the beam as light and as long as we possibly can, and the distances of G and D from C as small as may be consistent with other conditions.

The scale-pans and the cords, or apparatus by which they are suspended, must also be made as light as can be, compatible with the uses of the balance, as they increase the values of P and Q, whose sum is an element which diminishes the sensibility.

When equal weights act on A and B, the extremities of the beam, its stability is measured by its tendency to resume a state of rest, after its equilibrium has been disturbed. This tendency will depend upon the magnitude of the sum of the moments of the forces, about the point C, for any given position of the beam; *i.e.*, for any particular value of θ.

The sum of the moments of the three forces P, Q, and W about C, when A B is inclined at an angle θ to the horizontal, or C D at the same angle to the vertical, will be

$$W \cdot Cw + Q \cdot Cq - P \cdot Cp;$$

$$\text{or } Wb \sin.\theta + Q(c \sin.\theta + a \cos.\theta) - P(a \cos.\theta - c \sin.\theta).$$

When P and Q are equal, this expression becomes

$$Wb \sin.\theta + Pc \sin.\theta + Pc \sin.\theta;$$

$$\text{or } (W \cdot b + 2P \cdot c) \sin.\theta.$$

When θ is zero, sin. θ is also zero, and this expression becomes the same, or the sum of the moments is zero, which it must be, in order that there should be equilibrium. But for any other finite value of θ, the magnitude of the *stability* will be greater, as $W \cdot b + 2P \cdot c$ is greater; that is, as W, P, b and c are greater.

These conditions are contrary to those required for *sensibility*, which for any given value of a, demand that W, P, b and c shall be as small as possible.

Hence, while the arm of the balance remains of the same length, any increase of *sensibility* is made at the expense of its *stability*; but the quantities b, c, W and P remaining the same, we may increase the *sensibility* without injury to the *stability* by increasing a, or the length of the arm of the balance.

Where minute differences of weight are not matters of importance, and quickness of determination essential, as in weighing substances rapidly, which are not of great value in proportion to their weight, *stability* is of more importance than *sensibility*. The reverse, however, is the case where the substance is of great value in proportion to its weight, or where extreme accuracy is required.

In all that has been said, it must be remembered that the weight P includes that of the scale-pan, together with the apparatus by which it is suspended.

The scale-pan must be so suspended, that its centre of gravity, as well as that of the weight or substance placed in it, may be exactly in the vertical line passing through the extremity of the beam, from which it is suspended. From the mathematical expressions given above for *sensibility* and *stability*, both depending upon P, it follows that the same balance will have different degrees of these qualities according as it is used for determining greater or less weights. The quantities of substances which are used in philosophical or chemical balances being generally very small, a balance which is very *sensible* when no weight is placed in the scales, will be of almost equal *sensibility* for every weight with which it is intended to be used.

A needle is usually fixed to the beam in the direction of the line C G, which points vertically upwards or downwards when the beam is in a horizontal position. A graduated arc or scale attached to the support of the balance to indicate the arcs described by the extremity of this needle, as the beam oscillates, is a very convenient addition. When G is very near C, the oscillations will be very slow; in this case, the equality of the weights in the scale-pans may be ascertained by means of the index-needle, before the balance comes to a state of rest. When the weights are equal, the extremity of the needle will describe equal arcs on both sides of the vertical line; when they are unequal, the scale which preponderates will be indicated by a greater arc being described on that side than the other. This method renders *stability* of much less importance than sensibility.

Where great accuracy is required, the disuse of this long index-needle, almost in contact with the graduated arc, and the substitution in its place of a graduated arc attached to one end of the beam has been recommended. This arc is viewed through a fixed compound microscope, having a horizontal wire in the focus of the eye-piece; or by a mirror attached to the beam, in which the reflected image of a scale is viewed through a telescope.

In very accurate instruments the scale-pans are suspended from steel knife-edges, resting on agate planes fixed to the extremities of the beam. The balance should be constructed as much as possible of brass, as steel and iron are apt to acquire magnetic properties. Palladium has been used for the construction of the beam, and platinum is to be preferred for the scale-pans. When glass scale-pans are used, care must be taken not to excite their electrical properties; a difference of half a grain may be produced by merely cleaning one of the glass scales with a dry silk handkerchief. In constructing the beam, care must be taken by making it hollow, or if solid, by cutting out portions of it, to secure the greatest degree of lightness with the greatest length of arm which is compatible with its rigidity, or the retention of its form, under all the weights to which it is intended to be subjected.

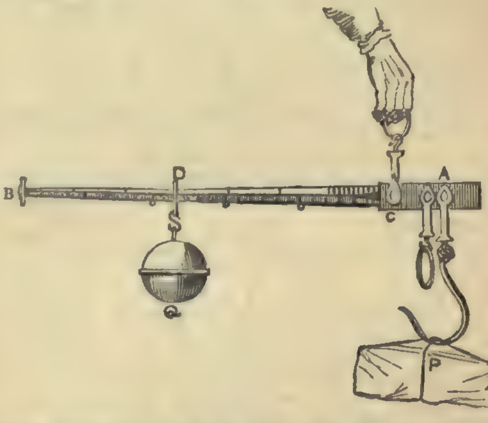
All very sensitive balances have a contrivance by which the knife-edges, which support the beam and scale-pans are lifted from the planes on which they play, whenever the instrument is not in use. The knife-edges are thus preserved from becoming blunt, or wearing the agate planes, and the beam is freed as much as possible from every strain, which would tend to alter its shape.

In addition to all these precautions, the balance should be enclosed in a glass case, for its preservation from dust and injury: to prevent error from the action of currents of air, a window at the side affords the means of introducing weights and the substance to be weighed, without removing the case. A cup containing quick-lime, or some other powerful absorbent of moisture, should also be kept within the case.

Ramsden constructed a balance for the Royal Society of such extreme *sensibility*, that when weighted with 10 pounds, it turned with about the thousandth part of a grain.

From the above description, it is manifest, that the construction of a perfect balance may be regarded as impossible, though one may be nearer than another to perfection. Borda invented a very simple method, by means of which very accurate results may be obtained by a balance sufficiently *sensitive* and well-constructed on its knife-edges, though the points of suspension of the scale-pans may not be equidistant from its fulcrum.

Fig. 103.



His ingenious device is to weigh the article whose weight is to be determined by weights or any other substance, such as sand, placed in the other scale: when equilibrium has been thus obtained, the article is removed and replaced by weights until equilibrium has been again restored. These latter weights determine that of the article; and thus any error arising from inequality of the arms of the balance is eliminated.

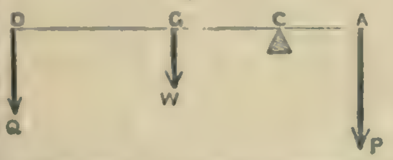
THE ROMAN STEELYARD OR BALANCE.—This balance consists of an iron or steel lever A B, (Fig. 103) with unequal arms A C and B C resting on a fulcrum with a knife-edge at C, which plays on a pivot passing through a support held or suspended by a ring. The substance P whose weight is to be determined, is suspended from the point A by a hook, while a constant weight Q, called the *counterpoise*, is attached to a ring D, which can be slipped along the longer arm C B. The edge of the arm C B is so graduated that the point D at which the counterpoise Q suspended from it balances P, determines the weight of the latter in pounds and ounces, or any other convenient denomination of weight for which the steelyard may have been graduated.

The steelyard is sometimes furnished with a second fulcrum and apparatus for its suspension, nearer to A than C; the position of the lever is then inverted, and another graduation on what was before the under edge of the arm B C, gives the weight of P for the new position of the fulcrum. The same instrument has thus two different ranges of weights for the same counterpoise, the fulcrum nearer to A being used for substances lying within a range of weights greater than that for which the other is graduated.

To Graduate the Roman Steelyard.—The Roman steelyard may be regarded as a heavy lever with unequal arms resting on a fulcrum C (Fig. 104).

Let W be the weight of the lever and the hook or scale-pan by which P is suspended, G the position of their joint centre of gravity, Q the weight of the counterpoise, together with the ring and chain by which it is suspended.

Fig. 104.



The steelyard may now be considered as a lever without weight, whose fulcrum is C, acted on by three parallel and vertical forces, P, W and Q, at the points A, G, and D, represented in magnitude and direction by the lines A P, G W, and D Q.

When these forces produce equilibrium, taking moments about the point C, we have

$$P \cdot A C = W \cdot G C + Q \cdot C D.$$

Hence, transposing, we have

$$Q \cdot C D = P \cdot A C - W \cdot G C$$

$$\text{or } C D = \frac{P}{Q} A C - \frac{W}{Q} G C.$$

Now let D_1, D_2, D_3, D_4, &c. (Fig. 105), represent the distances from C at which weights of one, two, three, four, &c., pounds, or any other unit of weight for which the steelyard is to be graduated, suspended from A are respectively balanced by the counterpoise.

Fig. 105.

Substituting, therefore, for P the numbers 1, 2, 3, 4, &c., and D_1, D_2, D_3, D_4, &c., for D in the above equation, we have

$$C D_1 = \frac{A C}{Q} - \frac{W}{Q} G C$$

$$C D_2 = 2 \frac{A C}{Q} - \frac{W}{Q} G C$$

$$C D_3 = 3 \frac{A C}{Q} - \frac{W}{Q} G C$$

$$C D_4 = 4 \frac{A C}{Q} - \frac{W}{Q} G C, \text{ \&c.}$$

In A C take a point B such that $B C = \frac{W}{Q} G C$, and make $B D_1 = \frac{A C}{Q}$, where Q represents the weight of the counterpoise, in the same unit which is chosen for the graduation, then make $D_1 D_2 = B D_1$, $D_2 D_3 = B D_1$, $D_3 D_4 = B D_1$, &c. D_1, D_2, D_3, D_4, &c., will mark the points at which the counterpoise Q will balance weights of 1, 2, 3, 4, &c., pounds suspended from A.

For

$$C D_1 = B D_1 - B C = \frac{A C}{Q} - \frac{W}{Q} G C.$$

$$C D_2 = B D_2 - B C = 2 B D_1 - B C = 2 \frac{A C}{Q} - \frac{W}{Q} G C.$$

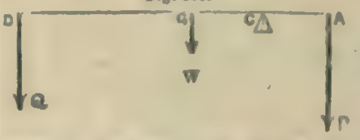
$$C D_3 = B D_3 - B C = 3 B D_1 - B C = 3 \frac{A C}{Q} - \frac{W}{Q} G C.$$

$$C D_4 = B D_4 - B C = 4 B D_1 - B C = 4 \frac{A C}{Q} - \frac{W}{Q} G C.$$

When the instrument is so constructed that the centre of gravity G of the steelyard and scale, or hook, lies in the vertical line passing through C, the quantity B C or $\frac{W}{Q} G C$ becomes zero, and the points of graduation are taken at equal intervals from C.

THE DANISH STEELYARD OR BALANCE.—This instrument differs from the Roman steelyard in these respects, that the counterpoise is fixed at one of the extremities, while the fulcrum is movable. The edge of the steelyard is graduated, and the point at which the fulcrum is placed to cause the fixed counterpoise to balance the substance whose weight is to be determined, marks its value.

Fig. 106.



To Graduate the Danish Steelyard.—Let P, W, Q, and the straight lines P A, G W, and D Q (Fig. 106), represent the same forces in this case, as in that of the Roman steelyard; in this instance, however, it is C and not D which is the movable point.

Then taking moments of the forces as before, about the point C, we have

$$\begin{aligned} P \cdot A C &= W \cdot G C + Q \cdot D C \\ &= W (A G - A C) + Q (A D - A C). \end{aligned}$$

By transposition $(P + W + Q) A C = W \cdot A G + Q \cdot A D$;

$$\text{or } A C = \frac{W \cdot A G + Q \cdot A D}{P + W + Q}.$$

Let C_1, C_2, C_3, C_4, &c., represent the points at which 1, 2, 3, 4, &c., pounds will be balanced by the counterpoise when the fulcrum is placed under these points. Hence substituting C_1, C_2, C_3, C_4, for C, and 1, 2, 3, 4, &c., for P in the preceding expression, we have

$$A C_1 = \frac{W \cdot A G + Q \cdot A D}{1 + W + G}$$

$$A C_2 = \frac{W \cdot A G + Q \cdot A D}{2 + W + G}$$

$$A C_3 = \frac{W \cdot A G + Q \cdot A D}{3 + W + G}$$

$$A C_4 = \frac{W \cdot A G + Q \cdot A D}{4 + W + G}.$$

The reciprocals of these quantities are in arithmetical progression, and therefore the distances of the points C_1, C_2, C_3, C_4, &c., from A will form an harmonical progression.

THE BALANCE OF QUINTENZ.—This balance, named after its inventor Quintenz, is frequently employed on railways for determining the weight of luggage, and affords a good example of a combination of levers. It is represented in Fig. 108. Fig. 107 is added for the purpose of showing its mechanism more clearly. A platform A B on which the body Q, which we wish to be weighed, is placed, is fixed firmly to an upright piece of framework B C. B C again is attached rigidly to an oblique piece D C fixed in D, as shown in Fig. 107, so that the whole portion A B C D forms one rigid and inflexible body. This rigid piece A B C D is supported at E by a knife-edge fulcrum, resting on the bar or lever F G, and at D by a rod H K, which is firmly fixed to D, and suspended by a hook at K from the lever L M N.

Fig. 107.

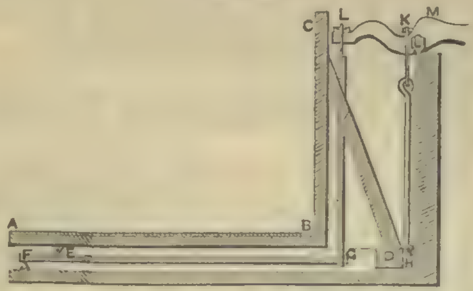


Fig. 108.

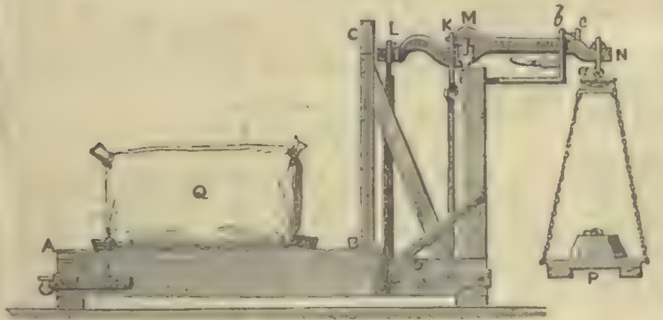


The whole weight, therefore, of Q and the framework A B C D rests on the points E and K.

The lever F G is supported by a fulcrum at one extremity F, while the other extremity G is suspended by a rod L G, hanging at L from the extremity of the lever L M N.

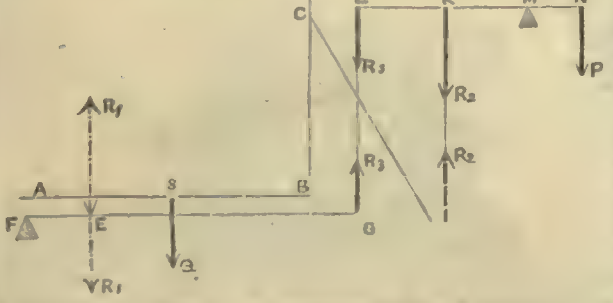
Lastly, the lever L M N is supported by a fulcrum M, which is fixed to the framework of the machine; the extremity N of this lever has a scale-pan suspended from it, in which weights may be placed.

The points E, L, and K are so chosen that $\frac{ML}{MK} = \frac{FG}{FE}$.

To avoid the consideration of the weights of the various parts of this machine, we will suppose that the weight of the scale-pan and the length of the arm M N of the lever L M N have been so chosen, as to produce an equilibrium of all the parts of the machine, and to keep L M N in a perfectly horizontal position, when no weight is placed on the platform A B.

To determine the weight P, which must be placed in the scale-pan suspended from N to balance a substance of a given weight placed on the platform A B, we will examine the conditions of equilibrium for the several parts of the machine.

Fig. 109.



Let the weights P and Q be represented in magnitude and direction by N P and S Q (Fig. 109.)

The weight of the substance placed on the platform A B being equal to a single force S Q passing through the vertical which passes through its centre of gravity, will be balanced by the reaction of the pressure R_1 which it produces on the fulcrum E, represented in magnitude and direction by ER_1, and the reaction R_2 of the tension it produces on the rod H K.

The pressure R_1 of the fulcrum E on the lever F G is kept in equilibrium by the reaction of the pressure it exerts on the fulcrum F, and the reaction R_3 of the tension it produces on the rod G L.

Finally, the lever L M N, resting on the fulcrum M, is acted on by three vertical forces P, R_2 and R_3, acting on the points N, K and L.

For the equilibrium of the rigid body A B C H we have as a condition

$$Q = R_1 + R_2.$$

For the lever F E G taking moments about E we have

$$R_1 \cdot EF = R_3 \cdot FG.$$

$$\text{Or } R_1 = R_3 \cdot \frac{FG}{EF}.$$

Lastly, for the lever L M N taking moments about M we have

$$P \cdot MN = R_2 \cdot MK + R_3 \cdot LM.$$

$$\text{Or } P \cdot \frac{MN}{MK} = R_2 + R_3 \cdot \frac{LM}{MK}.$$

But $\frac{LM}{MK} = \frac{FG}{EF}$ by the construction of the machine.

$$\text{Hence } P \cdot \frac{MN}{MK} = R_2 + R_3 \cdot \frac{FG}{EF} =$$

$$R_2 + R_1 = Q.$$

$$\text{And } \frac{P}{Q} = \frac{MK}{MN}.$$

If M N be taken ten times as long as M K, we have M N = 10 M K and Q = 10 P; and in this case a weight the tenth part of Q, when placed in the scale-pan, will produce equilibrium.

Instead of placing weights in the scale-pan P (Fig. 108), the arm of the lever M N may be graduated, and used as a Roman steelyard.

Before placing a body on the platform A B (Fig. 108) whose weight is to be determined, it is necessary to observe whether the arm of the lever M N is in a perfectly horizontal position. This is indicated by a horizontal pin *b* fixed to the framework of the instrument, being in the same line with a similar pin fixed to the arm of the lever. To bring these points into this position, small weights are added to or taken from a little cup *a*, placed under the point from which the scale-pan is suspended.

ROBERVAL'S BALANCE.—Many of the balances used in shops are constructed on the principle of this machine, which is interesting for its paradoxical character. It is apparently a lever, on the arms of which if two weights balance each other, they will still continue to do so from whatever points in those arms they may be suspended. The accompanying diagram will give an idea of the construction of this machine.

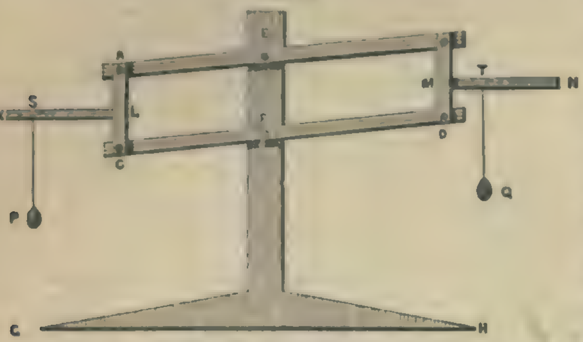
It consists of four bars, A B, C D, A C, and B D (Fig. 110); A B being equal to C D, and A C to B D. These four bars are united together by four pivots, A, B, C, and D; they also rest upon two pivots or axes E and F fixed to an upright bar E F, resting on a firm base G H.

The holes for the pivots E and F are so placed in A B and C D that B E is equal to D F.

Lastly, two bars K L and M N are fixed firmly at right angles to A C and B D, so that K L and A C form one rigid piece and M N and B D another.

The six pivots A, B, C, D, E, and F, are so constructed that the bars may move freely about them, with as little friction as possible, in the vertical plane while no lateral motion is permitted. From this construction it is evident that whatever position the framework A B C D may assume, when weights are suspended from the arms K L and M N, the four bars A B, C D, A C, and B D, will always form a parallelogram, and the arms K L and M N retain a horizontal position.

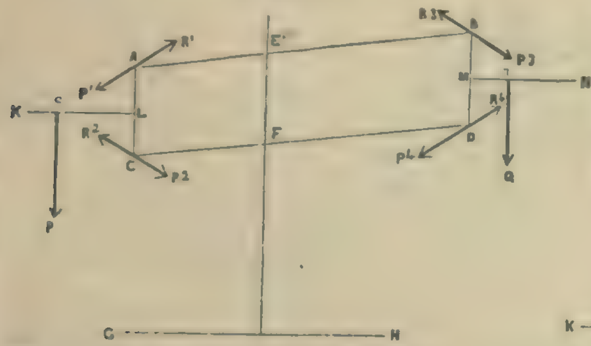
Fig. 110.



It is a peculiar property of this machine, that if two weights P and Q balance each other when suspended from two points S and T in K L and M N, they will also balance from whatever points in K L and M N they are suspended.

To show the properties on which this peculiar statical paradox depends, we shall neglect the weights of the various parts of the machine: or, which will come to the same thing, suppose the weights of its various parts so chosen that it shall be in equilibrium for every position in which the framework A B C D can be placed, when no weights are suspended from the arms K L and M N.

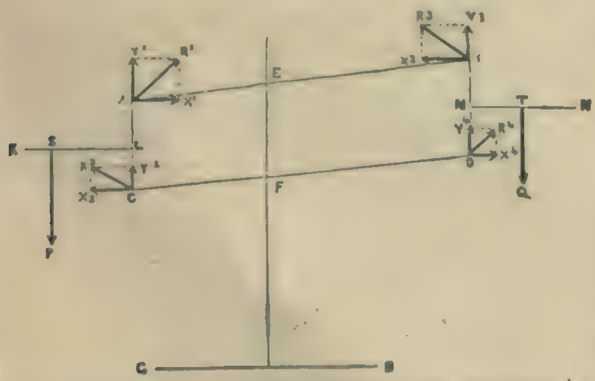
Fig. 111.



We also neglect the friction of the six pivots A, B, C, D, E, and F.

Let two weights P and Q, represented in magnitude and direction by S P and T Q (Fig. 111), be suspended from the arms K L and M N at the points S and T, and let us suppose that they balance each other

Fig. 112.



Also let the distances A E and C F be represented by a, E B and F D by b. Since K L and A C are rigidly connected, the pressure of P on S will be transmitted by the bars K L and A C to the pivots A and C, where it will produce two pressures P_1 and P_2.

These pressures are indeterminate, both in magnitude and direction.

Let P_1, the unknown pressure on A, be represented in magnitude and direction by AP_1; and P_2 that on C by CP_2.

As the machine is supposed to be in a state of equilibrium, P_1 will be counteracted by the reaction R_1 acting in the direction AR_1 (Fig. 112), AR_1 and AP_1 being in the same line, and $R_1 = P_1$.

Similarly P_2 will be counteracted by the equal and opposite reaction R^2, represented in magnitude and direction by CR_2.

Again, because the bars B D and M N are rigidly connected, the pressure of Q on T will be transmitted, and produce two pressures, P_3 and P_4, at B and D, which will be counteracted by equal and opposite reactions R_3 and R_4.

The bars K L and A C are kept in equilibrium by the three forces P, R_1, and R_2, acting at S, A and C in the directions S P, AR_1 and CR_2.

Resolving the forces represented by AR_1 and CR_2 into the vertical and horizontal forces X_1, Y_1, and X_2, Y_2, represented by AX_1, AY_1, CY_2, and CX_2 (Fig. 112).

We shall have by Prop. XVIII.

$$P = Y_1 + Y_2 \text{ and } X_1 = X_2.$$

The couple $X_1 \cdot AC$, whose tendency is to twist the rod A C, is entirely destroyed by the reaction of the pivots at A and C, and the forces Y_1 and Y_2 will be equal and opposite to two forces which will exert a pressure on the extremities A and C of the levers A B and C D.

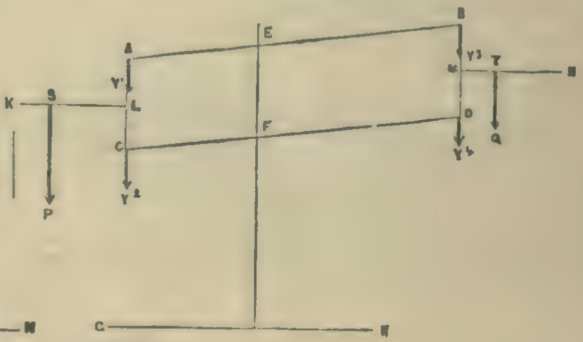
In a similar manner, by resolving the forces R_3 and R_4 into the horizontal and vertical forces X_3, Y_3, X_4, and Y_4, we shall have

$$Q = Y_3 + Y_4 \text{ and } X_3 = X_4.$$

The forces Y_3 and Y_4 being equal and opposite to two vertical pressures acting on the extremities B and D of the levers A B and C D.

Finally, we have the lever A B resting on the fulcrum E, kept in equilibrium by the forces Y_1 and Y_3 (Fig. 113).

Fig. 113.



Hence $Y_1 \cdot a = Y_3 \cdot b$.

Also for the lever C D we have

$$Y_2 \cdot a = Y_4 \cdot b.$$

Hence $(Y_1 + Y_2)a = (Y_3 + Y_4)b$;

But $Y_1 + Y_2 = P$, and $Y_3 + Y_4 = Q$;

Therefore $P \cdot a = Q \cdot b$.

Provided therefore that the pivots are strong enough to resist the lateral strains acting on them, the condition of equilibrium for the machine is, that P multiplied by a shall be equal to Q multiplied by b: a result entirely independent of the quantities c and d, or of the distances S L and M T.

In constructing balances on this principle, a and b are taken equal to each other, in which case E and F bisect A B and C D, and P and Q are equal.

WHEEL AND AXLE.—The second mechanical power is the wheel and axle; this machine, in its simplest form, consists of a circular wheel A B (Fig. 114) firmly fixed at right angles to a cylinder C D E F, so that both revolve together round a common axis G H.

The forces P and W are supposed to be applied by weights suspended from one extremity of the cord wrapped round the wheel or cylinder, to which the other extremity is attached. The forces, by this contrivance, always act at right angles to the circumferences of the wheel and cylinder.

The cords are supposed to be perfectly flexible, inextensible, and destitute of weight. Their friction on the surface of the wheel and axle, as well as the magnitude of their diameters, is also neglected.

Fig. 114.

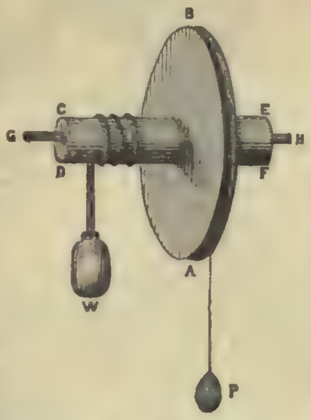


Fig. 115 represents a section of the wheel and cylinder perpendicular to their common axis.

Let A B be the radius of the wheel, and A C that of the cylinder or axle. Since the forces P and Q always act at right angles to the circumference of the wheel and axle, the force P may be represented in magnitude and direction by B P at right angles to A B, the force W by C W at right angles to A C.

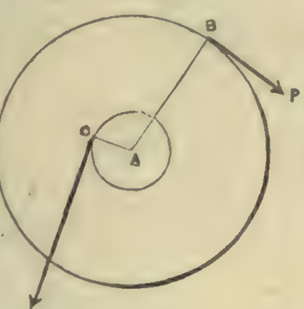
When these forces produce equilibrium, taking moments about A, we have

$$P \cdot AB = W \cdot AC \text{ or } \frac{P}{W} = \frac{AC}{AB},$$

that is

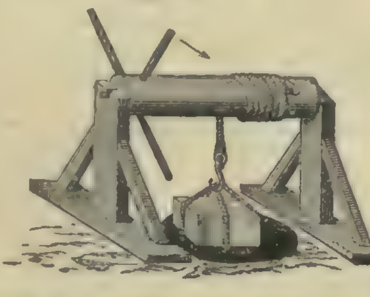
$$\frac{\text{The force acting on the surface of the wheel}}{\text{The force acting on the surface of the axle}} = \frac{\text{radius of axle}}{\text{radius of wheel}}.$$

Fig. 115.



This machine is only a modification of the lever; for referring to Fig. 115, we may consider it in its position of equilibrium as a bent lever, whose arms are A B and A C, and whose fulcrum is A.

Fig. 116.

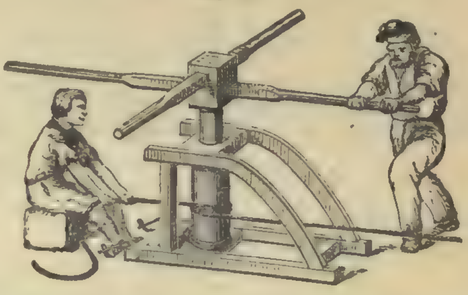


When it is in motion, we may regard the wheel and axle as made up of a number of spokes; these spokes come successively into action as levers, and thus the advantage of an endless leverage is produced, and the power and weight each act constantly in a straight line, instead of describing circular arcs as in the common lever.

Instead of the wheel, one or more bars are sometimes fixed at right angles to the axle, and these are often so disposed as to allow several men to act at once on the machine. When the axis of the axle is horizontal, a bar fixed at right angles to the extremity of the bar, forming what is called a winch, affords a convenient means for applying the force.

When the axis is horizontal, as in Fig. 116, the machine is called a *windlass;* when vertical, as in Fig. 117, a *capstan.*

Fig. 117.

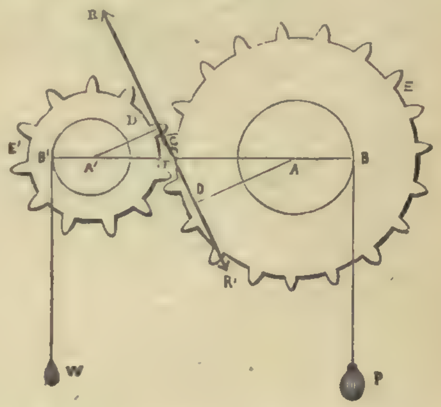


TOOTHED WHEELS.—The third mechanical power is the *toothed wheel;* it is extensively used in the construction of cranes, clock and watch-work, and almost every variety of machinery.

Toothed wheels consist of thin cylinders, having their circumferences indented or covered with projections called *teeth* or *cogs,* set at equal distances from each other.

If two such wheels have their axes placed in such a position that the surfaces of the wheels may be in the same plane, and the edges of their teeth touch each other, as in Fig. 118, and one of the wheels be made to revolve round its axis, its teeth will act in succession on the teeth of the other, and cause it to revolve round its axis in an opposite direction.

Fig. 118.



To determine the conditions of equilibrium for this machine, we will suppose A and A′ (Fig. 118) to be the axes about which the wheels revolve, and the weights P and W, which produce equilibrium, to be attached to the extremities of cords wrapped round, and having their other extremities fastened to, cylinders fixed perpendicularly to the wheels, and having a common axis with them.

Let A B and A′ B′ be the radii of these cylinders.

The weight P will communicate a tension to the rope B P, which will produce a pressure on the cylinder A B; this pressure will be communicated from the cylinder to the point C, where the tooth of the wheel C E is in contact with the tooth of the wheel C E′. In a similar manner, the pressure produced by W on the cylinder A′ B′ will be communicated to the same point.

These two pressures at C will act perpendicularly to the surfaces in contact, and when there is equilibrium they will destroy each other; consequently, they will be equal and opposite to each other. Let these pressures be represented by R, and their magnitudes and direction by C R and C R′.

From A and A′ draw A D and A D′ at right angles to C R, and join A A′ cutting C R in F. The wheel A E is kept in equilibrium by the force P acting in the direction B P, and R in the directions C R; and the wheel C E′ by the force W in the direction B′ W and R in the direction C R′.

Hence taking moments about A, we have $P \cdot AB = R' \cdot AD$
And taking moments about A′, we have $W \cdot A'B' = R \cdot A'D'$

Dividing one equation by the other $\frac{P \cdot AB}{W \cdot A'B'} = \frac{AD}{A'D'}$ or $\frac{P}{W}$

$$= \frac{AD}{A'D'} \cdot \frac{A'B'}{AB}$$

In the two triangles A D F, A′D′F, the angles at D and D′ are right angles, and the angle D F A = angle D F A′; hence the triangles are similar, and therefore

$$\frac{AD}{A'D'} = \frac{AF}{A'F}$$

and substituting this value we have

$$\frac{P}{W} = \frac{AF}{A'F} \cdot \frac{A'B'}{AB}$$

If we make A B = A′B′, the effect of the combination will depend upon the teeth of the wheels and their radii only, and then

$$\frac{P}{W} = \frac{AF}{A'F}$$

When the teeth are small in comparison with the radii of the wheels, A F and A′F will be nearly equal to these radii. And since the intervals between the teeth must be equal, in order that the wheels may work through a whole revolution, the number of teeth in each wheel will be proportional to their respective circumferences. Hence in this case

$$\frac{P}{W} = \frac{\text{radius of wheel } CE}{\text{radius of wheel } CE'} = \frac{\text{circumference of } CE}{\text{circumference of } CE'}$$
$$= \frac{\text{number of teeth in } CE}{\text{number of teeth in } CE'}$$

The edges of the teeth which come in contact with each other are sometimes formed of curves, which are portions of the curve called the involute of a circle. In this case, the point C retains the same position throughout the whole revolution of the wheel. The discussion of this property, as well as the best form of the teeth, requires a greater knowledge of the higher branches of geometry than can be assumed in an elementary work.

When the number of teeth in a wheel is small, the wheel is called a *pinion*, and the teeth *leaves*.

The axles about which the wheels revolve may be placed at right angles to each other, as in Figs. 119 and 120, or inclined at any angle to each other, as in Fig. 121.

Fig. 119.

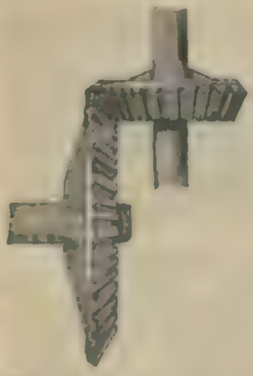


Fig. 120.

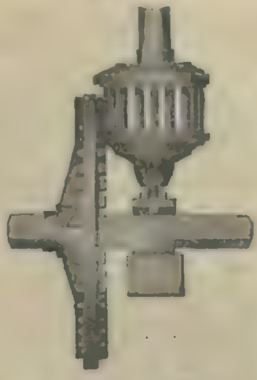

In Figs. 119 and 121 the pinions are placed on the surfaces of frustrums of cones, whose axes coincide with those of the wheels: the wheels are then called *bevelled wheels.* When the teeth project from the edges of the wheel, it is called a *spur* wheel; when they project from the surface of the wheel, as in Fig. 120, it is called a *crown* wheel.

Fig. 121.

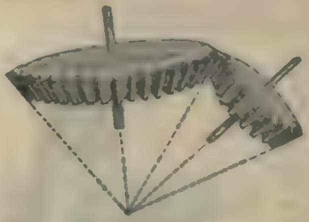

Fig. 122.

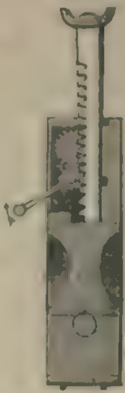

The teeth in which those of one of the wheels work, may be placed along the edge of a straight bar instead of the surface of a cylinder, as in Figs. 122 and 123; the bar being so confined as to allow it only to move in the direction of its length.

Fig. 123.

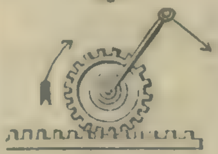

Fig. 124.

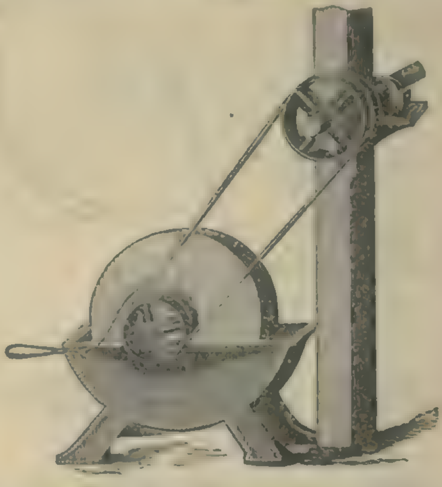
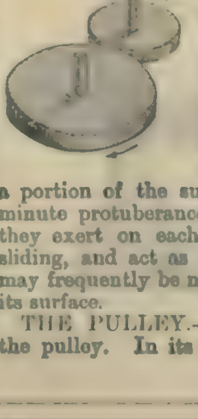


The arrangement in Fig. 122, where the wheel is made to revolve by a winch, is called a *jack*, and is often employed for raising heavy weights a small height.

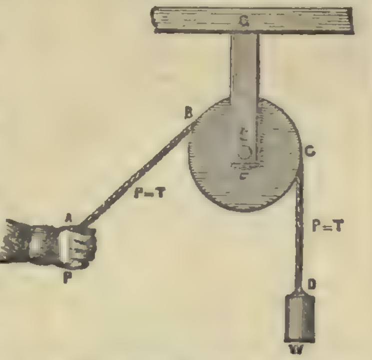
Fig. 125.



Wheels are sometimes turned by simple contact with each other, as in Fig. 125; and when they are at a distance from one another, as in Fig. 124, they may be made to act on each other by a band, strap, or chain passing over and in close contact with a portion of the surfaces of both. In these cases the minute protuberances of the surfaces, and the friction they exert on each other, prevent the surfaces from sliding, and act as minute teeth. A band which slips, may frequently be made to act by chalking or rosining its surface.

THE PULLEY.—The fourth mechanical power is the pulley. In its simplest form it consists of a solid circular wheel B C, Fig. 126, having a smooth groove cut in its circumference. This wheel revolves freely round an axis or pivot passing through its centre at right angles to its surface, and having its extremities fixed to a wooden or metallic frame F G. This frame may be either fixed or movable. The wheel is called the *sheaf*, *shiver*, *or rundle;* the axis the *gudgeon;* and the frame in which the axis is fixed, the *block* of the pulley.

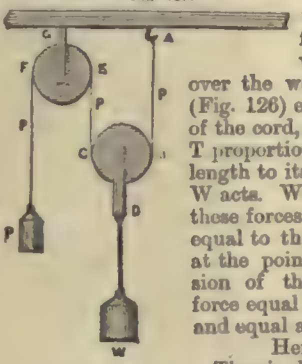
Fig. 126.



The force P is applied to one extremity of a cord passing freely over the grooved circumference of the sheaf, which moves with it round its axis, thus diminishing the friction of the cord; and the weight W, which is to be overcome, is attached to the other extremity of the cord

Several pulleys may be combined together, forming what is called a *system.* The cords which pass over the sheaves are supposed to be perfectly flexible and inextensible; the friction of the cords, as well as that of the axis, and when not specially mentioned, the weights of the blocks and sheaves, are not considered in our calculations.

Fig. 127.



The single pulley, with its block fixed, affords no mechanical advantage of the power over the weight, for the power P (Fig. 126) exerted on the extremity of the cord, communicates a tension T proportional to P throughout its length to its extremity D, at which W acts. When there is equilibrium, these forces P and W must be both equal to the tension T of the cord at the points A and D, or the tension of the cord will produce a force equal and opposite to P at A, and equal and opposite to W at D.

Hence P = W = T.

The single fixed pulley affords a convenient means for altering the direction of the application of a force to a machine. Thus a weight which acts vertically downwards, may be made to exert an equal force in any direction we require, by a proper position of the pulley and the support to which its block is fixed.

Single Movable Pulley.—Let a weight P be attached to one extremity of a cord passing over the fixed pulley F E (Fig. 127) round the movable pulley C B, and having its other extremity fastened to a fixed beam at A, the block of the pulley F E being fixed to the beam at G in such a manner that E C and A B shall be parallel. The weight W is attached to the block D of the pulley C B. Neglecting the weight of the pulley C B, P will communicate a tension throughout the cord, and this tension will produce a force P acting in the direction C E at E, and another force P acting in the direction B A at B (Fig. 127).

Hence when there is equilibrium, we shall have

$$W = P + P = 2P.$$

When the weight of the pulley is taken into account, this weight must be added to W. When the cords are not parallel, resolving the forces P acting at C, and P acting at B, into vertical and horizontal forces, as shown in Fig. 128, and equating the horizontal and vertical forces acting on B C, we have

$$P \sin. \phi = P \sin. \theta, \text{ hence } \phi = \theta$$

and W = P cos. θ + P cos φ = P cos. θ + P cos. θ = 2P cos. θ.

Where θ equals half the angle A B produced, makes with E C produced.

Fig. 128.

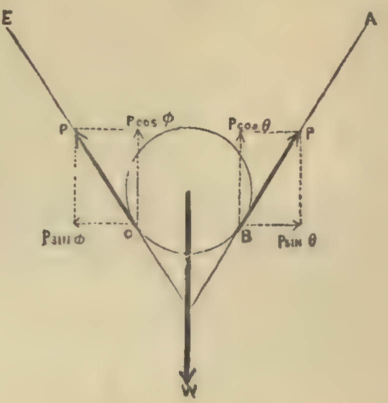


Fig. 129.

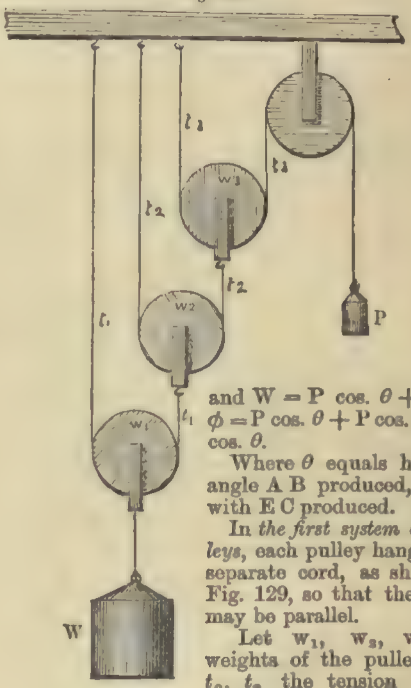


In *the first system of pulleys*, each pulley hangs by a separate cord, as shown in Fig. 129, so that the cords may be parallel.

Let w_1, w_2, w_3, be weights of the pulleys, t_1, t_2, t_3 the tension of the cords.

$W + w_1 = 2t_1$, $t_1 + w_2 = 2t_2$, $t_2 + w_3 = 2t_3$, and $t_3 = P$.

$$\text{Hence } P = \frac{w_3}{2} + \frac{t_2}{2} = \frac{w_3}{2} + \frac{w_2}{2^2} + \frac{t_1}{2^2} = \frac{w_3}{2} + \frac{w_2}{2^2} + \frac{w_1}{2^3} - \frac{W}{2^3}$$

If there had been four pulleys we should have had

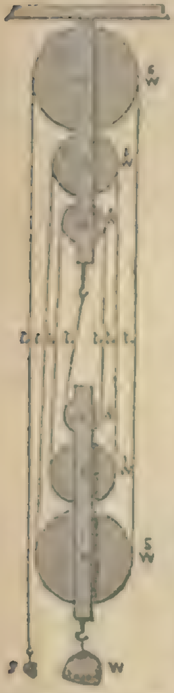
$$P = \frac{w_4}{2} + \frac{w_3}{2^4} + \frac{w_2}{2^3} + \frac{w_1}{2} = \frac{W}{2^4}$$

Neglecting the weights of the pulleys, w_1, w_2, &c., for three pulleys we shall have $P = \frac{W}{2^3}$, for four $P = \frac{W}{2^4}$ and generally for n pulleys $P = \frac{W}{2^n}$.

When the cords are not parallel, we may see, from the case of the single pulley, that each tension, t_1, t_2, t_3, &c., must be multiplied by the cosine of the angle which its cord makes with a line drawn parallel to the direction in which W acts.

This multiplication will necessarily diminish the tension, as the cosine will always be a fraction less than unity.

Fig. 130.



In *the second system of pulleys*, the cord to which P is attached passes over all the pulleys, as shown in Fig. 130. The pulleys are divided into two groups, the upper working in a common block which is fixed, and the lower in a common movable block. The other extremity of the cord to which P is attached, after passing over all the sheaves, is fixed to the upper block. W is attached to the lower block.

The weight or force P will communicate the same tension t_1 throughout the rope.

It is evident, therefore, that if we consider the ropes as parallel, and neglect the weight of the lower block and its sheaves when there is equilibrium, we shall have

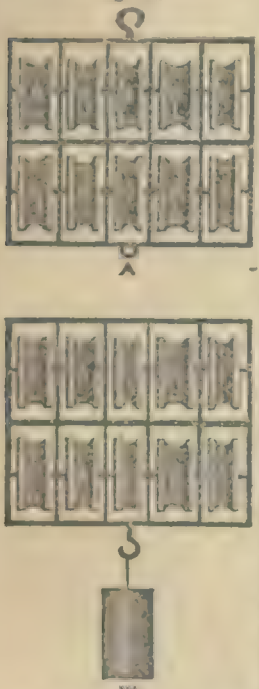
$$W = 6P$$

and generally we shall have $W = nP$ where n is the number of the portions into which the cord is divided by the two blocks.

When the weights of the sheaves and blocks are taken into consideration, it is evident that the weight of the lower block and its sheaves must be added to W.

If the positions of the cords be not parallel, each portion must have its tension multiplied by the cosine of the angle to which it is inclined to the direction of W, as in the first system of pulleys.

Fig. 131.



In Fig. 131 we have represented a very powerful arrangement, having the pulleys in each block arranged as shown in the figure. The sheaves of the upper row in the upper block, as well as those of the lower row of the lower block, are all of the same diameter; those of the lower row of the upper, and upper row of the lower, are equal to each other in diameter, though less than the former. The cord is omitted for the sake of clearness, but one extremity is fixed to the hook A below the lower block; it then passes in succession under each of the sheaves in the lower block, and over those in the upper in the order shown by the numbers attached to the sheaves in the figure: the power is applied to the extremity of the cord which passes over the pulley marked w_{20}.

As there are twenty portions of the cord between the two blocks, in this case W = 20P.

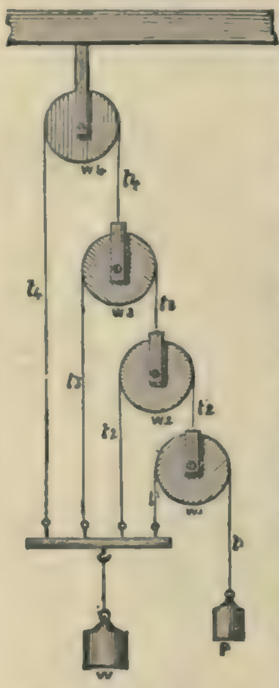
This arrangement permits the portions of the cords to be nearly parallel, and has the additional advantage that the power P acts immediately over the weight W, so that the parallelism of the cords will not be deranged, as it would otherwise be liable to be; it has, however, serious practical defects.

If the weight W be raised by the power P a given height, say for instance one foot, each portion of the cord between the two blocks must be raised the same height, which will necessarily cause P to descend 20 feet. From the arrangement of the cord, it is evident that one foot of the cord will pass over the pulley w_1, two feet over w_2, three feet over w_3, &c., and 20 over w_{20}.

Now since the sheaves w_1, w_2, w_3, &c., are of the same diameter, and revolve each round its own axis, and twice as much cord passes over w_2 as w, three times as much over w_3 as w_1, and so on; it follows that w_2 will revolve twice as fast, w_3 three times as fast, as w_1, and so on for the other sheaves.

This inequality of motion leads to great inequality in the wear of the various parts of the machine. If we attempt to remedy this defect by fixing the sheaves in the same row to a common axis, parts of the cord must necessarily scrape or slide over the grooves of the sheaves instead of moving with them; and this will lead to great increase of friction. To remedy these defects, Mr. White contrived the pulley known by his name. The sheaves in each block were cut out of one piece of wood or metal, being formed of a series of parallel and circular grooves, each increasing in diameter. The diameters of the grooves were made to bear to each other the same proportions as the portions of rope which were to pass over them—those for the lower block being as the odd numbers 1, 3, 5, 7, &c., and those in the upper as the even numbers 2, 4, 6, &c.

Fig. 132.



By this arrangement all inequality of wear was supposed to be obviated, and the friction was reduced nearly to that of the two axles of the blocks. But this ingenious contrivance is found practically to fail, as the elasticity of the cord, which is supposed by the arrangement to be inelastic or inextensible, is subject to continual change by the moisture or dryness of the atmosphere, and by the friction of the cord upon the grooves.

In *the third system of pulleys* each cord passes over a pulley, and has one extremity attached to the weight W, as shown in Fig. 132, and the cords are supposed to be parallel to each other.

Let w_1, w_2, w_3, w_4, represent the weights of the pulleys, t_1, t_2, t_3, t_4, the tension of the cords passing over them.

Then $t^1 = P.$

$t_2 = 2t_1 + w_1 = 2P + w_1.$

$t_3 = 2t_2 + w_2 = 2^2 P + 2w_1 + w_2.$

$t_4 = 2t_3 + w_3 = 2P^3 + 2^2 w_1 + 2w_2 + w_3.$

Therefore $W = t_1 + t_2 + t_3 + t_4.$

$= (1 + 2 + 2^2 + 2^3) P + (1 + 2 + 2^2) w_1 + (1 + 2) w_2 + w_3.$

$= (2^4 - 1) P + (2^3 - 1) w_1 + (2^2 - 1) w_2 + (2 - 1) w_3.$

The same reasoning may be extended to any number of pulleys n, in which case

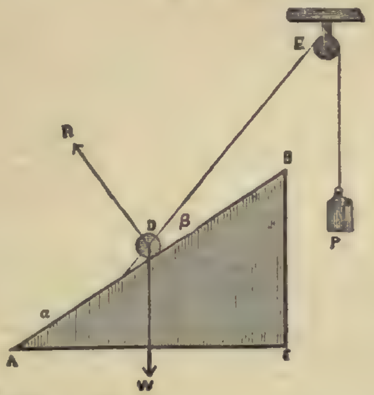
$$W = (2^n - 1) P + (2^{n-1} - 1) w_1 + (2^{n-2} - 1) w_2 + \&c. + (2 - 1) w_n.$$

When the weights of the pulleys are neglected, w_1, w_2, &c., w_n are equal to zero, and $W = (2^n - 1) P$.

When the strings are not parallel, their respective tensions must be multiplied by the cosine of the angle they make with the direction of W, as in the preceding systems.

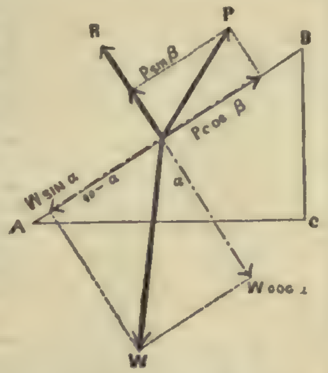
THE INCLINED PLANE.—The inclined plane is the fifth mechanical power. It consists of a plane surface A B, which is supposed to be perfect in hardness and smoothness, and inclined at some angle α to the horizontal line. A heavy body, whose weight is W (Fig. 133—1), resting on the plane, and supported by a force P acting in some direction D E constitutes the weight in this machine.

Fig. 133—(1).



Let β be the angle D E makes with B A, and B C be drawn at right angles to A C; α is called the inclination of the plane, B C its height, A B its length, and A C its base. When there is equilibrium, D will be acted on by three forces, the force P acting in the direction D E, the weight W acting vertically downwards, and the unknown reaction R produced by the pressure of the body D on the plane AB, which acts perpendicularly to the surface of the plane.

Fig. 133—(2).



Let R, P, and W be represented in magnitude and direction by D R, D P, and D W (2).

Resolving these forces parallel and perpendicular to the surface of the plane A B, as shown in Fig. 2, we have the following conditions of equilibrium :—

$$\text{W sin. } \alpha = \text{P cos. } \beta, \text{ or } \frac{\text{W}}{\text{P}} = \frac{\text{cos. } \beta}{\text{sin. } \alpha}.$$

The magnitude of R may be found from the equation

$$\text{R} + \text{P sin. } \beta = \text{W cos. } \alpha;$$

$$\text{or R} = \text{W cos. } \alpha - \text{P sin. } \beta = \text{W cos. } \alpha - \text{W} \frac{\text{sin. } \alpha \text{ sin. } \beta}{\text{cos. } \beta}$$

$$= \text{W} \left(\frac{\text{cos. } \alpha \text{ cos. } \beta - \text{sin. } \alpha \text{ sin. } \beta}{\text{cos. } \beta} \right) = \frac{\text{W cos. } (\alpha + \beta)}{\text{cos. } \beta}.$$

When P acts along the inclined plane in the direction D B, $\beta = 0$, and

$$\frac{\text{W}}{\text{P}} = \frac{1}{\text{sin. } \alpha} = \frac{\text{A B}}{\text{B C}} = \frac{\text{length of the plane}}{\text{height of the plane}};$$

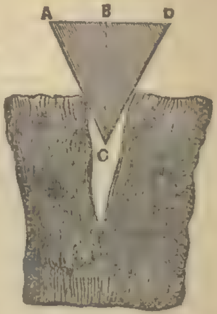
$$\text{also, R} = \text{W cos. } \alpha = \text{W} \frac{\text{A C}}{\text{A B}}$$

$$= \text{W} \times \frac{\text{base of the plane}}{\text{length of the plane}}.$$

Correctly speaking, the angles, &c., of (2) do not properly belong to the inclined plane of (1), unless the centre of gravity of the body D touches the plane A B, but to an imaginary plane passing through the point A and the centre of gravity of D.

THE WEDGE.—The sixth mechanical power is the wedge, which may be regarded as two equal and similar inclined planes A B C, B D C (Fig. 134), with their bases fixed together. It is used for cleaving substances, in which case the edge C is introduced into a cleft, and the surface A D struck by a hammer or mallet, so as to cause the wedge to enlarge the cleft and split the substance.

Fig. 134.

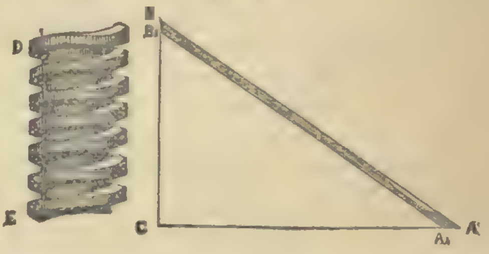


Considered as a statical machine, the power is a weight applied to A D sufficient to balance the pressures exerted by the substance into which the wedge is thrust on the sides A C and D C of the wedge, considering these surfaces as perfectly smooth.

The consideration of this machine is now omitted in many treatises, since "in the theory of the wedge, there are introduced so many conditions, which are perfectly inapplicable in practice, so many gratuitous assumptions and suppositions so inconsistent with practical truth, that the whole doctrine has little or no value. Nothing can more plainly demonstrate the inutility of the theory of the wedge, than that, in this theory, the power is supposed to be a pressure exerted on the back of the wedge, which is supposed to be capable of balancing the effect of the resistance in producing the recoil of the wedge. In all cases where the wedge is practically used, the friction of its faces with the resisting substance is sufficient to prevent the recoil; so that, strictly speaking, no force whatever is necessary to sustain the machine in equilibrium; and to move it, pressure is never resorted to—inasmuch as the slightest percussion is far more effective. The only general theoretical principle respecting the wedge, which obtains always in practice is, that its power is increased by diminishing the angle C D."*

THE SCREW.—The seventh mechanical power is the *screw*, and may be regarded as a modification of the inclined plane. If we take a triangular piece of paper A B C (Fig. 135), the angle at C being a right angle, in A C take a point A′, and through A′ draw A′ B′ parallel to A B. Then let the portion A A′ B′ B be blackened, and wrap the triangle A B C round a cylinder D E. Let now a groove be cut perpendicular to the surface of the cylinder, and following the direction of the dark spiral band, formed by the triangle A B C. The projecting portion between the groove is called the *thread* of the screw, and is evidently an inclined plane passing round the cylinder. The cylinder in which the groove is cut is called the *screw*. A hollow cylinder is now cut through a beam A B, and a spiral cavity, cut in the surface of the hollow cylinder, corresponding in magnitude to the thread of the screw, so that one may be regarded as the cast or mould of the other. This is called the *nut* of the screw.

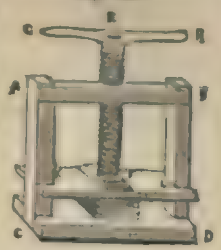
Fig. 135



---

* "*Mechanics;*" *Society for the Diffusion of Useful Knowledge.*

Fig. 136.



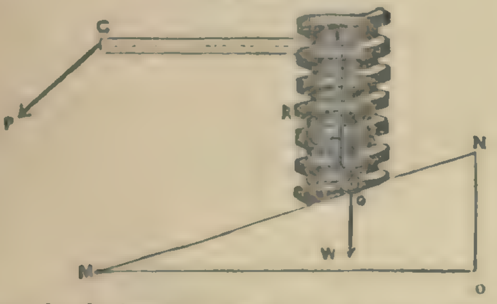
If A B (Fig. 136) be firmly fixed to the upright beams A C, B D, and these again to a plane base C D, the screw E F can be made to pass through the nut by causing it to revolve round its axis E F by means of the arms E H or E G, and as it moves through the nut its axis will always be vertical, and its extremity F will press upon a plane K L, so confined by the bars A C and B D in the frame A D C B, as to have only a vertical motion. The pressure of the screw will thus be communicated by K L to any substance placed between K L and C D.

To obtain the conditions of equilibrium of the screw, we neglect the weight of the screw itself, and the friction of the surface of the thread on that of the nut.

To simplify, as much as possible, the problem, we first suppose the portion of the thread which, by the action of a force P_1 at right angles to the extremity G of the lever G E (Fig. 136), communicates a pressure R_1 to the surface of the nut with which it is in contact, reduced to a single point Q (Fig. 137), and the surface of the nut unfolded into the inclined plane M N O.

The resistance R_1 which the surface of the nut opposes to the motion of Q, will be perpendicular to the surface M N of the inclined plane M N O, and the resolved portion of this force in a vertical position will give the pressure W_1, which the screw will communicate to the substance placed between K L and C D.

Fig. 137.



Let a be the length of the arm G E, b the radius of the cylinder of the screw, α the angle of the plane M N O.

Resolving R_1 vertically and horizontally, we have the following condition of equilibrium :—

$$W_1 = R_1 \cos. \alpha;$$

and taking moments about the axis of the screw,

$$a \cdot P_1 = b\, R_1 \sin. \alpha.$$

Now we may conceive the portion of the thread of the screw divided into a number of portions Q_1 Q_2, &c., Q_n, kept in equilibrium by forces P_1, P_2, &c., P_n, W_1, W_2, &c., W_n, and producing reactions R_1, R_2, &c., R_n on the surface of the nut.

$P_1 + P_2 +$ &c. $+ P_n$ will be the whole power P applied to the extremity of the arm G E, and $W_1 + W_2 +$ &c. $+ W_n$ will be the whole vertical pressure W which the screw will produce.

Then, as before, we shall have

$$\begin{array}{lll} W_2 = R_2 \cos. \alpha & \text{and} & aP_2 = bR_2 \sin. \alpha \\ W_3 = R_3 \cos. \alpha & & aP_3 = bR_3 \sin. \alpha \\ \text{\&c.} = \text{\&c.} & & \text{\&c.} = \text{\&c.} \\ W_n = R_n \cos. \alpha & & aP_n = bR_n \sin. \alpha \end{array}$$

Hence, adding these equations, we have

$$(W_1 + W_2 + W_3 + \text{\&c. } W_n) = (R_1 + R_2 + R_3 + \text{\&c. } + R_n) \cos. \alpha$$
$$a(P_1 + P_2 + P_3 + \text{\&c. } + P_n) = b(R_1 + R_2 + R_3 + \text{\&c. } + R_n) \sin \alpha$$

and dividing these equations, we have

$$\frac{W_1 + W_2 + W_3 + \text{\&c. } + W_n}{a(P_1 + P_2 + P_3 + \text{\&c. } + P_n)} = \frac{\cos. \alpha}{b \sin. \alpha}$$

$$\text{or } \frac{W}{aP} = \frac{\cos. \alpha}{b \sin \alpha}$$

$$\text{and } \frac{W}{P} = \frac{a}{b \tan. \alpha} = \frac{2 \pi a}{2 \pi b \tan. \alpha}$$

$$\text{or } \frac{W}{P} = \frac{\text{circumference of circle described by the extremity G of arm G E}}{\text{vertical distance between two threads of the screw}}$$

For if N G (Fig. 137) be the vertical distance between two threads of the screw, M O will be equal to $2\pi b$ and $N O = M O \tan. \alpha = 2\pi b \tan. \alpha$.

FRICTION.—In our previous investigations we have supposed all our surfaces in contact with each other to be perfectly smooth. (This perfect smoothness can never be attained in practice; the roughness, or want of smoothness, of two surfaces in contact with each other, opposes a resistance to their motion, over or along each other, which is called *friction*. From certain experiments it appears that friction may be due, in some measure, to the nature of the surfaces in contact with each other, and influenced by the molecular forces which the particles in contact may have with each other.

Experiments made with a number of different substances have led to the following laws :—

That the force of friction is proportional to the pressure acting on the surfaces in contact, so long as the materials of the surfaces in contact remain the same, and act at right angles to the direction of the pressure.

That for the same pressure, the friction is the same, whatever may be the magnitude of the surfaces in contact.

These laws are not strictly true, but are subject to considerable variation in certain extreme cases, as when the pressures are very great, and the surfaces in contact very small.

The friction of moving surfaces is also much less than that of the same surfaces in a state just bordering on motion.

For the state just bordering on motion, the friction of two smoothly planed pieces of wood, the grain being in the same direction, is half the pressure; for the same, the grain being in opposite directions, is one-fourth the pressure. The friction of two metallic surfaces is one-fourth the pressure; and of one surface metallic, and the other wood, one-fifth the pressure.

This friction may be greatly diminished by the use of lubricants, such as oil, tallow, black-lead, &c.

If the points in contact be mere lines, as in the case of the knife edge of the fulcrum of a lever, this friction may be considerably reduced. Thus, the friction of wooden surfaces is diminished in this case from one-fourth to one-twelfth the pressure, exerted by the surfaces in contact.

Having thus explained the leading laws of Statics, we shall proceed to investigate those of Dynamics.

ADDENDA.

[In the foregoing pages the student has had a full exposition of the theory of various mechanical arrangements, technically termed "powers." It has been thought desirable, however, to give further illustrations of the most commonly used machines; and accordingly such will be found in the annexed plate, respecting which the following observations may be made.

Figs. 1, 2, 3, represent the three orders of levers in their proper succession; the numerals on each lever and on the weights, and powers of application of force, will materially assist the student in understanding Propositions XXIII. and XXIV., as they show the position in which two unequal weights must be placed to neutralise each other's effect. The same observations apply to Fig. 4, which illustrates the bent lever. Figs. 5 and 6 are equally extended illustrations of the balance already described under the head of Levers. Figs. 7 to 10 illustrate various arrangements of the pulley; and Figs. 11, 12, and 13, refer to the affinity between the inclined plane and the screw. The following is a special description of each figure.

Fig. 1.—A lever of the first order. A, C, the lever; D, the fulcrum; W, the weight; P, the "power;" A, B, distance of weight from fulcrum; B, C, distance of "power" from fulcrum. In this cut, a "power" of one pound balances a weight of twelve pounds.

Fig. 2.—A lever of the second order. A, B, the lever; C, a cord (runs over pulley D), to which is attached the power, P, balancing the weight, W; E is the fulcrum.

Fig. 3.—A lever of the third order. Here the letters have the same signification as in Fig. 2, except that F is the point at which the power is applied.

Fig. 4.—The bent lever. A, B, the lever; C, the axis; D, a pulley over which runs a cord, E, supporting the power P, which thus balances the weight, W.

Fig. 5 is an application of the form of lever as a balance, described at page 721.

Fig. 6.—The Roman balance. A, B, is the lever; C, the fulcrum; *a*, *k*, an arm and ring by means of which the lever is suspended. The article to be weighed is suspended from the arm *e* by the hook *f*. If the lever be inverted, it is then suspended by *b*, *d*, as already explained at page 724.

Fig. 7 is a simple pulley, A; over it is stretched the cord B B, to which the "power" and weight P W, in this case equal, are attached. In Fig. 8, the power P is represented by a hand drawing upward the weight W, suspended to the pulley A, B. In Fig. 9, the power P balances the weight W, after the cord has been successively passed over pulleys A, B, C. The cord, however, is not continuous.* Fig. 10 is a further illustration of the system of pulleys described at page 730. A, D, and B, C, are two sets of pulleys, the lesser pair being smaller than the former. They are suspended at X; the cord stretches necessarily from the power P in the direction *e*, *k*, *o*, *u*, terminating at *s*, and balances the weight W.

Fig. 11 illustrates the inclined plane, of which A, B, is the base; C, D, the inclination; E, a descending weight; and F, G, the altitude. The theory of the inclined plane has been explained at page 731.

Fig. 12 shows an inclined plane, A, B, C, which if wrapped round a cylinder, as in Fig. 13, produces a screw whose threads are respectively *a*, *b*, *c*, *d*. C is the end of the plane, forming the terminal of the thread.—Ed.]

CHAPTER III.

DYNAMICS.

Introduction.—Every *body*, or material particle, is necessarily in a state of either rest or motion. A body strictly at rest is regarded as acted upon either by no force at all, or else by forces which oppose and neutralise one another. Investigations respecting forces which, acting upon a body or upon a system of bodies, thus keep the whole at rest, belong to the first division of Mechanical Philosophy—*Statics*. In this branch of the subject, we investigate the result of the several applied forces, which is *pressure* or *tension*, but no movement. In the second division, now to be treated of, the result of the applied forces, *motion*, falls under review: there may be pressure as well, but it is the motion or change of place of the body acted upon, that is the exclusive subject of *Dynamics*.

Of physical causes we know little or nothing: we observe motion or pressure, and we infer *force*—that is, some cause for the phenomena: but it is with the effects or phenomena alone that our observations and reasonings are concerned.

Ignorant, however, as we are of the essence of force, we cannot be under any doubt that it is the same in kind, when operating in the production of motion, as when operating in the production of pressure; for whenever, in the latter case, the resistance or obstacle is removed, motion necessarily ensues. But there is one consideration inseparably connected with that of motion, which has no place in statics: it is the consideration of *time*, an element which necessarily enters into the very idea of motion.

Nor can we conceive of a force which transmits its influence to a distant body—as the force of magnetism, or the force of gravity—as doing so independently of time. It is inconceivable that some interval does not elapse, however minute, between the cause and the effect: the transmission of a force through space must take time. A few years ago, the following question was proposed to the author of the present treatise:—A beam or bar uniformly strong—that is, resisting fracture in every part alike—is immovably fixed at one extremity, from which it hangs vertically; to the other, or lower extremity, is then attached a weight indefinitely great: where will the beam break? The condition is, that the beam has no tendency to break at one place more than at another, and yet the weight suspended to it is to be immeasurably great. The answer is, that time being required to transmit the force through the particles of the beam, the fracture takes place at the lowest part, the falling weight bringing with it only the lamina of material in immediate contact with it.

As the dynamical effect of force is motion, and as motion implies space passed through, and the time of passage, it is clear that, as in all physical inquiries, measuring causes by their effects, the measure of force must in some way be compounded of space and time.

The simplest kind of motion is *uniform* motion, or that in which the moving body passes through equal spaces in equal intervals of time; and the simplest path the moving body can describe, is a straight path. We can fully examine motion of *this* kind without any reference to force at all; we can take the motion as we find it, without any inquiry as to its origination; and ascertain all we wish to know respecting it. In fact, a body so moving is not, during the motion, acted upon by any force at all. Conceive an isolated body at rest, all other bodies and forces in nature being removed: it is plain that that body will remain at rest, for there is nothing to disturb its condition. In like manner, conceive such isolated body to be moving uniformly in a straight line: it must continue to move uniformly, for there is nothing to disturb its condition: to suppose a force to act upon it at any point of its path, and yet for the uniform onward motion to remain the same, would be to suppose a cause without an effect. A body, therefore, thus moving uniformly onward, is not actuated by any force whatever. It is true it could not pass from rest to uniform motion in a straight line without a cause—an impulse, for instance—but nothing acts upon it afterwards, or during its uniform motion; otherwise that uniformity would be interfered with.

---

* See Fig. 129, *ante*, p. 729.

It is this simplest kind of motion that we shall first consider, and shall then proceed to that which is due, not to instantaneous impulse, but to *force* continuously acting upon the moving body. The proper method of measuring this force will shortly be explained.

UNIFORM RECTILINEAR MOTION.—In applied, as well as in pure mathematics, certain fundamental positions or postulates must at the outset be assented to. In Dynamics there are three such postulates: they are known as the three laws of motion.[*] The first of these is as follows:—

A material particle, if at rest, and unacted upon by any external force, will remain at rest. A material particle, if in motion, and unacted upon by any external force, will continue its motion uniformly, and in a straight line. This law is only a formal enunciation of the *inertia* of matter, by which is meant, its incapability of altering, *of itself*, the state into which it is put by any external cause, whether that be a state of rest or a state of motion.

It is plain that the motion spoken of, being neither unchecked nor expedited, nor its direction any way interfered with, must be uniform in its *rate*, and rectilinear in its course—the course originally impressed.

The *rate* of a body's uniform motion is estimated by the extent passed over in some determinate portion of time—a second, a minute, an hour, &c. In dynamical investigations, the *second* is generally taken for the unit of time; and what in popular language is called *rate* of motion, is here called *velocity*; hence if a body move uniformly over ten feet every second of time, we say that it moves with a velocity of ten feet, or that its velocity is ten feet "per second" being understood. Putting the symbol v for velocity, we should therefore have $v = 10$ feet. As a second is taken for the unit of time, so a foot is taken for the unit of length. It is common, however, to call the length of track described by a moving body, the *space* passed through, and to represent this length by s; but it will be borne in mind that by s, length only is meant.

The symbol employed for *number of seconds* is t: it is to be carefully observed that t does not stand for the concrete quantity *time*, but only for the *number* of seconds in that time; so that *length*, viz., *feet*, is the only concrete quantity represented by the symbols v, s, t, which are related to one another as follows; namely:—

$$v = \frac{s}{t},\ s = vt,\ t = \frac{s}{v}$$

So that any two of the three quantities concerned being known, the third may be immediately found. If, however, t be not reckoned from the commencement of the uniform motion, but only after a certain space s' has been passed over by the moving body, then s being the whole length of path from the commencement, the three equations will be

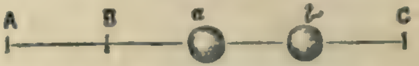
$$v = \frac{s-s'}{t},\ s = s' + vt,\ t = \frac{s-s'}{v}$$

Any one of these equations is sufficient for the entire theory of the motion of a body impelled by a single impulse, or influenced originally by any cause producing uniform motion.

It may, perhaps, be as well to remark here, that we speak of the path of a particle and of a body indiscriminately. In most works on Dynamics, all mention of *body* is avoided in this part of dynamics, and the motion of a single particle only considered. But this exclusion of body as an assemblage of particles is, we think, as injudicious as it is unnecessary. There *seems*, it is true, more mathematical precision of language in speaking of the line (s) traced out by a moving particle, than of what is described by a bulky body; but let it be only understood that by the path of a body we mean the line traced out by its centre of gravity, and all grounds for depriving the mass of volume, and reducing it to an indivisible isolated particle—of which indeed we can have no clear idea—will be removed. Throughout the present portion of dynamics, our investigations are entirely independent of mass or volume; and, consequently, to make a single physical particle the subject of those investigations, to the studied and systematic exclusion of body, is to perplex and mislead the learner—in fact, to convey to him the notion that what he is learning is applicable only to geometrical abstractions—to physical nonentities, and not to the actual material substances around us.

We shall now give an example of the application of the formulæ just established.

Fig. 138.



Two bodies (a, b, Fig. 138) animated by the uniform velocities, v, v', set out simultaneously from the points A B, and move in the direction of the straight line A B continued: required the time of their coming together.

Suppose a overtakes b at the point C, then

$$\text{A C} = vt,\ \text{B C} = v't;$$

that is, calling A C, s, and A B, s',

$$s = vt,\ s - s' = v't.$$

$$\therefore vt - s' = v't \therefore t = \frac{s'}{v - v'}$$

So that the abstract number denoting the units of time—that is, the number of seconds—will be found by dividing the space between the points of starting by the difference of the spaces denoting the velocities.

If uniform motion be the result of an impulse communicated to a body originally at rest, we may reasonably conclude that the velocity produced will be proportional to the intensity of the impulsive energy. For if a body receive a certain velocity in consequence of a certain impulse, it ought to acquire double that velocity if at any point of its path that impulse be repeated in the same direction; but if the second impulse, like the first, take place at the starting-point, it must unite with the first impulse, so that the consequence of a double intensity of impulse, will be a double velocity in the body impelled; and in like manner a triple intensity will produce a triple velocity; and so on.

VARIABLE RECTILINEAR MOTION.—When a moving body does not pass over equal spaces in equal times, the motion is not uniform, but variable. The rate at which the body moves, or its velocity at any instant, is the space it *would* describe in a second of time, measuring from that instant, provided all force were then withdrawn, and the body left to itself. Its motion during this second—as no force acts upon it—would of course be uniform.

Hence velocity in general is measured as follows:—

If the motion be uniform, the velocity is measured by the space actually passed over in a second. If the motion be variable, the velocity at any instant is measured by the space that *would be passed over* in a second, if all force were withdrawn at that instant, and the body left to proceed with the motion it then has.

ACCELERATING FORCE.—A body may so move as to acquire equal accessions of velocity in equal times—that is, it may move so that its velocity at any time t being v, we may have

at the times	t,	$t+1$,	$t+2$,	$t+3$,	$t+4$,	&c.
the velocities	v,	$v+v'$,	$v+2v'$,	$v+3v'$,	$v+4v'$,	&c.

Or the velocity may, in like manner, be retarded, v' being negative. Under such circumstances the velocity is said to be uniformly *accelerated*, or uniformly *retarded*.

The cause of the uniform acceleration or retardation of a body's velocity, we call *force*; and measuring causes by their effects, we take the amount of this constant acceleration or retardation, as the measure or representative of a constant force, continuously acting on the moving body.

---

[*] The three laws of motion are formally enunciated at the end of this chapter.

The symbol for this force is f, which, viewed only in its effects, denotes merely the velocity *generated* (or destroyed) in a second of time. In the illustration above, for instance, $f = v'$.

It is of importance that the student do not attach any other meaning to this symbol f, than that here assigned to it. The nature of the occult influence called dynamical force—or, as it is more frequently named, *accelerative* force—nobody can explain. In the present inquiry, we have to do only with its effect; and this we see is merely augmentation (or diminution) of velocity; and therefore, like velocity itself, it is expressed by *space*—that is, by linear measure: it is not the *force* that is accelerated, but the *velocity*.

If the force be constant or uniform, the acceleration of the velocity is also constant or uniform, as supposed above; but if the force be variable, the acceleration of the velocity is also variable. The only office of accelerative force is to produce accelerative velocity; and it is only by this latter phenomenon that we become cognizant of its activity, and can estimate its intensity.

Although, as remarked at the outset, we are altogether unacquainted with the essence of the thing called force, yet we may have abundant means of ascertaining whether its effects are constant or variable; and it must be carefully borne in mind that, in speaking of a constant force, or of a variable force, we have reference solely to the constant effect, or the variable effect. The force itself, whatever it may be, may in reality remain entirely unchanged; and yet, if it affect a body differently at different distances from its supposed seat of motion, we should call it a *variable* force. For example, there is a force familiar to everybody called *gravity;* and there can be no doubt that this force, like the magnitude of the earth itself, remains unchanged: yet as we find that the higher above the surface a body be taken, the less it will weigh, and the less will its velocity be accelerated, we say—exclusively in reference to these variable effects—that gravity is a variable force. It may be observed, however, that as this variation of weight and acceleration is insensible at moderate distances from the earth's surface, in all the ordinary applications of dynamics to terrestrial matters, gravity may without error be regarded as a constant force.

It is of importance that the student have correct conceptions of the sense in which the terms velocity and force are employed in these inquiries, and also that he should clearly perceive that *space* is the only concrete quantity concerned in the present portion of dynamics. The two propositions following, contain the whole theory of the rectilinear motion of a body under the influence of a constant accelerating force.

1. If a constant accelerating force f act on a body now at rest, during the time t, producing in it at the end of that time a velocity v, then $v = ft$. For since f expresses the velocity generated in each second, it follows that in the t seconds, the velocity v will amount to ft, $\therefore v = ft$.

2. If s be the space through which the body is moved from rest by the constant accelerating force f, in the time t, then $s = \frac{1}{2} ft^2$.

Suppose the time t to be divided into n equal parts; then since equal velocities are generated in equal times, the velocity generated in the time $\frac{t}{n}$ is the nth part of that generated in the time t; that is, by last proposition, it is $\frac{ft}{n}$. Consequently,

at the end of the times $\frac{t}{n}, \frac{2t}{n}, \frac{3t}{n}, \ldots \frac{nt}{n}$ or t

the velocities will be $\frac{ft}{n}, \frac{2ft}{n}, \frac{3ft}{n}, \ldots \frac{nft}{n}$ or ft..(A)

and at the *commencement* of the same intervals, the velocities will be

$$0, \frac{ft}{n}, \frac{2ft}{n}, \ldots \frac{(n-1)ft}{n} \ldots \text{(B)}$$

If the several velocities (A) were uniform during the several equal intervals of time, then the whole space S described would be

$$S = \frac{ft}{n} \cdot \frac{t}{n} + \frac{2ft}{n} \cdot \frac{t}{n} + \frac{3ft}{n} \cdot \frac{t}{n} + \cdots + ft \cdot \frac{t}{n}.$$

And if, in like manner, the several velocities (B) were uniform during those intervals, the whole space S′ described would be

$$S' = 0 \cdot \frac{t}{n} + \frac{ft}{n} \cdot \frac{t}{n} + \frac{2ft}{n} \cdot \frac{t}{n} + \cdots + \frac{(n-1)ft}{n} \cdot \frac{n}{t}.$$

Now, it is obvious that the space s actually described, is intermediate between the two spaces S, S′; being less than the former, and greater than the latter. And this is evidently true, however short the several equal intervals; that is, however large the number n may be.

But the shorter the intervals be made, the closer do the values S and S′ approach to each other, and therefore to the intermediate value s, till at length, when the intervals are diminished down to zero, by n becoming infinite, all three values S, s, S′ unite and become identical.

The determination of s is therefore reduced to the following algebraical problem; namely—to determine the value of S or of S′ when n becomes infinite.

Now the general expression for the value of S is

$$(1 + 2 + 3 + \ldots + n)\frac{ft^2}{n^2}$$
$$= \frac{n(n+1)}{2} \cdot \frac{ft^2}{n^2} = \left(1 + \frac{1}{n}\right)\frac{ft^2}{2}$$

In like manner, the general expression for the value of S′ is

$$\{0 + 1 + 2 + \ldots + (n-1)\}\frac{ft^2}{n^2}$$
$$= \frac{n(n-1)}{2} \cdot \frac{ft^2}{n^2} = \left(1 - \frac{1}{n}\right)\frac{ft^2}{2}$$

When n is infinite, since in that case $\frac{1}{n} = 0$, each of these expressions becomes $\frac{1}{2}ft^2$: consequently $s = \frac{1}{2}ft^2$. It appears then, from these two propositions, that if a body at rest be acted upon by a constant and uniform accelerating force f, during t seconds, the velocity acquired and the space described will be expressed by the equations

$$v = ft \text{ and } s = \tfrac{1}{2}ft^2 \ldots. (1)$$

From these two important equations we may proceed to deduce some inferences.

1. The space described in any time, reckoning from the commencement of the motion, is half the space that *would be* described in the same time, if the body were to move from rest with a uniform velocity equal to the last acquired velocity.

For since by (1) $s = \frac{1}{2}(ft)\,t$, and $v = ft \therefore s = \frac{1}{2}vt$; but vt is the space described in t seconds with the uniform velocity v: hence the space s, actually described under the influence of a uniform accelerating force, is half the space that would be described in the same time, if the body were to commence with the final velocity, and move uniformly.

2. The spaces described in equal successive portions of time, from the commencement of the motion, are to one another as the odd numbers 1, 3, 5, 7, &c.

For let t in (1) be successively 1, 2, 3, 4, &c., then the spaces from beginning are $\frac{1}{2}f \cdot 1$, $\frac{1}{2}f \cdot 4$, $\frac{1}{2}f \cdot 9$, $\frac{1}{2}f \cdot 16$, &c.; therefore the spaces for the successive portions of time given by subtracting these spaces from the beginning, each from the following, are $\frac{1}{2}f \cdot 1$, $\frac{1}{2}f \cdot 3$, $\frac{1}{2}f \cdot 5$, $\frac{1}{2}f \cdot 7$, &c.; so that the spaces described from the beginning are as the squares of the times; and the spaces described in the successive equal portions of time are as the numbers 1, 3, 5, 7, &c.

3. By means of the two equations (1), any one of the four quantities f, t, v, s, may be eliminated, and an equation deduced, involving only the other three; so that any one of the four things—force, time, velocity, and space—may be expressed in terms of any two of the others: thus, as the simplest algebraic substitutions show, we have the following equivalent expressions:

Expressions for v, ft, $\sqrt{2fs}$, $\frac{2s}{t}$

" " s, $\frac{1}{2}ft^2$, $\frac{1}{2}vt$, $\frac{1}{2}\frac{v^2}{f}$

" " t, $\frac{v}{f}$, $\sqrt{\frac{2s}{f}}$, $\frac{2s}{v}$

" " f, $\frac{v}{t}$, $\frac{2s}{t^2}$, $\frac{1}{2}\frac{v^2}{s}$

4. A uniform accelerating force is measured by twice the space described from rest in one second.

For putting $t = 1$, we have $f = \frac{2s}{t^2} = 2s$; so that if we can only measure the space through which a body, acted upon by a uniform accelerating force, moves from a state of rest, in one second, we can correctly determine the *uniform effect* of that force on the body: it will be double the space thus passed through. In other words, this double space will be the constant increment of the velocity at each succeeding second; that is, the constant *acceleration* of the velocity.

It is found by experiment, that the attraction of the earth upon bodies near its surface—that is, the force of gravity—causes a body to fall from rest a distance of 16·1 feet in the first second of time. Consequently, the force of terrestrial gravity—which force is usually represented by g—is $g = 32·2$ feet: that is, this force, continuously soliciting a falling body, will accelerate its velocity 32·2 feet every second.

It may not be amiss to repeat here, before proceeding to practical illustrations, that where there is uniform velocity, in a straight line, there is no force. We should be compelled to admit this, as a necessary consequence of our valuation of force in dynamics:—where there is no acceleration of velocity, there can be no force urging the body onwards in its path.

The student must all along remember, that when we speak of a force acting on a body, we always refer to the mechanical condition of the body at the particular instant that has brought it to where we find it. The impulse that, acting on a body at rest, puts it in a state of uniform motion, acts only during the instant of passing from rest to rectilinear motion: it expires, as it were, in the act; so that at whatever point in the path described, the moving body comes under our examination, we are compelled to say that no force—not even the force of impulsion—is acting upon it *then*.

We shall now give a few examples connected with accelerating force.

EXAMPLES OF ACCELERATING FORCE.—1. A body moves from rest with a uniformly accelerated velocity, and after the lapse of 3 minutes 5 seconds, is found to have passed over 400 feet: required the accelerating force.

Here the time, namely, t secs. = 3 mins. 5 secs. = 185 secs., and the space described, namely, $s = 400$ feet, are given to determine f. From the formula $s = \frac{1}{2}ft^2$ we have

$$f = \frac{2s}{t^2} = \frac{800}{185^2} = \frac{32}{37^2} = ·0234 \text{ feet.}$$

Consequently the accelerating force is such as to increase the velocity ·0234 feet every second.

2. How far will a heavy body fall in four seconds?

Using g for f, we have $s = \frac{1}{2}gt^2$, where $g = 32·2$, and $t = 4$, $\therefore s = 16·1 \times 4^2 = 257·6$. Hence the distance is 257·6 feet.

3. In what time will a heavy body descend 400 feet?

$$s = \frac{1}{2}gt^2 \therefore 400 = 16·1t^2 \therefore t = \sqrt{\frac{400}{16·1}} = 5 \text{ seconds.}$$

4. If a body be projected vertically upwards with a velocity of 400 feet per second, how high will it ascend?

It will ascend to that height from which, if it were let fall, it would acquire a velocity of 400 feet upon reaching the earth; therefore since

$$s = \frac{1}{2}\frac{v^2}{g} \therefore s = \frac{1}{2}\frac{400^2}{32·2} = 2484 \text{ feet.}$$

5. Through what height must a body fall so that the velocity acquired may be equal to that height?

$$s = \frac{1}{2}\frac{v^2}{g}, \text{ but } s = v \therefore 1 = \frac{1}{2}\frac{v}{g} \therefore v = s = 2g = 64·4 \text{ feet.}$$

6. Through what height must a body fall to acquire a velocity of 100 yards a second?—Ans. 139·75 feet.

7. A body is projected upwards with a velocity of 1500 feet per second: how high will it ascend?—Ans. 34938 feet.

8. What time will elapse, after projecting the body in the last example, before it again reaches the earth?—Ans. 93 seconds.

In the foregoing inquiries respecting the rectilinear motion of bodies under the influence of an accelerating force, we have supposed the force to move the body from *rest*. We are now to consider the case in which the force begins to act upon a body already moving in the direction of that force, or receiving an impulse in that direction. Suppose a body to begin its motion with a velocity v', and, from the commencement, to be acted upon by a uniform accelerating force f; then, as before, v being the velocity acquired in t seconds, and s the space passed through in that time, the acquired velocity will evidently be made up of the original velocity v' and the velocity ft communicated by the force f; for this force adds to the velocity f feet every second, or ft feet in t seconds, so that in t seconds the acquired velocity is $v = v' + ft$.

Again, in virtue of the initial velocity v' alone, the body would pass over the space $v't$ in t seconds; and in the same time f alone would cause it to pass over the space $\frac{1}{2}ft^2$: hence the combination of these is the whole space passed over; that is, it is $s = v't + \frac{1}{2}ft^2$; so that the formulæ for finding the velocity and the space described are

$$v = v' + ft, \; s = v't + \frac{1}{2}ft^2 \quad . \; . \; . \; . \; . \; . \; . \; . \quad (2)$$

If the initial velocity v' oppose that communicated by f, then v' is to be taken with a sign opposite to that of f.

From these two equations t may be easily eliminated, and a third equation obtained involving only the remaining quantities; thus, squaring the first, we have

$$v^2 = v^2 + 2v'ft + f^2t^2 = v'^2 + 2f(v't + \tfrac{1}{2}ft^2).$$

Hence, by the second equation,

$$v^2 = v'^2 + 2fs \quad . \; . \; . \quad (3)$$

As before, when gravity is the force, f is replaced by g.

Ex. 1. A body is projected vertically upwards, with a velocity of 480 feet per second; at what height will it be at the end of three seconds?

Here v', the velocity of projection, being 480 feet, this velocity continued uniform for 3 seconds would carry it to the height of 1440 feet; but gravity so counteracts its upward motion as to draw it back through a space of $\frac{1}{2}gt^2 = \frac{1}{2} \times 32.2 \times 3^2 = 144·9$ feet: hence the height to which the body is suffered to ascend is only 1440 — 144·9 = 1295·1 feet; that is, $s = v't - \frac{1}{2}gt^2 = 1295·1$ feet.

2. From an elevated position a body is projected vertically upwards with a velocity of 80 feet: required its place at the end of 6 seconds.

$$s = v't - \frac{1}{2}gt^2 = 80 \times 6 - \frac{1}{2}\,32·2 \times 6^2 = 480 - 579·6 = -99·6.$$

Hence, the place of the body is 99·6 feet *below* the place of projection.

3. With what velocity must a body be projected downwards from the top of a tower 150 feet high, to arrive at the bottom in two seconds?

$$s = v't + \tfrac{1}{2}gt^2 \therefore v' = \frac{s}{t} - \tfrac{1}{2}gt$$

$$= \frac{150}{2} - 16{\cdot}1 \times 2 = 42{\cdot}8 \text{ feet.}$$

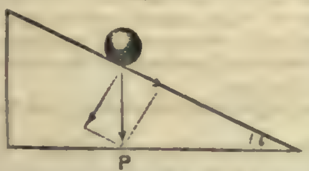
4. If a body be projected vertically downwards with a velocity of 20 feet, how far will it descend in 5 seconds?—Ans. 505·5 feet.

5. A body is projected upwards with a velocity of 100 feet: what will be its velocity when it has ascended 100 feet? (See Form 3.)—Ans. 51·6 feet.

6. In the preceding example, find at what time the body is 100 feet from the earth, as well in its descent as in its ascent.—Ans. 1·2 sec. and 4·7 secs. after projection.

MOTIONS OF BODIES DOWN INCLINED PLANES.—The fall of a body down an inclined plane is another instance of rectilinear motion under the influence of gravity. When a material substance is placed on an inclined plane, the force of gravity produces a certain vertical pressure P (Fig. 139): if we resolve this pressure in two directions, the one along the plane and the other perpendicular to it, the former component will be P sin. i, taking i for the inclination of the plane to the horizon; and to prevent the body from moving down, this is the force or pressure that must be counterbalanced.

Fig. 139.



As, therefore, P represents the pressure-force of gravity on the body in a vertical direction, and P sin. i the pressure in the direction of the plane, and as, when motion takes the place of these statical pressures, the accelerating force of gravity is proportional to them, we shall have for the acceleration down the plane,

$$P : P \sin. i :: g : g \sin. i.$$

Hence the body is urged down the inclined plane by the constant force,

$$g' = g \sin. i \quad . \; . \; . \; . \; . \; . \; . \; . \quad (1)$$

And, therefore, substituting this value of g' for f in the formulæ at page 736, those formulæ will then comprise the entire theory of motion down an inclined plane.

If l represent the length of the plane, and h its height, then $\sin. i = \dfrac{h}{l}$: consequently the accelerating force down the plane is

$$g' = g\frac{h}{l} \quad . \; . \; . \; . \; . \; . \; . \; . \quad (2)$$

And, therefore, the velocity acquired in descending down the whole length l, that is, in descending through the space $s = l$, by the action of this force, must be (page 736)

$$v = \sqrt{2g'l} = \sqrt{2gh} \quad . \; . \; . \; . \; . \; . \quad (2)$$

This expression we see involves only the height h of the plane, and is independent of its length l: hence the velocity acquired in descending down all planes of the same height is the same, and equal to the velocity acquired by falling vertically through that height.

But the velocities of two bodies, one falling through the perpendicular height, and one falling down the length of the plane, are respectively

$$v = gt \text{ and } v' = gt' \sin. i \quad . \; . \; . \; . \quad (4)$$

where t and t' are the respective times occupied in falling: these expressions are therefore equal; that is,

$$gt = gt' \sin. i \therefore \frac{t}{t'} = \frac{\sin. i}{1}$$

So that the time of falling through the height is to the time of falling down the plane, as the sine of the plane's inclination to unity.

If we wish to know what extent of length down the plane a body will pass through, while another falls through the whole height, then, referring to the expression for the space (page 736), we have

Vertical fall, $h = \frac{1}{2}gt^2$; inclined fall in time t, $s = \frac{1}{2}g \sin. i\, t^2$;

$$\therefore h : s :: 1 : \sin. i, \text{ or } s = h \sin. i.$$

If, therefore, from B we draw the perpendicular B D, the length A D will be that fallen through by one body moving down the plane A C, while another body falls through the height A B, because

$$AD = AB \cos. A = AB \sin. C.$$

If we draw the vertical D B′, and B B′ perpendicular to D B, then, by this theorem, the time of falling down the oblique line D B would equal the time of falling down the vertical D B′, for D B = D B′ cos. D; but D B′ = A B, since A B is a parallelogram, therefore the time of falling down the vertical A B is the same as the time of falling down either of the oblique lines A D, D B at right angles to one another: hence this remarkable property of the circle, namely: If from the extremities A, B, (Fig. 141) of the vertical diameter A B, chords be drawn, as in the annexed diagram, a body would fall down either of them in the same time that it would fall through the vertical diameter A B.

Fig. 140.

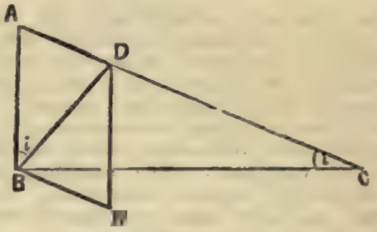


Fig. 141.

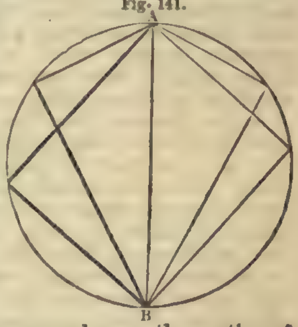


The following are a few examples on the motion of bodies down inclined planes:—

1. If the length of an inclined plane be 60 feet, and its inclination to the horizon 30°, what velocity would a body acquire in falling down it for two seconds?

By the formula (4), since $\sin. 30° = \frac{1}{2}$, we have $v = gt \sin. i = 32{\cdot}2 \times 2 \times \frac{1}{2} = 32{\cdot}2$ feet per sec. Hence the velocity is the same as would be acquired by a vertical fall in one second.

2. How long would a body be in falling down an inclined plane whose length is 100 feet, and inclination 60°?

Substituting the acceleration $g \sin. i$ for f, and l for s, in the expression for t, at page 736, and remembering that $\sin. 60° = \frac{1}{2}\sqrt{3}$, we have

$$t = \sqrt{\frac{2l}{g \sin. i}} = \sqrt{\frac{200}{32{\cdot}2 \times \frac{1}{2}\sqrt{3}}} = \sqrt{\frac{400}{32{\cdot}2 \times \sqrt{3}}}$$

$$= \frac{20}{\sqrt{(32{\cdot}2 \times \sqrt{3})}} = 2\tfrac{2}{3} \text{ seconds.}$$

3. A body is projected up an inclined plane whose height is $\frac{1}{6}$th of its length, with a velocity of 50 feet. Find its place and velocity after six seconds have elapsed.

In this case the force $g\dfrac{h}{l}$ (equation 2) *retards* the motion of the body, and must therefore be considered as negative: hence, from equation (2) page 736, we have

$$s = v't - \tfrac{1}{2}g\frac{h}{l}t^2$$

$$= 50 \times 6 - 16{\cdot}1 \times \tfrac{1}{6} \times 36 = 6\,(50 - 16{\cdot}1) = 203{\cdot}4 \text{ feet.}$$

$$\text{Also } v = v' - g \cdot \frac{h}{l}\,t$$

$$= 50 - 32{\cdot}2 = 17{\cdot}8 \text{ feet, the velocity required.}$$

4. If a body be projected up an inclined plane whose length is ten times its height, with a velocity of 30 feet, in what time will the velocity be destroyed, and the body begin to roll down?

The time is obviously the same as would be required to produce a velocity of 30 feet in a body falling from rest down the same plane: hence, substituting the acceleration $g\frac{h}{l}$ for f in the expression for t (page 736), we have

$$t = \frac{vl}{gh} = \frac{30 \times 10}{32{\cdot}2 \times 1} = \frac{300}{32{\cdot}2} = 9{\cdot}3 \text{ seconds.}$$

In the foregoing investigations, the student will observe that no allowance is made for the friction of bodies rolling down inclined planes; nor, whether bodies fall vertically, or obliquely as in this article, is the resistance of the air taken into account. These hindrances to free motion can be estimated only by practical and experimental researches, under various circumstances and conditions. The resistance of the air cannot be provided against, as is obvious; but in pieces of delicate machinery, many ingenious contrivances are resorted to, to diminish friction, and to render the departure from rigid mathematical theory as trifling as possible. The subject of friction will come under consideration in the section on Applied Mechanics.

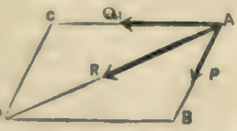
THE PARALLELOGRAM OF VELOCITIES.—The forces considered in Dynamics are influences of the same kind as those considered in Statics; they merely exhibit their effects in a different manner. What in Statics produces pressure, would in Dynamics—that is, if the thing pressed were removed—produce motion: the effects in both cases being proportional to the causes:—a double pressure from the same body, like a double acceleration of velocity, implies a double force.

It may, however, be proper here to anticipate a difficulty which the student may possibly feel: he may perhaps reason thus:—"A weight of ten pounds produces a pressure ten times that of one pound, yet the one pound weight, if let fall, is accelerated just as much as the ten-pound weight; whereas, from what is here said, it would seem that the heavier weight ought to be accelerated ten times as much as the lighter, seeing that its pressure is ten times as great."

But this apparent difficulty can arise only from a wrong conception of what is stated above: we are not comparing the pressure of *different* bodies under the same force acting upon all their particles, but the pressure of the *same* body under different acting forces: for example, if the same body were acted upon, now by the force of gravity, and hereafter if the same body, or an equal body, were acted upon by a force only half that of gravity, then, as stated above, the effect in the former case, whether that effect be pressure or acceleration, would be double the like effect in the latter case. If it were otherwise, than the statical measure of force (pressure) and the dynamical measure (acceleration of velocity) could not each of them be a correct measure or expression of the intensity of what we call force.

It has been fully proved in Statics (page 694), that if two forces P and Q act at A, and A B, A C represent their directions and intensities respectively, then will A D represent in direction and intensity their united effect.

Fig. 142.



The statical effect remains the same however long the forces or pressures act, for *time* is no element of consideration in Statics. But the dynamical effect is that at the instant the body acted on by the forces is at A, the continuous action of the forces, *afterwards*, not entering into consideration.

The parallelogram of *velocities* is independent of the parallelogram of forces. It will be remembered that the velocity of a body at any point of its path, is the space it *would* pass over in a unit of time, provided its rate or speed at that point were uniformly continued during the unit of time.

Suppose the body, when at A, were animated with a velocity that would alone carry it uniformly along A B to B, and with another velocity that would alone carry it uniformly along A C to C in the same time: these velocities may be considered as communicated by two simultaneous impulses in the directions A B, A C: the thing to be shown is, that the body would be carried uniformly along A D, and would arrive at D in the time spoken of.

For while the body is moving uniformly from A to B, conceive that the line A B, with the moving body on it, is carried parallel to itself, and with the second uniform velocity, up to C D: by the hypothesis, it will have arrived at C D in the same time that the body will have arrived at the extremity of the moving line: consequently, at the end of that time the body will be found at D. And that it will have arrived there with a uniform motion along the diagonal A D, will appear from considering, that if any point of its path were out of that diagonal, the uniform relation of the component velocities, namely A B : A C, would there be destroyed. That the diagonal is described with a uniform velocity—or that equal portions of it are passed over in equal portions of the time, is plain, because the uniformly moving line A B passes over equal portions of the diagonal in equal portions of the time.

Since, in the preceding figure, trigonometry gives for A D the expression

$$AD^2 = AB^2 + BD^2 - 2\,AB \cdot BD \cos. ABD,$$

and since $-\cos. ABD = +\cos. BAC$, if the directions of the component velocities v, v' make an angle a with each other, then the resultant velocity V will be

$$V^2 = v^2 + v'^2 + 2vv' \cos. a$$

From attending to the former part of the preceding examination, it will be seen that, however irregular the motion that would carry A to B, and however irregular the motion that would carry it to C, in the same time, the resultant of the two motions would necessarily carry it to D in that time, although not by the path A D, except the two component motions, during simultaneous portions of the time, are always as A B to A C. This truth will be of considerable importance in the next article on projectiles.

ON THE MOTION OF PROJECTILES.—If a body be projected obliquely upward or downward, the attractive force of gravity will cause it to take a curvilinear path. If the velocity of projection be considerable, and the body projected present much surface to the atmosphere, the resistance of the air will greatly modify the form of the curved path, and the range of the projectile; and it is no easy matter to determine one or the other. But if the body be supposed to move free from such obstruction (as in vacuum), all the circumstances connected with the flight of a projectile can be readily ascertained, as also, with a close degree of approximation, even in actual practice, if the velocity of projection be but small.

Supposing atmospheric resistance to be removed, the path of the projectile will always be the conic section called a *parabola* (see Practical Geometry, page 610), as we now proceed to show.

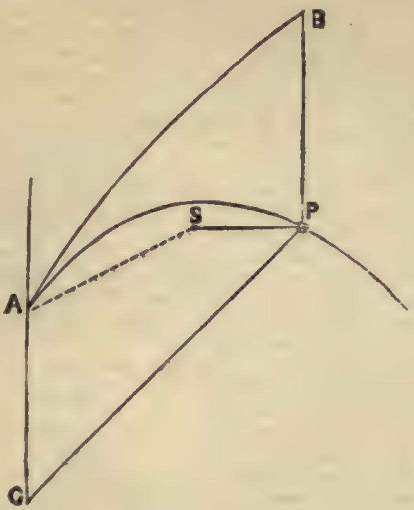
PATH OF PROJECTILE A PARABOLA.—Let A B (Fig. 143) be the direction in which a body is projected from the point A, with a velocity v. If no other motion were impressed upon the body, it would move uniformly along A B with the original velocity v, and in t seconds would arrive at B, supposing $AB = vt$. But as gravity acts on the body from the commencement, this force alone, in t seconds, would draw the body down, along A C, to C, supposing $AC = \frac{1}{2}gt^2$ (page 736).

Consequently, completing the parallelogram B C, the body in t seconds is found at P, as proved at the close of last article. Now

$$CP = AB = vt, \text{ and } AC = \tfrac{1}{2}gt^2$$

$$\therefore \frac{CP^2}{AC} = \frac{2v^2}{g} \therefore CP^2 = \frac{2v^2}{g} \cdot AC \quad . \quad . \quad . \quad (1)$$

Fig. 143.



This is what is called the *equation to a parabola*, A B parallel to C P being a tangent to the curve at the point A, and A C being parallel to the axis. The equation is usually written thus: $y^2 = ax$, where y is the ordinate C P of any P, and x the abscissa A C, of that point, while a is any constant multiplier of the abscissa. The equation when A is at the *vertex* of the curve, is investigated at page 610 of the PRACTICAL GEOMETRY. It follows, therefore, that the projectile in its flight always traces out a parabola: the constant multiplier in its equation is $\frac{2v^2}{g}$. It is known, from the theory of the parabola, that this constant multiplier is also 4 S A, S being the focus of the curve: it is further known, and is proved at the page just referred to, that the distance A S of any point A in the curve from the focus, is always equal to the distance of the same point from the *directrix*. Let this distance be called h, then

$$4\,\mathrm{SA} = \frac{2v^2}{g} = 4h \therefore v^2 = 2gh \quad . \quad . \quad . \quad . \quad (2)$$

But this value expresses the square of the velocity which a body would require, from the force of gravity g, by falling from rest, from the height h; consequently, the velocity of projection is equal to that which the body would acquire by falling from the directrix of the parabola, which it traces, down to the point of projection.

VELOCITY AT ANY POINT OF THE PATH.—It has just been shown that A being the point of projection, and v the velocity of projection, that velocity will be $v = \sqrt{(2g \cdot \mathrm{SA})}$. But any point P of the path may be regarded as the point of projection, and the corresponding velocity as the velocity of projection; so that the expression (2) applies equally to any point in the curve traced, h being the distance of that point below the directrix, and v the velocity at the same point. Hence, the velocity of the projectile at any point of its course is the same as the velocity it would acquire by falling vertically from the directrix down to that point. And it further follows, that at equal heights, in ascending and descending, the projectile will have equal velocity.

GREATEST HEIGHT.—In order to ascertain the greatest height to which the projectile will ascend, we must of course know the velocity of projection, and the direction of that velocity. It will also be convenient to replace this velocity by two component velocities equivalent to it in effect:—the one a horizontal velocity, and the other a vertical velocity (see page 738). If a be the angle of projection, that is, the angle of elevation of the initial direction above the horizontal line, then the velocity v of projection, will be equivalent to the horizontal velocity $v.\cos.a$, combined with the vertical velocity $v.\sin.a$.

Now, it is plain that gravity, which acts only in a *vertical* direction, cannot in any way disturb the *horizontal* velocity $v.\cos.a$, so that this velocity is the same at every point of the path. But the vertical velocity $v.\sin.a$, having the whole influence of gravity to check and oppose it, will be utterly destroyed and reduced to 0, when gravity has acted sufficiently long to impress on the body (supposing it left free to obey its solicitations) a downward velocity, equal to the upward velocity $v.\sin.a$. The spaces through which a body must fall to acquire this velocity, or the height to which it must ascend to lose this velocity, is

$$s = \tfrac{1}{2}\frac{(\text{velocity})^2}{g} = \tfrac{1}{2}\frac{v^2\sin.^2 a}{g} = h\sin.^2 a \text{ (by equa. 2)}$$

Hence, the greatest height to which the projectile discharged in a given direction can ascend, will be found by multiplying the height (h) through which a body must fall, to acquire the velocity (v) of projection, by the square of the sine of the angle (a) of elevation.

With the same projectile, velocity v, the highest point to which the projectile can ascend under different elevations, will of course be that due to the elevation of 90°; and we see accordingly, that the multiplier $\sin.^2 a$ is greater for this value of a, than for any other.

TIME OF FLIGHT.—The time occupied in the flight of the projectile, that is, the time from discharging it till it falls to the horizontal plane passing through the point of departure, will of course be double the time in which the vertical velocity is destroyed, as the body must fall to the horizontal plane with the same vertical velocity with which it left it. The time in which, by gravity, the velocity $v\sin.a$ would be generated, is

$$t = \frac{\text{velocity}}{g} = \frac{v.\sin.a}{g}$$

$$\therefore 2t = 2\frac{v.\sin.a}{g}, \text{ the time of flight.}$$

The time of flight, therefore, as might be expected, is the greater (with the same velocity of projection), the nearer the direction of projection approaches to the vertical; since sin. a increase if a increase and does not exceed 90°.

RANGE OF THE PROJECTILE.—The range is the distance on the horizontal plane, through the point of departure, at which the projectile falls. It has just been seen that the time of flight is $2\frac{v.\sin.a}{g}$, and since the horizontal velocity $v.\cos.a$ is uniform all this time, we have only to find the space due to the velocity $v.\cos.a$ in the time $2\frac{v.\sin.a}{g}$, that is, we have

$$\text{Range} = v\cos.a \times 2\frac{v\sin.a}{g} = \frac{v^2 \times 2\sin.a\cos.a}{g} = \frac{v^2}{g}\sin.2a$$

Hence, with the same velocity v of projection, the range increases as sin. $2a$ increases, and this it does as a increases from $a = 0$ up to $a = 45°$: therefore, with the same velocity of projection, the range at an elevation of 45° will be greater than at any other elevation whatever. And since the sine of an angle is the same as the sine of its supplement, that is, since sin. $2a$ is the same as sin. $(180 - 2a)$, it follows that the elevation $90° - a$ gives the same range as the elevation a: hence the ranges of projectiles, at any elevations above 45°, are the same as the ranges at elevations as much below 45°.

The length of the *maximum* range, that is, when $a = 45°$, is shown above to be $\frac{v^2}{g}$; v being the initial velocity, and this, as proved above (equation 2), is the same as $2h$: so that the length of the maximum range is equal to twice the height due to the velocity of projection.

If the range of a shot with a known elevation of the piece be ascertained, it will be easy to determine what the range would be with the same charge of powder at any other elevation. For calling the maximum range, or that due to the elevation $a=45°$, R, and the range due to any other elevation (a') r', we have, from the result just deduced, $r'=R \sin. 2a'$; so that by help of the maximum range, any other range, with the same charge, may be easily found. Or if we know any range r, corresponding to the elevation a, then to determine the range r', corresponding to another elevation a', we have the two equations,

$$r'=R \sin. 2a' \text{ and } r=R \sin. 2a$$

$$\therefore \frac{r'}{r}=\frac{\sin. 2a'}{\sin. 2a} \therefore r'=\frac{\sin. 2a'}{\sin. 2a}.r.$$

The following are the principal results in the foregoing theory of projectiles in a non-resisting medium :—

$$\text{Time of flight, } t=2\frac{v}{g}\sin. a=2\sin. a\sqrt{\frac{2h}{g}}$$

$$\text{Range, } r=\frac{v^2}{g}\sin. 2a=2h\sin. 2a',$$

$$\text{Greatest range, } R=\frac{v^2}{g}=2h,$$

$$\text{Greatest height, } H=h\sin.^2 a.$$

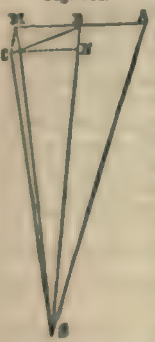
Where g is 32·2 feet, a the angle of elevation, v the velocity of projection, and h the height from which a body must fall from rest to acquire that velocity.

These results, however, ought to be regarded as but purely theoretical. In practice, the resistance of the air is so great in high velocities, as to render them almost useless : the mathematical doctrine of projectiles, through a resisting atmosphere, is full of difficulties ; and as the laws of resistance are as yet but insufficiently established, practical men must be guided chiefly by the results of actual experiments. The experiments in gunnery, by Dr. Hutton, as given in his *Mathematical Tracts*, may be consulted with advantage.*

CIRCULAR MOTION—CENTRIFUGAL FORCE.—If a body move uniformly in the circumference of a circle, the force to which that motion is due, must reside in the centre of that circle. This is only a particular case of the following more general proposition : namely, that if a body describe any curve, in virtue of a force continually diverting it from its wonted rectilinear path, that force must reside in a point such that, conceiving a line to join that point with the moving body, this line, moving with the body, must sweep over equal sectional areas in equal times.

This may be readily proved by first establishing the direct proposition, namely—that if a body describe a curve about any centre of force, and a line be supposed to unite that centre with the body, equal areas will be described in equal times.

Fig. 144.

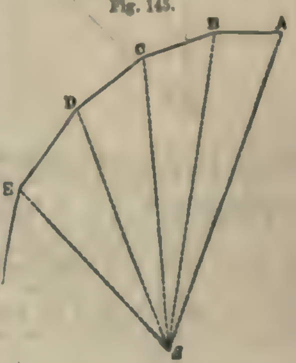


Let an attractive force at S (Fig. 144), act upon a body at the distance S B ; and to simplify the inquiry, imagine at first, that instead of acting continuously, the force exerts itself only at short regular intervals ; that, in fact, it consists of only equal successive impulses.

Let A B be the rectilinear path described by the body during any one interval between two successive impulses. At B the impulse is repeated, and the course of the body is diverted into the new path B C, which is described during the next interval ; at the end of which another impulse, in the direction C S, bends its path again, and so on. In the two intervals here considered, the triangular areas S A B, S B C, will have been described ; and it will be easy to show that these areas, thus described in equal times, are equal. For if, when the body was at B, no fresh impulse had been given to it, it would have moved forward uniformly to M, describing B M, the continuation of A B, equal to A B ; in which case the triangular areas S A B, S B M, would, of course, have been equal : it remains to show that the latter of these is also equal to the triangular area S B C.

The impulse from S, if it had acted alone on the body when at B, would have brought it to some point N in B S, in the prescribed interval of time ; and its uniform motion along A B, if undisturbed, would in the same interval have brought it to M. In virtue of these two uniform motions, the one from B to N, and the other from B to M, in the same time, the actual motion of the body is along the diagonal B C of the parallelogram M N. Hence M C being parallel to B S, the two triangles B M S, B C S, upon the same base B S, are between the same parallels, and are therefore equal ; therefore the triangle B C S is equal to the triangle A B S. It follows, therefore, that in the equal times, equal triangular spaces have been described.

Fig. 145.



In the same manner as it has now been shown, that the triangular area S A B, described in the first interval of time, is equal to that S B C described in the second equal interval, so may it be shown that the triangular area described in the third interval, is equal to that described in the second, and so on. Hence these triangular areas, in the margin (Fig. 145), being all equal, it follows, uniting any number of them in one area, that equal areas are thus described in equal times.

As this is true, however small the individual intervals of time between the impulses may be, it is true when these intervals are insensibly small, or when the successive impulses follow in one continuous force, and the lines A B, B C, &c., unite in one continuous curve. Hence, when a body is constrained to move in a curve, by the continuous action of a central force, equal areas are described about the centre of force in equal times.

Conversely, if equal areas are described about a point in equal times, the centre of force governing the motion of the body must be at that point.

Suppose the two equal areas S A B, S B C, to be described about S in equal times (Fig. 144) : then if the force acting on B were not in the direction B S, M C, parallel to the direction of the force, would not be parallel to B S ; that is, two triangles S B C, S B M on the same base B S, though *not* between the same parallels, are equal, which is impossible (Euc. 40 of I).

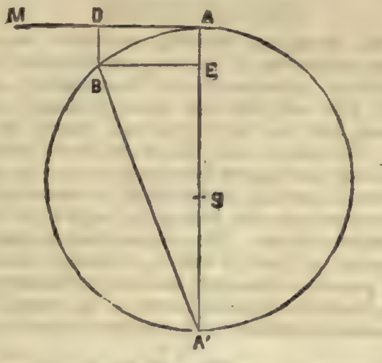
It follows from this, that, if a body under the influence of a continuous force, move uniformly in the circumference of a circle, the force must be at the centre of that circle, because equal sectional areas are described in equal times, since equal arcs are.

The force by which a body moving in a curve is drawn at any instant towards the centre of attraction S, is called the *centripetal* force at the distance the body is at that instant : the opposing force with which the body tends to fly off from the centre, and proceed in a rectilinear path, is called the *centrifugal* force. In circular motion these forces are everywhere exactly equal ; for neither, at any point of the circular path, prevails over the other, the distance from the centre of force S being everywhere the same. Let the arc A B (Fig. 146) be described in one second of time : draw B E perpendicular to A S ; then in one second, the body, originally at A, will have fallen from its wonted straight path A M, a distance = A E towards the attractive force at S : hence, 2 A E expresses the intensity of that force (page 736) acting on A. Join BA′; then since the arc A B differs insensibly from its chord (for the time of describing it may be regarded as minute as we please), we may regard A B A′ as a right-angled plane triangle, since the angle B is in a semicircle; therefore (Euc. 8, VI).

---

* These, however, have become of little use if applied in calculating the velocity of bullets and balls of a conical shape, as used in the rifle and rifled ordnance, by which the elements of resistance and "windage" are so materially lessened.—ED.

Fig. 146.



$$\text{AE} : \text{AE} :: \text{AB} : \text{AA}'$$

$$\therefore \text{AE} = \frac{\text{AB}^2}{\text{AA}'} = \frac{\text{AB}^2}{2\,\text{AS}} \therefore 2\,\text{AE} = \frac{\text{AB}^2}{\text{AS}}.$$

Now 2 A E represents the accelerating force at S, or, taken in an opposite direction, it represents the centrifugal force f, and A B represents the velocity v in the curve; consequently the centrifugal force $f = \frac{v^2}{r}$, where r = radius.

If as usual π be made to stand for the number 3·14159, &c., the whole circumference of the circle will be $2\,\pi\,r$; therefore, calling the whole time of describing the circumference—that is, the periodic time—t, and remembering that the uniform velocity v is equal to the whole space divided by the whole time, we have

$$v = \frac{2\,\pi\,r}{t},\ f = \frac{4\pi^2 r}{t^2}.$$

In the foregoing reasoning we are required to take t so many *seconds;* but the unit of time may be regarded as much smaller than this as we please; and thus the error of confounding the arc A B with its chord may be entirely removed, so that we may conclude rigorously that—

The centrifugal force in a circle varies as the radius divided by the square of the time of describing it: thus, for another circle, we should have $\text{F} = \frac{4\pi^2 \text{R}}{\text{T}^2}$;

$$\therefore f : \text{F} :: \frac{r}{t^2} : \frac{\text{R}}{\text{T}^2};$$

where f, F stand for the centrifugal or centripetal forces at the respective centres of circles of radii r, R, and in which the periodic times are t, T. If $\text{R} = r$, that is, if the circles are equal, the centrifugal forces F, f are inversely as the squares of the times T, t.

An interesting application of these results is to the determination of the centrifugal force at different places on the surface of the earth, from knowing the time of one rotation on its axis. But in studying this application, the student will not fail to observe that the circular path of a body, on the surface of the rotating earth, is not described under the same circumstances as the circular path is considered to be described in the present article. *Here* there is no solid matter interposed between the circulating body and the central force; there is nothing to prevent its falling to the centre at any point of its orbit; it is kept always at the same distance from the centre, simply because the force pulling it towards that centre is exactly balanced by that driving it from it: the centrifugal force is just sufficient to deprive the body of all weight or pressure towards the centre. With the earth it is different: if a perforation be bored in the earth, beneath a body on its surface, the body will fall down it; because the centrifugal force, driving it from the centre, is less than the attracting, or centripetal, force pulling it the other way.

CENTRIFUGAL FORCE AT THE EARTH'S SURFACE.—The earth, by its diurnal rotation, carries round, with a uniform velocity, every point on its surface in 86164 seconds. At the equator, the radius R is about 20922000 feet; therefore the centrifugal force F at the equator is

$$\text{F} = \frac{4\,\pi\,\text{R}}{\text{T}^2} \times \frac{4\,\pi \times 20922000}{86164^2} = \cdot 111245 \text{ feet.}$$

As this force opposes the force of gravity, it follows that if the earth had no rotation on its axis—that is, if no centrifugal force existed—gravity at the equator, instead of being what it really is, namely, $g = 32\cdot088$ feet, would be $\text{G} = g + \cdot111245$, and thus the weight of a body there would be a $\frac{\cdot111245}{32\cdot088}$ part more than it actually is.

The ratio of G to F being

$$32\cdot119 : \cdot1112 \text{ or } 289 : 1 \text{ nearly};$$

$$\therefore \text{F} = \frac{\text{G}}{219} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

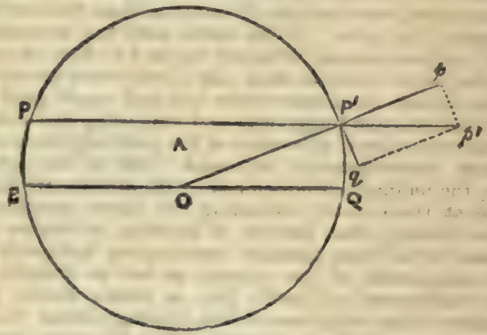
Now every parallel to the equator being carried round in the same time T, as the equator itself, by representing the centrifugal force in the parallel whose latitude is l, and radius r, by f, we shall have

$$\frac{f}{\text{F}} = \frac{r}{\text{R}} \therefore f = \text{F}\frac{r}{\text{R}} = \frac{\text{G}}{289} \cos l \quad . \quad . \quad . \quad (2)$$

Since, as is evident, $r = \text{R} \cos l$.

The force of gravity is not diminished by the whole of the centrifugal force, except at the equator; because in any parallel P A P′ (Fig. 147) this force acts, not in the direction P′ p wholly opposed to the force of gravity, but in the direction P′ p'. If, therefore, we decompose the force P′ p in the perpendicular directions P′ p, P′ q, the former component, being directly opposed to the force of gravity, and the latter component being a force acting tangentially, and therefore urging the particle P towards the equator, we shall have

Fig. 147.



Force opposing gravity, $\text{P}'\,p = \text{P}'\,p' \cos.\ p\ \text{P}'\,p' = f \cos.\ l$.

Hence (2) the expression for the diminution of gravity, in consequence of centrifugal force, at latitude l, is

$$\text{Diminution of equatorial gravity G in lat. } l = \frac{\text{G}}{289} \cos.^2 l.$$

Consequently the amount of diminution varies as the square of the cosine of the latitude.

The other component P′ q of the centrifugal force at P, being tangential, tends to drive the particles of the revolving body from the region of the poles to that of the equator, and to cause the body to assume the figure of an oblate spheroid, which is the figure that the earth has assumed: the expression for the tangential force is

$$\text{Tangential force, P}'\,q = f \sin.\ l = \frac{\text{G}}{289} \sin.\ l \cos.\ l$$

$$= \frac{\text{G}}{578} \sin.\ 2l,$$

which therefore varies as the sine of twice the latitude. The force thus tending to accumulate matter about the equatorial regions, is obviously greatest at lat. 45°, for there $2\,l = 1$.

From the foregoing principles we may readily determine the time in which the earth must perform its diurnal rotation, in order that the centrifugal force at the equator may be exactly equal to the force of gravity there; that is, in order that a body at the equator may have no weight.

Let T' represent the time of rotation corresponding to which the centrifugal force would be equal to that of gravity G; then the time at present being T, since the centrifugal forces in the same circle are inversely as the squares of the times of describing that circle (page 741), we have equation (1)

$$G : \frac{G}{289} :: T^2 : T'^2;$$

$$\therefore T' = \frac{T}{\sqrt{289}} = \frac{T}{17}.$$

Hence, if the diurnal rotation of the earth were performed in the 17th part of the time really occupied—that is, if it were to turn round seventeen times as rapidly—bodies at the equator would lose all their weight; and would, therefore, if placed at a small distance above the surface, remain suspended without any support. If the rotation were more rapid than this, no body could remain on the surface: everything would be repelled from it by the centrifugal force.

It has been demonstrated, however, that a spheroid, if fluid, and of the same density as the earth, could not remain in equilibrium if it were to rotate in a shorter time than 2h. 25m. 36s. (See *Airy's Tracts*, second edition, p. 150).

From what has now been shown, it will be observed that the superior accumulation of matter about the equatorial regions of the earth arises from two circumstances, or rather it is a twofold effect of the same cause. The centrifugal force generated by the diurnal rotation, acting in planes perpendicular to the axis, and on all the particles in each plane, and on the remoter particles of the plane more intensely than on the nearer, necessarily occasions the surface of the earth about the equator to recede more from the axis of rotation than the surface nearer to the poles. If the earth were not a rotating body, and an external influence opposed to that of gravitation were to diffuse itself like a belt round the equatorial regions, the matter under this belt would yield to the influence, and bulge out; and supposing the entire surface to be fluid, the waters of the polar regions would become proportionately depressed. But in the actual case, the bulging out occasioned by the direct centrifugal force at the equator, exceeding the direct centrifugal force at every other parallel of latitude, is further increased by all these parallels contributing indirectly to the enlargement of the equator, as well as directly to the enlargement of itself; for, as shown above, the equator is the only one of the rotating circles which expends none of the force upon it in a tangential direction. Every other circle—every parallel of latitude on either side, contributes tangentially its own supply of matter towards the equatorial regions; this supply, however, becoming less and less as the parallels recede from that of 45°.

On account of the solid materials of which a portion of the earth is composed, and the particles of which resist separation by their cohesion, the effects of centrifugal force are in some degree counteracted; but it is the general opinion of philosophers, that the present solid parts of the earth were once in a fluid or semi-fluid state —in fact, in a state of fusion; and that the outer crust has become solidified by cooling.

But those portions of the earth's surface which still remain fluid, observably yield to the tangential influence of the centrifugal force. There is a tendency, as observation shows, in the waters north and south of the equator to flow towards that circle; and as they flow from parts where the velocity of the diurnal rotation is less than the velocity at the equator, the streams from high latitudes are gradually left more and more behind in their lateral approach to the equator, where the diurnal velocity is greatest. As this velocity is towards the east, we may therefore expect to meet with great westerly currents in the open seas north and south of the equator which is conformable to experience.

MOVING FORCES.

In the foregoing remarks we have confined our attention exclusively to motion, unconnected with any considerations in reference to the quantity of matter moved. And although we have repeatedly used the term *body*, yet we have paid no regard to bulk or weight. The forces with which we have been dealing have, indeed, throughout been supposed to be analogous to the force of gravity, which gives the same velocity, in the same circumstances, to a single particle of matter as to the largest volume. We propose now to enter upon a few inquiries in which it will be necessary to take into account, *quantity of matter;* and as preliminary to these, some explanation must be given of the sense in which certain terms, hereafter to be employed, are to be understood.

Every person has a tolerably clear notion of *weight:* if two substances, however differing in bulk or volume, have the same weight at the same place, we infer that they contain the same quantities of matter; this is briefly expressed by saying that they are equal in *mass.* Yet mass and weight are not to be regarded as expressing the same thing; if any mass, or quantity of matter, were weighed at the pole, and then the same mass weighed at the equator, these weights would be different; though of course the transportation of the matter, from the pole to the equator, could not produce any change in its constitution.

A solid body may be considered as made up of particles or atoms, the aggregate of which constitute its volume: these particles may be packed (so to say) more closely in one body than in another of the same volume; so that the former may contain a greater quantity of matter than the latter; that is, a greater number of particles. Referring to this more compact constitution of the body, we say that it is more *dense* than the other body. *Density*, therefore, has reference to the quantity of matter in a given bulk; and if of two bodies of equal bulk, one be found to weigh, at the same place, *m* times as much as the other, the former is said to have *m* times the density of the other; it contains *m* times the quantity of matter, and is therefore *m* times the mass of the other.

The proper way, therefore, to represent the mass of any volume V, with a view to a correct comparison with other volumes, is this: Mass = Density × Volume; or, in symbols, $M = D\,V$. And it is to be observed that density is employed only comparatively, not absolutely; as when we say that lead has about eleven times the density of water, we mean that about eleven times as much matter is packed into a given volume of lead, as into an equal volume of water; so that the mass of a cubic inch of lead is eleven times the mass of a cubic inch of water.

As already observed, the mass of a body is proportional to its weight at the same place: the dynamical effect of this weight (W), or rather its dynamical measure, is Mg, where M is the mass, and g the force of gravity acting on it. And, in like manner, if a force f analogous to, but different in intensity from gravity, were to act on the mass M, the dynamical measure of the effect would be Mf, which is called the *moving force;* so that in the equation $F = Mf$, M is the mass, or quantity of matter moved; f is the accelerating force acting on it, and F is the moving force, the dynamical measure of the effect. In statics this would be pressure or tension.

The product of the mass, by the velocity with which it moves, is called the *momentum* of the body; as the velocity increases, therefore, so does the momentum. In uniform velocity, the momentum is constant: in uniformity accelerated velocity, additional momentum is generated every second; the increments of momentum being constant, like the increments of velocity. In the preceding expression for F, namely, $F = Mf$, f is no other than the constant increment of velocity generated in one second; consequently the momentum generated in one second, expresses, in fact, the moving force F; just as the velocity generated in one second represents the accelerating force f.

This latter force, as sufficiently seen in the preceding remarks, is all we have to attend to in investigating the motion of any single body subjected to its influence. As it acts upon all the particles of the body alike, the consideration of the number of these particles, or the mass of the body, would be superfluous. But when, instead of a single isolated body, we have to examine into the motions of a system of bodies, connected together by any ties, as cords, rods, &c., or mutually acting upon one another in any way; then, as it is easy to perceive, the quantity of matter in each body becomes an important item of consideration.

From what has now been said, the student will be prepared to give his assent to the following expressions, where V represents volume, and D density :—

The mass $M = D\,V$;

The moving force $F = M f \therefore f = \frac{F}{M}$ the accelerating force;

The momentum $= M v$.

But in order that he may attach an intelligible meaning to these symbols and relations, and may not mistake their proper signification, we shall here exemplify their interpretation in a particular case.

Suppose the volume of a body, that is, its magnitude, to be 10 cubic feet, and that in each cubic foot there is three times the quantity of matter that there is in a cubic foot of some standard substance—say pure water. Then, representing the density of water by unity or 1, the quantity of matter in the body before us, that is, the mass M will be

$M = D\,V = 3 \times 10 =$ the mass of 30 cubic feet of pure water;

that is to say, there is as much matter in the proposed 10 cubic feet as there is in 30 cubic feet of pure water.

If this mass move with a uniform velocity of 12 feet per second, the momentum of it, or the force of the blow with which it would strike an obstacle, would be

$M v =$ the momentum of 30 cubic feet of pure water, or of 30 cubic feet of a substance of the same density as water, moving at the same rate,—viz., 12 feet per second.

If the velocity of the moving mass, instead of being uniform, is constantly accelerated, the constant acceleration being $f = 6$ feet per second, then there is an acceleration or accumulation of momentum; and as, when uniform, the momentum is $M v$, so the constant accumulation of it, called the moving force, is

$M f =$ the moving force (or constant accumulation of momentum) of 30 cubic feet of a substance of the same density as water accelerated 6 feet per second.

When the velocity of the moving body is uniform, there is no moving force; that is, there is no accumulation of momentum, because there is no accumulation of velocity. If motion be not the result of the force f acting on the body, the effect must be pressure or weight.

The preceding explanation of the sense in which the symbols are to be understood, may be varied a little as follows:—Let the quantity of matter in a cubic foot of pure water be taken for the unit of mass, and the density of pure water for the unit of density.

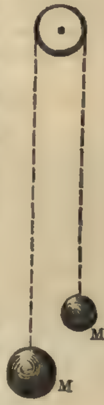
Let the momentum of a cubic foot of pure water, or of a substance of equal density, moving with a uniform velocity of one foot per second, be taken for the unit of momentum. Let the accumulation of momentum, or the constant quantity of momentum generated in one second in a cubic foot of pure water, or in the same volume of a substance of equal density, moving with an accelerating velocity of one foot per second, be taken for the unit of moving force. Then V representing the *number* of cubic feet in the volume of any body B, M the *number* of units of mass, v the *number* of feet per second in the velocity, and f the *number* of feet per second of acceleration, we shall have

$M = D\,V$, the number of units of mass in the body B;
$M v$, the number of units of momentum;
$M f$, the number of units of moving force.

We shall now proceed to some applications of the theory of moving forces.

APPLICATIONS OF MOVING FORCES.—1. Two heavy bodies whose masses are M M′, are connected together by a string which passes over a fixed pulley: required the circumstances of the motion.

Fig. 148.



Let M be the greater of the two masses; then M — M′ is the mass which, acted upon by gravity, causes M to descend and M′ to ascend. The moving force F, therefore, to which the motion is due, is $F = (M - M')\,g$; and, therefore, the accelerating force f, which, as above, is equal to F divided by the entire mass moved, is

$$f = \frac{M - M'}{M + M'}\,g.$$

And since the velocity generated in t seconds is ft, and the space passed over $\frac{1}{2}ft^2$ (page 736), we shall have, for the velocity of M downwards, or of M′ upwards in t seconds,

$$v = \frac{M - M'}{M + M'}\,gt, \text{ and for space, } s = \frac{1}{2}\,\frac{M - M'}{M + M'}\,gt^2.$$

These expressions determine the velocity with which M descends at the end of t seconds, and the space through which it will have fallen in that time.

TENSION OF THE STRING.—If the string were fastened to the pulley, so as to prevent motion, M, acted upon by the accelerating force of gravity g, would exert upon it a pressure or tension Mg; but this is diminished in consequence of a part of the accelerating force, namely f, acting upon M, and wholly expended in producing motion: hence the pressure or tension suffered by the string is only the difference between the two pressures, namely:

$$T = M\,(g - f) = M\left(g - \frac{M - M'}{M + M'}\,g\right) = \frac{2\,M\,M'}{M + M'}\,g.$$

This, therefore, is the expression for the tension of the string. With regard to the other mass, M′ not only is the accelerating force of gravity g, acting downwards upon M′, wholly exerted in stretching the string, but the upward accelerating force f in addition: hence the pressure or tension due to M′ is

$$T = M'\,(g + f) = M'\left(g + \frac{M - M'}{M + M'}\,g\right) = \frac{2\,M\,M'}{M + M'}\,g,$$

the same as before; as of course it ought to be.

PRESSURE ON THE AXIS OF THE PULLEY.—What is tension as respects the string, becomes, of course, pressure when acting on the pulley. As the tension of the string is on each side the same, namely, T, as determined above, therefore the pressure on the pulley is twice this—namely:

$$\text{Pressure on axis of pulley} = \frac{4\,M\,M'}{M + M'}\,g.$$

It is scarcely necessary to remind the student, that any mass multiplied by g, in other words, the moving force due to gravity, is mere weight when exerted statically.

Thus, calling the weights of the masses M and M′, W and W′ respectively, we shall find that the foregoing expression for T is the same as $T = \frac{2\,W\,W'}{W + W'}$.

For the expression at first given may evidently be written thus, namely:—

$$T = \frac{2\,Mg \cdot M'g}{Mg + M'g}.$$

Suppose, for instance, the weights hanging to the string were 7 lbs. and 5 lbs. respectively; then the tension of the string would be $\frac{2 \times 7 \times 5}{7 \times 5}$ lbs. = 5⅚ lbs.; that is, a weight of 5⅚ lbs. would, if suspended to a fixed string, produce the same tension as is actually produced in the moving string. In like manner, the axis of the pulley sustains a pressure equal to 11⅔ lbs. As the masses are proportional to the weights, we may, in a similar way, get a numerical expression for the accelerative force *f*—that is, by substituting the weights for the masses in the above value of *f*. Thus, taking the weights as here assumed, we have

$$\text{Acceleration, } f = \frac{7-5}{7+5}\,32{\cdot}2 = 5{\cdot}36 \text{ feet per second,}$$

the accelerating force that gives motion to the system being ⅙th of the accelerative force of gravity.

As already noticed, the moving force M*g*, which combines quantity of matter with the force acting upon it, is *pressure* or *weight* when motion is not the result of the action of the force on the mass. The symbol *g*, therefore, which stands for acceleration in Dynamics, should stand for pressure or weight in Statics, as in the expression for T given above; namely,

$$T = \frac{2\,Mg \cdot M'g}{Mg + M'g} = \frac{2\,W\,W'}{W + W'}$$

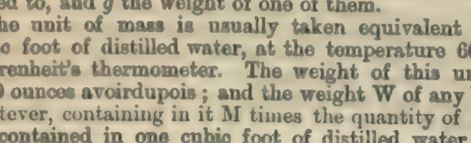
The learner, therefore, will not fall into the mistake of regarding such an expression as W = M*g* equivalent to the statement, that "weight is equal to mass multiplied by 32·2 feet." This would, of course, be absurd. The symbol *g* here stands for "the weight impressed by gravity on the unit of mass," whatever that unit may be selected to be. The unit of mass being assumed or fixed upon by common consent, then, in the above expression, M is the *number* of these units in the body referred to, and *g* the weight of one of them.

The unit of mass is usually taken equivalent to a cubic foot of distilled water, at the temperature 60° of Fahrenheit's thermometer. The weight of this unit is 1000 ounces avoirdupois; and the weight W of any body whatever, containing in it M times the quantity of matter contained in one cubic foot of distilled water, will always be W = M × 1000 ounces; and the same would obviously be the case if the unit of mass were anything else, *g* representing always the weight of that unit.

Whenever, in any mechanical inquiry, the investigation involves the mixed consideration of motion and statical pressure, although the motion and the pressure may be equally due to the same thing, and the same symbol (*g* for instance) be employed indifferently for the one or other of these different effects, yet as the *effect* is all that we intend the symbol to represent, it is plain that its signification in the one case must be different from its signification in the other. And it is of importance that the student always bear this in remembrance: he will find some further reference to the matter under the head of HYDROSTATICS.

2. Two weights W, W′ (Fig. 149), connected by a string passing over a small pulley C, are placed upon the two inclined planes C A, C B: it is required to determine the circumstances of their motion.

Fig. 149.



Let, as before, M, M′ represent the two masses. The moving force of W, in the direction W A, is M*g* sin. *i*; and the moving force of W′ in the direction W′B is M′*g* sin. *i*′: these oppose one another; so that the moving force F, to which the motion is due, is the difference of them; namely:—

$$F = (M \sin. i \backsim M' \sin. i)\,g.$$

And consequently the accelerating force *f*, which is equal to F divided by the sum of the masses moved, is

$$f = \frac{M \sin i \backsim M' \sin i'}{M + M'}\,gt.$$

This therefore is the expression for the accelerating force which urges W down the plane C A, and which, consequently, draws W′ up the plane C B.

And since the velocity generated in *t* seconds is *ft*, and the space passed over $\frac{1}{2}ft^2$, the velocity acquired by W downwards, or by W′ upwards, in *t* seconds, is

$$v = \frac{M \sin i \backsim M' \sin i'}{M + M'}\,gt;$$

and the space described is

$$s = \frac{M \sin i \backsim M' \sin i'}{2\,(M + M')}\,gt^2.$$

If the two planes were vertical, the problem would become identical with the last; we should then have sin. *i* and sin. *i*′ each equal to 1; and we see that the expressions for *v*, *s* would be those already deduced.

If only one of the planes were vertical, the problem would be converted into this—namely, to determine the circumstances of the motion when one body W, hanging vertically, draws another body W′ up an inclined plane. In this case, sin. *i* = 1; and we have only to put this in the preceding expressions, in order to obtain the necessary particulars of the motion.

Again, if one of the planes were vertical and the other horizontal, the problem would be to determine the motion when W, hanging vertically, draws W′ along a horizontal plane. In this case, sin. *i* = 1, and sin. *i*′ = 0; so that the accelerating force would be

$$f = \frac{M}{M + M'}\,g.$$

TENSION OF THE STRING.—For the tension of the string, under the original conditions, we have, if W be the descending weight,

$$T = M\left(g \sin. i - \frac{M \sin. i - M' \sin. i'}{M + M'}\,g\right)$$
$$= \frac{M\,M'}{M + M'}\,(\sin. i + \sin. i')\,g$$

which becomes the same as the expression for T in the last problem, when sin. *i* and sin. *i*′ are each of them 1. By substituting W for M*g*, and W′ for M′*g*, in each of the foregoing formulæ, numerical expressions will be obtained, as in the former problem.

3. Two weights W, W′ are attached, the latter to a wheel, and the former to its axle: to determine their motions.

Let M be the mass of W acting at the axle, and M′ the mass of W′, acting at the rim of the wheel: let also R be the radius of the wheel, and *r* that of the axle.

Then the moving forces M′*g*, M*g* acting at the distances R, *r* from the centre of motion, if free, would have the respective effects M′*g* · R, and M*g* · *r*, which, connected as they are, oppose each other. And if *f*′, *f* be the actual accelerations of W′, W, the moving forces, at the distances R, *r* from the centre of motion, are actually M′*f*′ · R, and M*f* · *r*; so that

$$M'g \cdot R - Mg \cdot r = M'f' \cdot R + Mf \cdot r \quad . \quad . \quad . \quad . \quad (1)$$

The accelerations *f*′, *f* must be to each other as the radii R, *r*, the velocities themselves being always in this constant ratio, since the wheel and axle both turn in the same time; therefore $f' = \frac{R}{r} f$, therefore

$$(M' \cdot R - Mr)\,g = \left(M\,\frac{R^2}{r} + Mr\right) f$$

$$\therefore f = \frac{M'\,Rr - Mr^2}{M'\,R^2 + Mr^2}\,g$$

the accelerating force of the ascending weight W.

And since $f' = \frac{R}{r} f$, we have

$$f = \frac{M'\,R^2 - M\,Rr}{M'\,R^2 + Mr^2}\,g$$

for the accelerating force of the descending weight W′.

The velocity, in t seconds, of the former, is

$$v = ft = \frac{M'\,Rr - Mr^2}{M'\,Rr + Mr^2}\,gt$$

and the space, $s = \frac{1}{g}\,ft^2 = \frac{1}{2}\,\frac{M'\,Rr - Mr^2}{M'\,R^2 + Mr^2}\,gt^2$

And for the latter we have

$$v' = \frac{M'\,R^2 - M\,Rr}{M'\,R + Mr^2}\,gt$$

$$s' = \frac{1}{2}\,\frac{M'\,R^2 - M\,Rr}{M'\,R + Mr^2}\,gt^2$$

The student will perceive that the first member of the equation (1), expressing the difference between the moving forces that *would* act if the weights were free, is the whole amount of moving force in actual operation; which whole amount is obviously expressed by the second member of the equation.

IMPACT OR IMPULSE.—In this article we propose to consider the circumstances of the motions of bodies moving in certain straight lines from the effects of impulse, and impinging against one another.

Let any specified quantity of matter be considered as the unit of mass: if it be projected by any given impulse, it will move with a constant velocity proportional to the intensity of that impulse; this velocity may therefore be taken to represent the magnitude of the impulsion. If we take two such units of mass, and two such impulses act on them simultaneously, and in the same direction, the relative positions of the moving masses will be always preserved; so that if the two units be blended into one mass, and the two impulses be thus made to unite and form a double impulse, the same velocity will be impressed on the compounded mass. And it is plain that if M such units be blended into one mass, which receives an impulse M times the intensity we have supposed to be applied to the single unit, the same velocity would still be impressed.

Consequently, when any body whose mass is M moves from the effect of an impulse, the correct expression for the intensity of that impulse must be Mv = the mass multiplied by the velocity, and which, as before stated (p. 743), is the *momentum* of the mass: hence the momentum measures the intensity of the impulse.

COLLISION OF BODIES: DIRECT IMPACT.—When two bodies moving by impulsion in the same straight line come into collision, the shock is called direct impact. Suppose the bodies which thus impinge to be entirely inelastic, or of such materials that they are blended by the impact into one mass, our object will be, from knowing the intensity of each separate impulse—that is, the momentum of each body—to determine the momentum of the blended mass; and thence the circumstances of its motion. The following example will illustrate how the necessary particulars are to be ascertained:—

Example.—Two inelastic bodies, whose masses are M, M′, move in the same straight line, with velocities v, v': required the velocity of their united masses after impact.

The momentum of M is Mv, and that of M′, $M'v'$, the combination of these—namely, $Mv + M'v'$, is the momentum of the united mass $M + M'$.

But if v be the velocity of this mass, its momentum must be $(M + M')\,v_1$: hence, to determine the velocity v_1 after the collision, we have the equation

$$(M + M')\,v_1 = Mv + M'v'.$$

$$\therefore v_1 = \frac{Mv + M'v'}{M + M} \quad \ldots . \ (1),$$

the velocity required.

This result is on the supposition that the bodies are moving in the same direction, or that one of them, M′, overtakes the other; but if they are moving in opposite directions so that the two meet, then the expression for v_1 will be

$$v_1 = \frac{Mv \backsim M'v'}{M + M'} \quad \ldots . \ (2).$$

If Mv exceed $M'v'$, then, after the collision, the mass will move in the direction in which M was proceeding; but if $M'v'$ exceed Mv, it will move in the direction in which M′ was proceeding, as is obvious.

If $Mv = M'v'$, then the collision, at meeting, will destroy the motion of each, and bring both bodies to a stand-still, since v_1 will then be 0.

If one of the masses M′ be at rest, then since $v_1 = 0$, the velocity after impact will be

$$v' = \frac{Mv}{M + M'} \quad \ldots . \ (3).$$

In all cases, the momentum after impact must be the sum of the momenta before impact, regarding those which act in opposite directions as having opposite signs; so that the momentum lost by one body, by the collision, is exactly equal to the momentum gained by the other. In the case (3) above, the momentum of the whole mass, after impact, being $(M + M')\,v_1 = Mv$, and the momentum gained by M′, which was at rest, being $M'v_1$, this must be the momentum lost by M. This loss of momentum in M shows that the mass M′ opposes a resistance to the communication of motion, and $M'v_1$ expresses the value of that resistance, which, as the mass was at rest, can be due only to the inertia of the body.

Let us now suppose that the bodies, instead of being perfectly inelastic, are perfectly elastic; and that, as in the former case, they move so as to impinge at some point in the common line described by their centres of gravity.

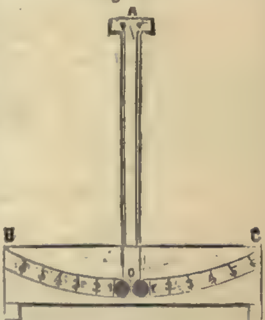
Elastic bodies are such as yield to the force of impact, and undergo a compression, and therefore a change of figure: the elasticity is that inherent force which the body exerts to recover its original form.

If the restoring force which the body exerts to recover its original figure be equal to the impressing force at the point of impact, so that the original form of the body is perfectly restored, and in the same length of time that it took to alter that form, the elasticity is said to be perfect.

In the case of perfect elasticity, whatever velocity one body loses during the action of the compressing force, it afterwards loses just as much more during the action of the restoring force; and whatever velocity the other body gains during the compression, it gains as much more during the restitution. For, at the end of the time occupied in the compression, there is the same communication of momentum as in the case of inelastic bodies: at that instant the bodies, then in the closest union, must have equal velocities. The force of restitution, exactly equal to that of compression, then acts; and another effect, the opposite to that of collision, takes place: the collision brings the bodies together; the force of elasticity drives them asunder.

No bodies in nature are perfectly elastic, or completely inelastic. The most elastic substance at present known is glass. Newton, by a contrivance similar to that represented in Fig. 150, determined a very close approximation to the defect from perfect elasticity of several substances. If two balls of the same substance, and in every other respect equal, were suspended from A by slender threads, and each let fall from equal distances, measured from the vertical, on the graduated arc B C, they would, after collision at o, each return to the point in the arc from which it started, if the elasticity were perfect. With ivory balls, the elasticity bore to

Fig. 150.



perfect elasticity the ratio of 8 to 9; with glass balls, the ratio was 15 to 16. From recent experiments, of a different kind, Mr. Eaton Hodgkinson has determined the ratios to be, for ivory ·81, and for glass ·94; the latter ratio differing but very little from that deduced by Newton. The fractional or decimal part that the elasticity is of perfect elasticity in any substance, is called the *modulus of elasticity* of that substance.

Example.—Two perfectly elastic bodies, whose masses are M, M′, moving with velocities v, v', strike with direct impact: it is required to determine their velocities afterwards. While the compression continues, the bodies move as one mass; and therefore with the velocity

$$v_1 = \frac{Mv + M'v'}{M + M'} \ldots\ldots (1)$$

So that M will lose the velocity $v - v_1$, and M′ will lose the velocity $v' - v_1$; and these express the velocities communicated, but in opposite directions, by the force of restitution. Hence the velocities, after impact, will be

$$\text{of the mass M, } v - 2(v - v_1) \ldots\ldots (2)$$
$$\text{and of the mass M}', v' - 2(v' - v_1) \ldots\ldots (3)$$

Or, substituting for v_1 its value (1), we have

$$\text{velocity of M, } v - 2\,\frac{M'(v - v')}{M + M'} \ldots\ldots (4)$$

$$\text{velocity of M}', v - 2\,\frac{M(v' - v)}{M + M'} \ldots\ldots (5)$$

If each mass be multiplied by the velocity it has after impact, the sum of the products will be $Mv + M'v'$; which is also the sum of the momenta before impact: hence the sum of the momenta after impact is the same as the sum of the momenta before impact. If we subtract (3) from (2), the remainder will be $v' - v$: hence the difference of the velocities is the same both before and after impact.

If $M = M'$, that is, if the bodies are perfectly equal in mass, as well as perfectly elastic, the expressions (4) and (5) show that, after impact, the bodies will exchange their velocities, M′ moving with the velocity v, and M with the velocity v'. Hence, if one of the bodies be perfectly at rest, the other which strikes it will impart to it its entire velocity, and will itself rest in its place.

If the elasticity be imperfect, the foregoing formulæ will require modification. Let e be the modulus of elasticity of the impinging bodies; that is, let the force of restitution after compression be only the eth part of that of compression: then the *additional* velocity lost by M from the action of this force, instead of being equal to that lost directly—namely, $v - v_1$, will be only $e(v - v_1)$; and the additional velocity lost by M′, only $e(v' - v_1)$; so that the velocities after the impact will be

$$\text{of the mass M, } v - (1 + e)(v - v_1)$$
$$= v - (1 + e)\frac{M'(v - v')}{M + M'}$$

$$\text{and of the mass M}', v' - (1 + e)(v - v_1)$$
$$= v_1 - (1 + e)\frac{M(v' - v)}{M + M'}$$

The momenta after impact will be, for M, the first of these expressions multiplied by M; and for M′, the second multiplied by M′: the original momenta are for the former, Mv, and for the latter $M'v'$. Hence, the momentum lost by one of the bodies, by the impact, is gained by the other: for, as the above expressions show, this momentum is

$$\text{for M, } (1 + e)\frac{MM'(v - v')}{M + M'}$$

$$\text{and for M}', (1 + e)\frac{MM'(v' - v)}{M + M'}$$

which are the same in value, but opposite in signs.

When the bodies are perfectly elastic, it has been seen above, as an immediate consequence of equations (2) and (3), that the sum of the momenta before impact is the same as the sum of the momenta after impact; and also that the difference of the velocities of the two bodies must be the same after impact as before; that is, calling the velocities after impact V_1 and V', we must have

$$MV + M'V' = Mv + M'v'.$$

$$\text{Also} \quad V - V' = v' - v.$$

$$\therefore M(V - v) = M'(v' - V'),$$

$$\text{and} \quad V + v = v' + V'.$$

Now, if we multiply these two last results together, we shall have the equation

$$M(V^2 - v^2) = M'(v'^2 - V'^2).$$

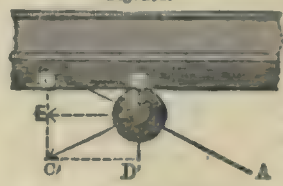
$$\text{Consequently} \quad MV^2 + M'V'^2 = Mv^2 + M'v'^2.$$

We may therefore conclude that when the bodies are perfectly elastic, the sum of the products of each body into the square of its velocity, is the same both before and after impact.

A particular name is given to the product of a mass into the square of the velocity with which it moves—it is called the *vis viva*, or the *living force*; so that in the collision of perfectly elastic bodies there is no loss of *vis viva* occasioned by the impact. The consideration of the force, thus called the *vis viva*, enters largely into certain inquiries connected with the motion of fluids.

1. A ball whose elasticity is e, strikes a perfectly hard plane—the raised edge of a billiard-table, for example: required the motion of the ball after the impact. Let A B (Fig. 151) be the straight line described by the centre of the ball before impact, and call the angle A B D′, a; then, v being the velocity along A B C, let it be represented by B C. The components of this velocity—the one perpendicular to the plane, and the other parallel to it—are B D, B E. The component B E is not modified by the impact; but B D, by the force of restitution, is converted into B D′: hence, compounding the velocities B E, B D′, the path, and velocity v_1, after impact, will be denoted by B C′.

Fig. 151.



The velocity B D′ is $e \times BD' = ev\cos. a$.

The velocity B E is $v\sin. a$;

because the velocity parallel to the plane is unaltered by the impact,

$$\therefore v_1{}^2 = (ev\cos. a)^2 + (v\sin. a)^2 = v^2(e^2\cos.^2 a + \sin.^2 a)$$
$$= v^2(e^2\cos.^2 a + 1 - \cos.^2 a) = v^2\{1 - (1 - e^2)\cos.^2 a\} \quad . \quad . \quad . \quad . \quad (1)$$

For the direction B C′, after impact, we have

$$\cot. a' = \frac{BD'}{DC'} = \frac{ev\cos. a}{v\sin. a} = e\cot. a \ldots\ldots (2)$$

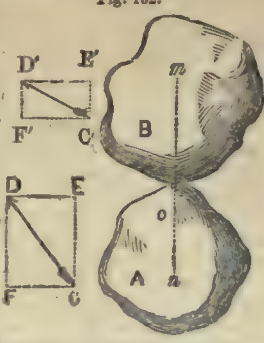
If the elasticity be perfect, that is, if $e = 1$, then, from (1) and (2), $v_1 = v$; and $a' = a$: hence, in the case of perfect elasticity, the ball will rebound with the velocity with which it struck; and the path it takes will make an angle of reflection equal to the angle of incidence.

But if the elasticity be imperfect, that is, if e be less than 1, then, from (1), v_1 will be less than v; and, from (2), cot. a' will be less than cot. a; and consequently a' will be greater than a: hence, in the case of imperfect elasticity, the velocity after impact will be less than the velocity before impact; but the direction after impact will make a greater angle with the perpendicular than the direction before impact.

2. The following diagram (Fig. 152) represents two bodies, A and B, impinging upon each other at the point o; C D, representing in magnitude and direction the velocity of the former, and C′D′, in magnitude and direction,

the velocity of the latter. Let *mn* be the line perpendicular to their surfaces at *o*. By the resolution of velocities, A may be regarded as animated by two velocities, of which one, C E, is parallel to *nm*, and the other, C F, perpendicular to the same line. In like manner, B may be regarded as animated by the velocity C′ E′, parallel to *nm*, and the velocity C′ F′ perpendicular to *nm*.

Fig. 152.



If A and B, at the instant of contact, were animated solely by the velocities C F, C′ F′, they would merely slide one past the other, and would experience no impact or shock: the shock they suffer is therefore due solely to the velocities C E, C′ E′; and even then, that any shock may take place, the former velocity must exceed the latter.

The intensity of the impact is the same, therefore, as if the two velocities C E, C′ E′, alone existed; and the two bodies will move as in the case of direct impact, only that these motions will be combined with the unchanged velocities C F, C′ F′: we shall therefore only have to compound the velocity of A in the direction *nm*, after the direct impact spoken of, with the velocity C F, perpendicular to *nm*, in order to obtain the magnitude and direction of A after the shock; and in a similar way are the magnitude and direction of the velocity of B to be found.

NOTE.—It must be noticed by the student, that what has here been taught respecting the collision of bodies, concerns only their rectilinear motions—their actual advance in space. Unless the line of direction in which two bodies strike, pass through the centre of gravity of each, rotation, as well as translation in space, will invariably be the result: the motion of translation is all that is sought to be determined in discussions on the collision of bodies; and it can be proved that this progressive motion is not in the slightest degree modified by the rotation of the impelled body. More advanced principles have fully established the following general proposition, viz.—When a body is acted upon by any impulsive forces, of which the resultant does not pass through the centre of gravity, the body will have in consequence a double motion:—1, the centre of gravity will move as if the forces were immediately applied to it; and 2, the body will rotate as if this centre were absolutely fixed. But want of space compels us to bring the subject to a close: our object has been merely to present to the young student a clear and perspicuous development of the fundamental principles of Dynamics, and not to carry him forward into those higher and more imposing applications of those principles, which necessarily demand a knowledge of much more recondite mathematical theories.

The student who has carefully mastered what is here delivered, will, we hope, find his study of the more advanced dynamical researches somewhat facilitated by the previous perusal of this elementary tract. Before concluding it, however, it is proper to give a formal enunciation of what have been called Newton's Three Laws of Motion: these, as already observed at page 734, are certain dynamical axioms, or postulates, assuming principles of too fundamental a character to admit of being rigorously established either by abstract reasoning or by experimental proof. In the foregoing pages we have, in general, tacitly taken these for granted, in several special topics of inquiry: we have preferred this course, to the usual custom of stating the three laws of motion in all their generality at the outset of the subject, because we think that their meaning and applicability cannot be clearly understood and perceived, till some familiarity with the language of Dynamics, and with a few of its more elementary problems, has been acquired.

THE THREE LAWS OF MOTION.—There are various forms of expression in which Newton's three laws are delivered by different writers on Dynamics: the following enunciation of them will perhaps be found as intelligible as any.

First Law.—A body once at rest, will remain at rest, unless acted upon by some external force; and if moving in any direction, will continue to move in that direction, unless acted on by some external force.

Second Law.—When a force acts upon a body in motion, the effect of this action is the same, in magnitude and direction, as if it acted on the body at rest.

Third Law.—This was stated by Newton as follows:—"Action and reaction are equal and contrary;" that is to say, A cannot act mechanically upon B, without A itself being reacted upon equally, but in an opposite direction.

The conjoined effect of velocity, and the moving mass, is *momentum*, as defined at page 743; and this momentum is the dynamical evidence of the "action" referred to in the law, which therefore merely affirms, that whatever momentum a body communicates in any direction, *that* momentum it loses in that direction; or, which is the same thing, it receives an equal momentum in a contrary direction.

A great deal of abstract argument, and of mechanical contrivance and experiment, have been employed to demonstrate the truth of these positions; we have neither space nor inclination to enumerate them: some things *must* be taken for granted, as fundamental or primitive principles, in every department of science. Reflection and common sense, exercised in the examination of such first principles, will usually produce a stronger amount of conviction of their truth than persuasive arguments or approximative experiments. Their verisimilitude, which renders it hard even to imagine a contravention of them, must be accepted instead of rigid proof: and when it is known that the results of the remotest investigations, all primarily resting on the truth of these assumptions, are in every instance verified by actual experience, the original *primâ facie* probability of their correctness becomes elevated into absolute certainty.

We may remark, in conclusion, that the fundamental principles of Dynamics, and the strict mathematical theories and deductions founded on them, find their fullest verification only in the movements of the heavenly bodies. Terrestrial mechanics is encumbered with many considerations operating as hindrances and drawbacks to the rigid application of those theories. Machines of human contrivance perform their functions through the intervention of rods and bars, wheels and pinions; and thus the consideration of *friction*, an obstacle that sometimes largely modifies the purely mathematical results, becomes imperatively necessary in practical mechanics. But the machinery of the heavens, without any physical ties to hold it together, goes on in obedience to an Almighty Immaterial agency; and thus the phenomena exhibited are in the completest harmony with the accurate deductions of mathematical science.

The modifying influence of friction, in the ordinary mechanical arrangements, will be examined into in the treatise on APPLIED MECHANICS.

The following particulars will often be found of service in dynamical inquiries:—

Force of gravity in the latitude of London, 51° 31′ 8″ N, 32·1908 feet.

Force of gravity in the latitude of Paris, 48° 50′ 14″ N, 32·1820 feet.

Force of gravity near the Equator, latitude 0° 1′ 34″ S, 32·0881 feet.

Force of gravity at Spitzbergen, latitude 79° 49′ 58″ N, 38·2526.

Length of the pendulum beating seconds in the latitude of London, 39·139 inches.

Equatorial diameter of the earth, 7925·465 geographical miles.

Polar diameter of the earth, 7898·972 geographical miles.

A French metre = 39·3708 English inches.

A French gramme = 15·434 grains.

CHAPTER IV.

HYDROSTATICS.

Hydrostatics is the science which treats of fluids, when maintaining a state of rest or equilibrium under the action of mechanical forces or pressures. Fluids are distinguished from solid bodies by obvious and remarkable peculiarities; and, in consequence of these differences, the statics and dynamics of the latter become only partially applicable to the former; so that the statics of water, and the dynamics of water, require a distinct and separate consideration. These two divisions of the general science of mechanics, thus applied exclusively to water, and such-like fluids, are called respectively *Hydrostatics* and *Hydrodynamics.*

To define a *fluid* would be to describe exactly what it is—its internal constitution, as well as the phenomena peculiar to that constitution, which it presents to our senses. But this is beyond our power: we know that, in common with all material existences connected with this earth, it has weight; but that, unlike solid bodies, it is without that entire cohesion of parts by which a solid preserves its shape in whatever position it be placed, and in virtue of which it is moved, as a whole, by a force applied only to a part.

It is this comparative absence of cohesion from among the constituent particles of a fluid, that renders those particles so freely movable among themselves, that causes them so readily to yield to any impression, and to obey the slightest effort to separate and detach them, as also to admit of the passage of solid bodies through them. It is the want of cohesion, too, that causes a fluid to change the figure it is made to assume, when supported in a vessel, as soon as any of that support is removed. A fluid presses laterally as well as vertically; and, in consequence of the lateral pressure, tends to spread itself horizontally when left unconstrained.

In all these particulars it differs entirely from a solid body: in *this* all the particles mutually cohere, and, in the absence of violence, maintain their relative positions. In a fluid, on the contrary, they are entirely free to interchange situations, and to move among themselves.

In this general statement of the characteristic differences between a solid and a fluid, it is to be borne in mind that we refer only to fluids such as we find them on this earth—fluids acted upon by the force of gravitation, and therefore having weight. If we conceive a vessel of water to be suspended in space, and gravity and every other force to be removed, then the fluid having no weight, there would be no pressure on the vessel in any direction; so that the water would preserve the shape of the vessel even though the latter were removed. In the absence of all force, there would be nothing to disturb the original arrangement of the component parts of the fluid mass.

TWO KINDS OF FLUIDS.—Fluids are divided into compressible fluids and incompressible fluids: the former are those which by pressure may be forced to contract into smaller space—such a fluid is the air we breathe, and every kind of gas. The incompressible fluids are those which cannot by pressure be reduced to smaller bulk. Whether, in strictness, any such fluid actually exists, is more than we can say; because, however it might resist compression from the mechanical forces at our command, it would be presumptuous to conclude that compression was impossible. This, there is reason to believe, is not the case with any fluid: water was formerly thought to be incompressible; but, by great mechanical force, it has in a slight degree been actually reduced to smaller compass. Still this, and the other common liquids, are so little compressible, that no practical error can arise from treating them as incompressible fluids.*

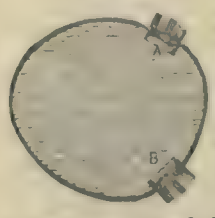
They are also classed under the heads of Elastic Fluids and Inelastic Fluids: the former are such as yield to compression; and upon the pressure being removed, expand to their former bulk. Air and gases are elastic fluids. Water, and liquids generally, are of course regarded as inelastic, as they do not admit of compression (in this sense) in any degree worth notice.

FLUID ELASTICITY.—The term elasticity, as applied to fluids, is not precisely the same in meaning as when applied to solids. A solid body is elastic when, having yielded to the force of a blow, an equal force, called the force of restitution, is exerted in the opposite direction, restoring the body to its original figure: there is no condition as to whether or not what is called the force of compression, actually causes the body to contract into smaller compass. But as regards fluids, elasticity refers to their contraction by pressure into smaller bulk, and their subsequent expansion to the original volume when the pressure is withdrawn. It is in this sense that the elasticity of fluids is to be understood. But taking the term with the signification attached to it in the mechanics of solid bodies, fluids may certainly be considered as elastic: a quantity of water poured down from any height on a hard substance, will to a certain extent rebound, and disperse itself in spray; and so likewise will it do if poured upon water itself. A flat stone, or an oyster-shell, thrown very obliquely on the surface of a pool of water will also rebound; and even a cannon-ball will do the same; but in none of these instances is the fluid compressed into smaller bulk.

TRANSMISSION OF PRESSURE.—The fundamental property of water and all other fluids is, that a pressure applied to any part of their surface is transmitted equally in all directions throughout the entire volume of the fluid: this is called the principle of equal pressure, and may be proved in various ways: for instance, if a vessel be perforated all round at any depth, and glass tubes, however bent, be inserted in the apertures, and then water or any other liquid be poured into the vessel, we find that when the level of the perforations is reached, the water presses into the tubes; and however high we raise the level of the water in the vessel, to the same level it always rises in each tube—thus showing, that on the same extent of surface at the same depth, there must be the same pressure.

Again: let a vessel of any shape be filled with water, (Fig. 153), and to any two equal perforations in its sides, let pistons A, B, be fitted; let the proper amount of pressure be applied to the piston A to keep the fluid in its place, and also the proper amount of pressure to the piston B. Then it will be found that any additional pressure applied to one of the pistons is transmitted to the other; so that equal additional pressures must be applied to both pistons to keep the fluid in its place, or to prevent one of the pistons from being forced outwards.

Fig. 153.



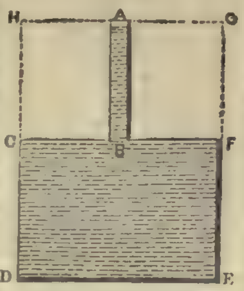
And if the vessel were covered with such pistons, the same pressure would be transmitted to each of the others that is applied to any *one* of them.

This very remarkable property of fluids is perfectly general, having place whatever be the contour or external form of the vessel: if, for instance, the form be that in Fig. 154—namely, A B C E F, then the downward pressure at B, arising from the weight of the water in the tube A B, produces an equal upward pressure upon every portion of surface, equal to the base of the tube, between B and C, and between B and F. Also the pressure of the fluid upon the base D E of the vessel is the same as it would be if the vessel were enlarged to the form H E, and the compartments H B, G B filled up with the fluid, the sides or partitions B C, B F being removed; for before the removal of these sides, the upward pressure on B C is the same as the downward pressure on it, from the weight of the fluid afterwards introduced into H B; the two pressures therefore neutralise one another, and thus there is no additional pressure sustained by the bottom of the vessel D E: in like manner is there no additional pressure from the additional fluid in the compartment G B.

---

* By late experiments, it has been shown that fresh water contained in a vessel, and sunk to great depths in the ocean, undergoes evident compression.—Ed.

Fig. 154.



This is a property of fluids so extraordinary, that it has been called the *Hydrostatic Paradox*; namely, that the quantity, and therefore the weight of the fluid, may be indefinitely increased, and no increase of pressure be sustained by the bottom of the vessel, the pressure on the bottom being due entirely to the *height* of the fluid, and quite independent of its other dimensions.

Suppose in any vessel C B (Fig. 155), a solid body M, as a mass of lead, were suspended; then if a fluid be poured in to fill up the empty space about M, the pressure on the bottom of the vessel will be the same as if the mass M were removed, and its place supplied by additional fluid: the pressures on the sides, too, of the vessel must remain unaltered, whether the mass M be of lead or of the fluid; for the mass, whatever it be, so that it be incompressible by the surrounding fluid, cannot in any way modify the pressures exerted on the bottom and sides of the vessel when filled wholly with the fluid. It may be observed here, that not only is the *pressure* on the bottom of the vessel the same when the fluid in it is only the border of fluid surrounding M, as when, M being removed, it is quite full; but the *weight* of the entire vessel and contents is the same in both cases, though M be firmly supported by the beam E—for only so much of M is thus supported as is equal to the excess of its weight above the weight of the fluid which fills up the space occupied by M upon the removal of that body. The pressure of a fluid on the base of a vessel is no indication or measure of the weight of the fluid: the pressure on the base A B is the same whether the vessel filled with the fluid be C A B D, or E A B F (Fig. 156), though the weights are of course different.

Fig. 155.

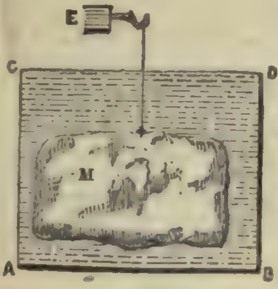


Fig. 156.

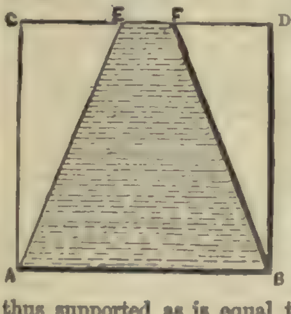
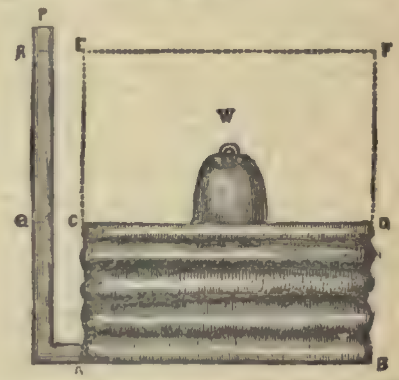


It thus happens, that by enlarging the base of a vessel, and narrowing the upper part, or by narrowing the upper part only, we may cause the pressure of the contained fluid on the base to *exceed* its weight in any given ratio: for instance, if the vessel be of the form of a cone, standing on its base, the pressure on the base will be three times the weight of the fluid itself. For the pressure on the base will be the same as if that base supported a cylinder of fluid instead of a cone of the same height; and we know that the content of the cylinder is three times the content of the inscribed cone.

Paradoxical as the statement may seem, that the pressure on the base is three times the whole weight of the fluid, the fact may be readily explained on the principle of the equal transmission of fluid-pressure. If the hollow cone be of heavy metal, and of sufficient weight to be completely water-tight when merely placed on the base, then, however great this weight of metal, if only the cone be sufficiently high, and water be poured into it through an orifice at the top, the upward pressure of the fluid will act with greater and greater intensity against the interior surface, till at length the cone will be seen to rise, forced upwards by the superior pressure, and the water will escape. This will be the subject of a problem hereafter. Equal pressures upward and downward have no effect on the weight.

HYDROSTATIC PARADOX.—But what is more emphatically called the hydrostatic paradox is this:—A B, C D (Fig. 157) are two stout boards connected together, like the boards of a pair of bellows, by a water-tight leathern band: if water be introduced into the enclosure through the pipe P or otherwise, the upward pressure of the fluid will separate the boards; and upon stopping the further supply of water, the fluid will stand at the same level both in the tube and in the receptacle C B; so that the small portion of water in the tube up to Q, balances or keeps in equilibrium the large body of water C B. If now a heavy weight be placed on the board C D—a weight equal to that of a mass of water that would fill up the space E D above the board—then the additional small portion of water filling the tube up to R would keep that weight supported.

Fig. 157.

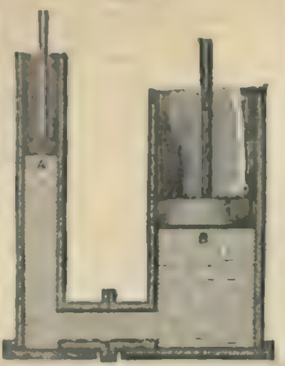


If, instead of water, the cavity C B be inflated with air, by a person standing on C D, and blowing into the tube P Q with his mouth, the same effect will take place; the person may thus easily raise himself higher and higher, and may therefore literally be said to be "blowing himself up." Such a contrivance is called the *hydrostatic bellows*.

All the phenomena hitherto enumerated are necessary consequences of the transmission of fluid-pressure in all directions. In the illustration just given, the downward pressure of the slender column of water P Q is transmitted as an upward pressure upon every area equal to the section Q of the entire surface C D; and thus the downward pressure of the body of water E D, or of the equivalent weight W, is counterbalanced.

BRAMAH'S HYDROSTATIC PRESS.—The hydrostatic bellows is little more than a philosophical toy for illustrating, in a popular and striking manner, that peculiar and important property of fluids by which pressure on a small surface is communicated undiminished to every portion, equal in area, of a large surface. Without the aid of levers, or pulleys, or wheels, or other such mechanical contrivances for accumulating and concentrating force, this fundamental property of water enables us to command as great a pressing force as we please at the expense of as little applied power as we please. One of the most interesting and useful exemplifications of this is furnished by Bramah's hydrostatic press, a machine the principle of which will be sufficiently understood from the following diagram (Fig. 158),

Fig. 158.



without entering into minute details of its construction. Water communicates with two cylinders of metal, as in the figure: one of these cylinders is of considerably larger section than the other. Water-tight pistons A, B being fitted to both, any force or pressure applied downwards to the smaller A, acts upwards upon the larger B with an intensity as many times the applied pressure as the area of it is contained in the area of B; so that by diminishing the diameter of A, or by increasing the diameter of B, we may make the upward pressure upon B as many times the downward pressure upon A as we please. Suppose, for instance, the diameter of the cylinder A is half an inch, and that of the cylinder B one foot; then as the areas of circles are proportional to the squares of their diameters, we shall have

$$(\tfrac{1}{2})^2 : 12^2 :: \text{applied pressure} :: \text{resulting pressure} = 576 \text{ times the applied pressure};$$

so that a pressure of 1 cwt. applied to the piston A, will produce a pressure of 576 cwt., or nearly 29 tons upon the piston B. It is plain that, by means of a lever, applied to the piston-rod A, the downward pressure may be increased to any required amount; and, in fact, by increasing the disparity in the diameters of the cylinders, and using only a moderate leverage on A, the transmitted pressure may be made as great as the metal cylinders can sustain. Something of this kind, no doubt, takes place in nature: water finds its way down the chinks and crevices of rocks and mountains, settling in whatever cavity within there may be to receive it. This cavity in time becomes filled, and a number of slender and irregular columns of water reaching from the reservoir to the surface, the upward and lateral pressure of the reservoir becomes at length greater than the rocky receptacle can sustain, a rupture takes place at the weakest part, and devastation is spread around. On a small scale, this effect is actually produced artificially in mining; where water-pressure is sometimes thus introduced for the purpose of blasting rocks.

It may not be altogether unworthy of notice here, that the Creator has provided a remarkable preventive for these destructive effects of fluid-pressure when exerted through a high column. The sap of trees, extending from the roots to the height of 80 or 100 feet, if it gravitated like the column of water in a Bramah's press, would rupture the trunks of the largest trees; but when fluid is introduced into *very narrow* tubes, an upward force, called capillary attraction, acts on the fluid in opposition to its downward pressure; and it is this force which sustains the sap in trees, and neutralises the downward pressure of the fluid.

EXPLANATION OF TERMS.—In the treatise on Dynamics (page 742), the meaning of the term *mass* was explained, and the distinction shown between it and weight. The weight or pressure produced by a mass M under the influence of gravity, may be denoted thus; namely, $W = Mg$. But in applying this notation, care should be taken to preserve consistency of meaning between the two members of the equation. M should be regarded as so many units of mass, just as, in Dynamics, t is regarded as so many units of time: the unit of mass may be arbitrarily chosen; and whatever it be,

$$\text{one unit of mass} \times g = \text{weight of the unit};$$

so that here g is not to be regarded as the symbol for the accelerating force of gravity, but for the *weight-force*—the force which gives to the mass M its weight or pressure; and employing M as an abstract number, namely, the number of units of mass, we have

$$1 \times g = \text{weight of the unit of mass};$$

that is, in the present inquiry, g stands for the following effect—namely, the weight impressed by gravity on the unit of mass. This is a definite and perfectly intelligible measure of the effect of gravity as a statical force; with the acceleration produced by it we have here no concern; and when, as in the current works on this subject, it is said, "let M represent mass, and g the accelerating force of gravity, and we shall have $W = Mg$," the language is calculated to mislead the student into the supposition, that the mass of a body is the 32nd part of its weight, which is of course an absurdity. The term "accelerating force" should never be employed in any statical inquiry, as it is unintelligible without reference to motion: the effect of the influence so called is, in statics, continued but stationary pressure or weight, and nothing else.

In order to estimate the mass or quantity of matter in any body, it is necessary—as in all other cases of measurement—to have reference to some conventional standard, as the unit of measure: accordingly, by general consent, the mass-unit is the quantity of matter contained in the volume unit (a cubic foot, or cubic inch) of distilled water at a certain temperature. Consequently, g stands for the weight of a cubic foot or inch, as may be agreed upon, of distilled water: as the cubic foot weighs just 1000 ounces, this is the unit to be preferred; so that the expression $W = Mg$ implies, that if we take the number of cubic feet in a body of distilled water containing the same quantity of matter as (and therefore of the weight of) W, then 1000 oz. multiplied by that number will give W, the multiplying *number* being all that is represented by M.

If a body contain D times as much matter as a body of distilled water of equal volume, the former is said to have D times the density of water; so that the density of water being taken = 1, that is, being taken for the unit of density, D will denote the density of the body: hence, if V be the volume, or rather the *number* of cubic feet in the body, DV will be the number of cubic feet in its equivalent, as to quantity of matter, of water; and therefore

$$W = Mg = DVg \quad . \quad . \quad . \quad . \quad (1)$$

Also if a body weigh S times as much as a body of distilled water of equal volume, the *specific gravity* of the former is said to be S. By the specific gravity, therefore, of any substance, is simply meant the ratio of the weight of any volume of it, to the weight of an equal volume of distilled water.

Both the density and specific gravity of any substance are expressed by the same abstract number: thus the density of mercury, as compared with distilled water, is 14; its specific gravity also is 14; but the density refers entirely to the mass, the specific gravity to the weight. As there is 14 times as much matter in a cubic foot of mercury as in a cubic foot of distilled water, the density of the former is 14 times that of the latter; and since, as a consequence of this superior density, a cubic foot of mercury is 14 times as heavy as a cubic foot of distilled water, the specific gravity of mercury is 14 also.

Hence, W and V denoting weight and volume as before, we have

$$W = S\,Vg \ (g = \text{one thousand ounces}) \quad . \quad . \quad . \quad . \quad (2)$$

INTERPRETATION OF SYMBOLS.—From the explanations now given, it will be perceived that the symbols to be hereafter employed have the following significations; namely:—

M = the *number* of cubic feet in a body of water containing the same quantity of matter (and therefore of the same weight) as the body proposed.
V = the *number* of cubic feet in the body proposed.
D = the *number* by which a volume of water must be multiplied, to give the same quantity of matter as is contained in an *equal* volume of the proposed body.
S = the *number* by which a volume of water must be multiplied to give the same weight as an *equal* volume of the proposed body. Hence, D and S

are the same abstract numbers; but the former refers to quantity of matter, and the latter to weight.

$g = 1000$ oz. avoirdupois: the weight or pressure communicated by gravity to a cubic foot of distilled water, at a temperature of 60° Fahrenheit.

All these symbols, except the pressure or weight g produced by gravity, are abstract numbers: the symbol W is of course the concrete quantity *weight*, as in common language. And weight—including under this term both pressure and tension—is the only concrete magnitude with which we have to do in Statics.

FLUID PRESSURES.—1. When a fluid is at rest, its upper surface is horizontal.

Let P Q (Fig. 159) be any two points in the upper surface of a fluid at rest, and the vertical lines P A, Q B be drawn, A B being a horizontal line of particles of the fluid. Then as A B is in equilibrio, the pressures on the extremities A, B in the horizontal direction must be equal; but the pressure on A, in the direction A B, is the same as the vertical pressure of the column of particles P A; and the pressure on B, in the direction of B A, is the same as the vertical pressure of the column of particles Q B. But these pressures are equal; therefore the column of particles P A is equal to the column of particles Q B; that is, the points P, Q are equally distant from the horizontal line A B, and are therefore themselves in a horizontal line; and in the same way is it shown that *any* two points on the upper surface are in a horizontal line, and therefore that the entire surface is a horizontal plane. It is evident, too, that if A B be the upper surface of a fluid sustaining a lighter fluid that does not mix with it, the separating surface A B will be horizontal; for, from what is shown above, every point of A B is pressed alike.

Fig. 159.

It must be observed, that what are called vertical lines, are lines perpendicular to the surface of the earth; and the upper surface of a fluid, here shown to be perpendicular to these verticals, will therefore be a surface parallel to that of the earth—a spherical surface; but it is customary to call but a small portion of such a large surface, a plane.

It is upon this property of fluids that the value of levelling instruments depends; that is, instruments which serve to show whether or not any two points are at the same horizontal level. The common level consists of a bent tube (see Fig. 160), open at the ends, which are turned up. The tube is nearly filled with a fluid, generally mercury, which supports two floats bearing sights, with a slender wire across, the wires being at equal distances from the floats. When held in the hand, the two surfaces bearing the floats are necessarily horizontal, however the tube itself may be inclined; and consequently the two wires are always on the same horizontal plane; also, whatever other objects, seen through the sights, may be on the same level as the wires, must likewise be in the same horizontal plane, or on the same level.

Fig. 160.

2. The pressure perpendicular to a surface immersed in a fluid, is equal to the weight of a column of the fluid whose base is the area A of the surface, and whose altitude is the perpendicular depth of the centre of gravity of the surface.

For let the vertical length of any linear column of particles pressing on the surface be a_1, and the point of the surface pressed be P_1. Regarding this point as a small area, we have for the pressure or weight of the column, SgP_1a_1, S being the specific gravity of the fluid. In like manner, for another vertical column of length a_2, pressing on another point P_2, we have SgP_2a_2; and so on. Hence, the whole pressure perpendicular to the surface is

$$Sg\,(P_1a_1+P_2a_2+P_3a_3+\ .\ \ .\ \ .\ \ .)$$

But if G be the depth of the centre of gravity of the assemblage of points P_1, P_2, P_3, &c., that is, of the proposed surface A, then by Statics,

$$P_1a_1+P_2a_2+P_3a_3+\ .\ .\ .\ .=(P_1+P_2+P_3+\ .\ .\ .\ .)\,G$$

$$\therefore \text{ Pressure perp. to the surface}=SAG\,.\,g$$

where AG is the volume V of a column of fluid of base equal to the area A and height G; so that $W=SVg$. Hence, if a given area A, immersed in a fluid, revolve round its centre of gravity, the pressure perpendicular to its surface must be the same in every position. Also if the area be a rectangle, the pressure upon it, when it forms the bottom of a vessel, will be double the pressure upon it when it forms one of the vertical sides; so that the pressure upon the four sides of a cubical vessel filled with liquid, is equal to twice the pressure on the base, that is, to twice the weight of the fluid.

If the sides of a vessel filled with fluid are all vertical, the entire pressure on the sides is equal to the weight of a column of the fluid whose base is the rectangle formed by developing the sides into a plane, and whose height is half that of the fluid.

By means of the preceding proposition, it is easy to find the amount of pressure sustained by a rectangular dam, or by a pair of flood-gates. If we multiply the area of the dam, or flood-gate, by half the depth of the water, we shall have the volume of water the weight of which will be the pressure. For example: let the water be 8 feet deep, and the breadth of the flood-gate 6 feet; then the area of the surface pressed is 48 feet: hence, $48\times4=192$ cubic feet of water $=12000$ pounds $=5\frac{5}{14}$ tons.

Since the centre of gravity of a straight line is at its middle point, if two straight lines a_1, a_2 be placed vertically in a fluid, the upper extremities of each being on the surface, then pressure on a_1 : pressure on

$$a_2 :: a_1\frac{a_1}{2} : a_2\frac{a_2}{2} :: a_1^2 : a_2^2$$

that is, the pressures are as the squares of the lengths. But if the lines are inclined to the surface of the fluid at the angles α_1, α_2 respectively, the perpendicular depths of the centre of gravity are

$$\tfrac{1}{2}a_1 \sin.\ \alpha_1, \text{ and } \tfrac{1}{2}a_2 \sin.\ \alpha_2$$

The pressures are therefore as

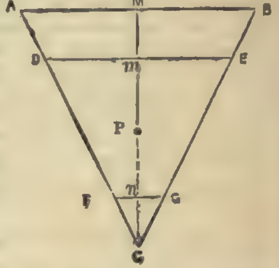
$$a_1\times\tfrac{1}{2}a_1 \sin.\ \alpha_1 : a_2\times\tfrac{1}{2}a_2 \sin.\ \alpha_2,$$

or as $$a_1^2 \sin.\ \alpha_1 : a_2^2 \sin.\ \alpha_2 ;$$

that is, as the squares of the lines into the sines of the angles of inclination, or as the squares of the lines themselves if the inclinations are equal.

If a triangle be immersed at any inclination in a fluid, with its vertex downwards and its base horizontal, and at the surface of the fluid, then the pressures on any two lines DE, FG (Fig. 161), the one as distant from the base as the other is from the vertex, will be equal.

Fig. 161.



For draw C M bisecting A B, and therefore bisecting the parallels D E, F G in m and n.

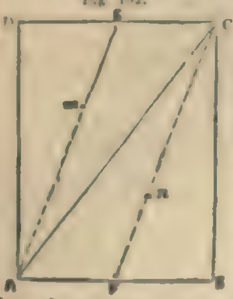
Now the pressures on D E, F F are as D E . Mm : F G . Mn; that is, as D E . Cn : F G . Cm. But Cn : Cm :: F G : D E; hence the pressures are as D E . F G : F G . D E; that is, they are equal.

If the triangle be reversed, C being at the surface of the fluid, the student may easily prove that the pressures on any two parallels are as the squares of those parallels, or as the squares of their depths.

3. If one of the sides of a vessel filled with fluid be a

rectangle, and if this rectangle be divided by a diagonal two triangles, then the pressure on one triangle will be double that on the other.

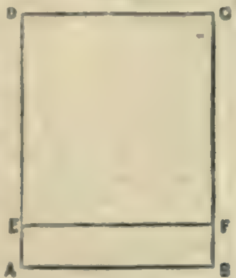
Fig. 162.



For let A B C D (Fig. 162) be the rectangle, and A C a diagonal. Let A E bisect D C, and C F, A B; and take $Em = \frac{1}{3}EA$, and $Fn = \frac{1}{3}FC$: then m and n are the centres of gravity of the two triangles. The depths of these centres are to one another as $Em : Cn$; that is, as $\frac{1}{3} : \frac{2}{3}$, or as $1 : 2$; and as the areas of the two triangles are equal, therefore the pressures upon them are as $1 : 2$.

4. Problem.—To divide the preceding rectangle, by lines parallel to the base, into n rectangles, so that the pressure on each may be the same.

Fig. 163.



Let E B (Fig. 163) be the lowest rectangle; then, since the centre of gravity of a rectangle is its middle point, the depth of the centre of gravity of A C is $\frac{1}{2}DA$, and of that of E C, $\frac{1}{2}DE$. The pressures, therefore, on these rectangles are as

$$DA \times \tfrac{1}{2}DA : DE \times \tfrac{1}{2}DE,$$
$$\text{or as } DA^2 : DE^2.$$

But the pressure on A C is divided into n equal pressures, and the pressure on A C into $n-1$ equal pressures: hence

$$DA^2 : DE^2 :: n : n-1.$$

$$\therefore DE = \sqrt{\frac{n-1}{n}}\,.\,DA.$$

$$\therefore EA = DA - DE = DA\left\{1 - \sqrt{\frac{n-1}{n}}\right\}$$

If, for instance, the rectangle is to be divided into two rectangles, so that the pressure on each may be the same—that is, half the whole pressure—then since $n=2$, $DE = \frac{1}{\sqrt{2}}DA = \frac{1}{2}DA\sqrt{2}$.

It appears from this proposition, that in constructing a flood-gate, or an upright embankment, to resist the pressure of water against it, it is unnecessary to make the material equally strong throughout; the proper degree of strength being secured at the bottom, where the pressure is greatest, the strength upwards may be diminished in the proportion of DA^2 to DE^2; that is, the strength may decrease as the square of the depth decreases.

Problem.—To determine the pressure upon the internal surface of a hollow sphere filled with fluid.

The centre of gravity of the surface pressed, is at the centre of the sphere, so that the distance of the centre of gravity from the surface of the fluid is the radius r. The area of the surface of the sphere is $4\pi r^2$, where π stands for 3·1416: hence, the pressure is the same as that of a cylindrical column of the fluid of base $4\pi r^2$ and altitude r.

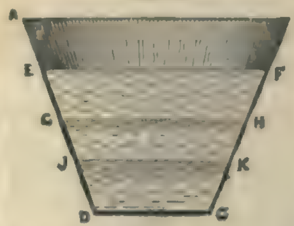
If S be the specific gravity, the weight of this column of the fluid is $4\pi r^3Sg$; but the volume of the sphere is $\frac{4}{3}\pi r^3$, and therefore the weight of the contained fluid is $\frac{4}{3}\pi r^3Sg$. Hence the pressure on the internal surface of the sphere is three times the weight of the contained fluid.

If a cone have its base equal to the surface of the sphere, and its altitude equal to the radius of the sphere, the pressure on the base of the cone will be the same as that on the surface of the sphere, when both are filled with the same fluid (page 749).

Problem.—To determine the pressure on the horizontal base of a vessel containing different fluids.

Let E F, G H, J K (Fig. 164), be the surfaces of the different fluids; these surfaces are all horizontal (p. 751). Let p, p_1, p_2, p_3, be the perpendicular depths of the several layers of fluid J C, G K, E H, A F, and S, S_1, S_2, S_3 their respective specific gravities: then the pressures of these several layers on the base D C will be,

Fig. 164.



$$DC\,.\,pSg,\ DC\,.\,p_1S_1g,\ DC\,.\,p_2S_2g,\ CD\,.\,p_3S_3g$$

and consequently the whole pressure on the base will be

$$DC\,(pS + p_1S_1 + p_2S_2 + p_3S_3)g$$

that is, the pressure on the base is found thus: multiply the area of the base by the sum of the products of the perpendicular thickness of each fluid into its specific gravity: the number of cubic feet, in the result, will be the number of 1,000 ounces of pressure.

If the depths of the several layers of fluid are all equal, then the pressure on the base will be

$$DC\,.\,p\,(S + S_1 + S_2 + S_3)\,g$$

so that if we multiply the area of the base by the perpendicular height of one of the layers of the fluid, and the product by the sum of the specific gravities, the result will be the number of 1,000 ounces of pressure.

Example.—A cylindrical vessel is filled with mercury to half its height, and the remainder is then filled with water. Supposing the specific gravity of mercury to be 14, required the pressure on the base, and on the concave perpendicular surface.

Let a be the height of the cylinder, and r the radius of its base: then the area of the base of the cylinder will be πr^2; and since $S = 14$, and $S_1 = 1$, we shall have for the pressure on the base

$$\pi r^2\,.\,\tfrac{1}{2}a\,(14+1)\,1000 \text{ oz.} = \frac{15}{2}\pi r^2a \times 1000 \text{ oz.}$$

The pressure on the concave surface of the lower half of the vessel is the same as if the water in the upper half were removed, and a column of mercury $\frac{1}{14}$th as high substituted in its stead, making the height of the entire column of mercury $(\frac{1}{2} + \frac{1}{28})a$. Hence, the area of the lower half of the concave surface being $2\pi r\frac{1}{2}a$, and the depth of the centre of gravity of it $\frac{1}{4}a + \frac{1}{28}a = \frac{2}{7}a$, we have for the pressure on that surface

$$2\pi r\tfrac{1}{2}a\,.\,\tfrac{2}{7}a\,.\,14g = 4\pi ra^2 \times 1000 \text{ oz. } (=g)$$

The pressure on the upper half of the surface is $2\pi r\frac{1}{2}a\,.\,\frac{1}{4}ag = \frac{1}{4}\pi ra^2g$: therefore the whole pressure on the concave surface is $4\pi ra^2g + \frac{1}{4}\pi ra^2g = \frac{17}{4}\pi ra^2 \times 1000$ oz. $(=g)$.

Or the pressure on the concave surface may be found thus:—remembering the fundamental principle, that a pressure exerted on the surface of a fluid is transmitted in all directions;

Pressure on lower half of cylinder by the mercury alone,

$$2\pi r\tfrac{1}{2}a\,.\,\tfrac{1}{4}a \times 14g$$

Pressure of the water on the surface of the mercury,

$$2\pi r\tfrac{1}{2}a\,.\,\tfrac{1}{2}a \times 1g$$

Pressure of the water on the upper half of the cylinder,

$$2\pi r\tfrac{1}{2}a\,.\,\tfrac{1}{4}a \times 1g$$

Sum of the pressures,

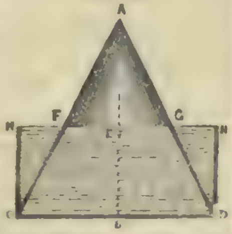
$$\frac{17}{4}\pi ra^2g = \frac{17}{4}\pi ra^2 \times 1000 \text{ oz. } (=g).$$

In a similar manner may the united pressures of layers, equal or unequal, of different fluids be always ascertained: the bottom layer exercises its own pressure, and this is increased by the weight of the whole superincumbent mass: the second layer in like manner exercises its own pressure, increased by the weight of the mass above *it*; and so on.

PROBLEM.—A hollow cone rests in a vessel with its base on a smooth horizontal plane, and water is poured in at the top of the cone. How high will the water rise before it lifts the cone off its support and escapes? (See Fig. 165).

As the water rises in the cone, it exercises an upward pressure on its slant sides, which increases as the perpendicular height of the fluid increases; and as soon as this upward pressure becomes equal to the downward pressure or weight of the conical shell, the equilibrium is just maintained, and no more water; that is, no more upward pressure can be sustained by the cone, which will therefore be lifted up, and give egress to the water: we have therefore to find the height of water, the upward pressure of which is just equal to the weight of the cone.

Fig. 165.



The upward pressure, thus just balanced by the weight of the cone, would be equally balanced if a cylinder on the same base, and of the same altitude as the water, were to surround the cone, and the vacant space to be filled with the fluid. Thus if B E (Fig. 165) were the height of the water, and if a cylinder H D were to surround the cone, and the space H F C to be filled with water, the downward pressure or weight of the water in this space would replace the weight of the cone, so that the equilibrium would remain undisturbed if the cone were withdrawn; we have therefore to determine the height B E of the cylinder, so that the weight of water contained between it and the cone may be exactly equal to the weight of the cone.

Let A B = a, B C = b, A E = x: then the volume of the cone A C D is $\frac{1}{3}\pi b^2 a$; and the volume of the cone A F G, being to that of A C D as x^3 to a^3, is $\frac{1}{3}\pi b^2 a \times \frac{x^3}{a^3}$: hence the volume of water in the frustum F D is

$$\text{volume of water in F D} = \tfrac{1}{3}\pi b^2 a\left(1-\frac{x^3}{a^3}\right)$$

$$\text{weight of the same} = \tfrac{1}{3}\pi b^2 a\left(1-\frac{x^3}{a^3}\right)g \;.\;.\;.\;(1)$$

the specific gravity of the fluid being 1.

Also, if the cone were removed, the volume of water in the cylinder H D would be

$$\text{volume of water in cylinder} = \pi b^2(a-x)$$
$$\text{weight of the same} = \pi b^2(a-x)\,g \;.\;.\;.\;(2)$$

Hence, subtracting (1) from (2), we have for the weight of water between the cylinder and cone—that is, for the upward pressure of the water in the cone on its sides,

$$\text{upward pressure on cone} = \pi b^2 g\left\{(a-x)-\tfrac{1}{3}a\left(1-\frac{x^3}{a^3}\right)\right\}$$

If, therefore, the weight of the cone be w, we shall have to solve the cubic equation

$$\pi b^2 g\left\{(a-x)-\tfrac{1}{3}a\left(1-\frac{x^3}{a^3}\right)\right\} = w$$

$$\text{or}\qquad x^3-3a^2x+2a^3=\frac{3a^2w}{\pi b^2 g}$$

$$\text{or}\qquad \left(\frac{x}{a}\right)^3-3\left(\frac{x}{a}\right)+2=\frac{3w}{\pi b^2 ag}$$

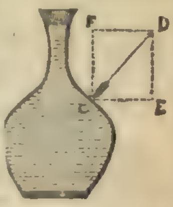
The upward pressure of the fluid compels an equal pressure downwards on the base; the water in the cavity between the cone and cylinder is just sufficient to balance the upward pressure, or to replace the resistance of the sides, the pressure on the base remaining undisturbed; and it is thus that the base of the cone supports not only the water in it, but also an amount of pressure equal to the weight of the additional water between the cone and cylinder.

In any vessel containing fluid, where all the *vertical* pressures are downwards—that is, where the sides do not any of them incline inwards—the sum of the vertical pressures must be equal to the weight of the fluid. For every vertical line of particles presses downwards with the weight of those particles; so that the whole vertical pressure is the whole weight of the fluid.

The pressure is, therefore, the same as it would be if the fluid were to become solid, and the sides of the vessel to be removed; and the effect is the same as if the entire pressure or weight were concentrated in the centre of gravity.

The horizontal pressure at any depth, is of course the same all round the vessel at that depth, the pressure of every horizontal line of particles being equal to the pressure of a vertical line of particles reaching from the surface to the horizontal line. The downward vertical pressure on the bottom of a vessel can exceed the weight of the fluid contained in the vessel, only when one or more of its sides, or a portion of a side, inclines inwards, occasioning an upward pressure, which reacts downwards on the base, the excess of the pressure on which, above the weight of the fluid, is just equal to this additional pressure; and the vertical pressure on the bottom can fall short of the weight of the fluid in the vessel, only when a side, or portion of a side, inclines outward, occasioning a downward pressure on that side. The whole downward pressure on the sides, together with that on the base, makes up the weight of the fluid.

Fig. 166.



Take, for example, the case of a common decanter: the pressure at any point C (Fig. 166) is in the direction of the straight line perpendicular to the surface. This may be decomposed into two pressures, of which one C E is horizontal, and the other C F vertical: this last pressure being directed upwards in the figure, if the point C had been near to the bottom, it would have been directed downward, on account of the curvature there being in a contrary direction. If we conceive the pressure at every point of the interior surface of the decanter to be decomposed in like manner into a horizontal and vertical pressure, there will be a series of horizontal pressures like C E, and a series of vertical pressures like C F. The horizontal components mutually destroy one another; otherwise the decanter would tend to move horizontally, which is not the case. Of the vertical components, some are upward pressures and the others downward pressures: they may, therefore, be replaced by a single vertical force, which will act upward or downward, according as the component vertical forces upward or downward prevail.* If this simple resultant pressure act upward, the pressure on the bottom of the decanter will exceed the weight of the liquid, because the downward pressure on the bottom, *minus* this upward pressure, must be equal to the weight: on the contrary, if the resultant be a downward pressure, then because the downward pressure on the bottom, *plus* this other downward pressure, is equal to the weight, the pressure on the bottom will be less than the weight.

PROBLEM.—To determine the resultant of all the pressures of a fluid upon the surface of a body immersed in it.

Instead of the immersed body C (Fig. 167), conceive the fluid it displaces to become solidified: the surrounding pressures will keep the solidified fluid at rest, just as if it were in its original state. But for these pressures, the mass would fall downwards in virtue of its weight: the resultant of the pressures, therefore, just balances the weight, and acts in a direction opposite to that of gravity; that is, vertically upwards through the centre of gravity of the mass. And as the surrounding fluid exerts the same pressures, whatever be the body whose surface is pressed, it follows that the resultant of the pressures on the surface of any solid body, is equal in intensity to the weight of the fluid displaced by it, and is directed vertically upwards through the centre of gravity of the fluid displaced.

---

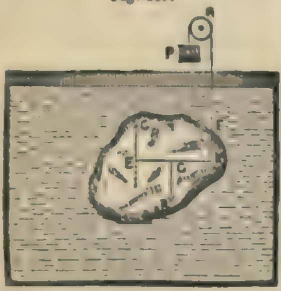
* See *Statics; ante*, p. 726.

When the solid floats at rest, the weight of the fluid displaced is equal to the weight of the solid; and the centre of gravity of the solid and that of the displaced fluid are in the same vertical line.

For the pressure of the fluid on the portion of surface immersed, and the weight of the solid, are the only forces acting: hence, as the body is at rest, the resultant of the pressures on it must be equal and opposite to the downward pressure, or weight, of the body, and act in the same vertical straight line. But since, as just shown, the resultant of the pressures (equal to the weight of the displaced fluid) is directed upwards through the centre of gravity of the fluid displaced, and the weight of the solid is directed downwards through the centre of gravity of the solid, it follows that the resultant of the pressures, that is, the weight of the fluid displaced, is equal to the weight of the solid, and that the centres of gravity of both are in the same vertical line. If, instead of floating on the surface, the body be kept from sinking by a force, acting along a string, just sufficient to keep the body at rest, the conditions of equilibrium may be found as follows:—

Let G be the centre of gravity of the body suspended in the fluid by the string F A: let E C, G B be verticals through the centre of gravity of the displaced fluid and through the centre of gravity of the body. Let also

Fig. 167.



W = weight of the body, and W′ = weight of fluid displaced;

T = tension of the string;

V = volume of the fluid displaced;

and D = density of the fluid.

The body is kept at rest by the forces $W' = D\,Vg$, acting in the direction E C; W, acting in the direction G B; and T, acting in the direction F A. These three forces must therefore be all in one plane; and T must be $= W - W'$. Through G draw E G perpendicular to E C, F A; then as the body is at rest, the moments of the forces W, W′ to turn the body about K in opposite directions, are equal (STATICS, p. 716).

$$\therefore W \,.\, GK = W' \,.\, EK = D\,Vg \,.\, EK.$$

Hence the weight acting over the pulley A upon the body at F, just sufficient to keep the body from sinking, is $W - W'$; and in order that it may be kept from turning, there must be the condition $W \,.\, GK = W' \,.\, EK$. Should the body be lighter than the fluid, and tend to float instead of to sink, then the force on F to prevent its rising will of course be $W' - W$; the other condition to prevent turning remaining the same.

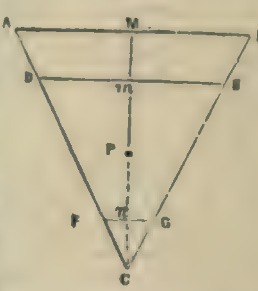
As noticed at page 749, if the vessel be full before plunging the body into the fluid, the quantity of the fluid which the immersion of the body causes to run over will occasion no diminution of the weight of the vessel and contents, nor yet any modification of the pressures on the bottom and sides: for the body merely fills the place of the bulk of fluid which its immersion drives out of the vessel. The circumstances as to the weight and pressures are the same as if the fluid, that originally occupied the space now filled by the body, had become solidified while at rest in the vessel. The weight P in the above diagram, and which measures the tension of the string, measures the excess of weight in the body above the weight of the water it displaces.

THE CENTRE OF PRESSURE.—The pressures of a fluid against the different points of a plane surface may be regarded as a system of parallel forces, acting perpendicular to the plane: the resultant of these forces is therefore perpendicular to the plane; and the magnitude or intensity of the resultant has already been shown (page 751) to be equal to a column of the fluid whose base is the surface pressed, and whose altitude is equal to the depth of the centre of gravity of the surface below the level of the fluid. The centre of pressure is that point of the surface to which, if a single force equal and opposite to the resultant of the pressures were applied, the plane would be kept at rest.

PROBLEM.—To find the centre of pressure of a fluid on a triangle whose base is horizontal and at the surface of the fluid.

Let A B C (Fig. 168) be the triangle, and draw C M to bisect the base A B; also let D E, F G be two lines parallel to A B, and drawn so that the distances M m, n C may be equal. These lines being horizontal are uniformly pressed throughout, so that the centre of pressure on each is at its middle point; and, as already proved at page 751, the pressure on one, is the same as the pressure on the other. Consequently we may regard the extremities m, n of the line m n as pressed by equal forces: the resultant of these is therefore equal to the sum of both applied to the middle point P, which point is evidently the middle point of C M.

Fig. 168.

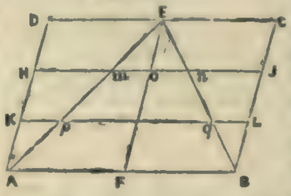


Whatever two lines be taken equidistant from M and C, the point of application P of the resultant remains the same; and as the whole pressure on the triangle may be regarded as made up of all these linear pressures, it follows that the resultant pressure must pass through P, which is therefore the centre of pressure on the triangle.

PROBLEM.—To find the centre of pressure of a fluid on a parallelogram, one of whose sides coincides with the surface of the fluid.

Let A C (Fig. 169) be the parallelogram, and draw E F bisecting the opposite sides D C, A B. The centre of pressure is necessarily in E F, as the pressures on each side of it are equal. Draw E A, E B, as also horizontal lines H J, K L, &c. Then the pressure on one of these lines, as H J, is to the pressure on A B as E o to E F; that is, as m n to A B. Hence, representing the pressure on A B by the line A B, the lines m, n, p, q, &c., will correctly represent the pressures on H J, K L, &c. Consequently if the fluid were all removed, and a pressure equal to that originally on A B be applied to that line, and also a pressure to every line p q, m n, &c., in the triangle, the pressures being always proportional to the lengths of these parallels, the parallelogram, in which the pressed triangle is inscribed, will still be at rest. But the resultant of all the pressures, thus uniformly diffused over the triangle, must pass through the centre of gravity of the triangle. Hence the centre of gravity of the triangle is the centre of pressure of the fluid on the parallelogram; and consequently the centre of pressure on the parallelogram, one of whose sides is at the surface of the fluid, is on the bisecting line E F, and at a depth equal to two-thirds the depth of the opposite or lowest side of the parallelogram. Again: suppose the upper side of the parallelogram to be below the surface of the fluid, but parallel to it; let H J, for instance, be the upper side of the parallelogram, and D C the surface of the fluid. Then, as shown above, the pressure on the parallelogram H C may be replaced by a pressure uniformly diffused over the triangle E m n; and the pressure on the parallelogram A C, by the extension of the pressure on E m n uniformly over the triangle E A B: hence the pressure on the parallelogram A J may be replaced by a pressure uniformly spread over the trapezium A m n B. Con-

Fig. 169.



sequently the centre of pressure of the parallelogram A J is the centre of gravity of the trapezium A $m n$ B.

As, in the first case, when the upper side of the parallelogram is at the surface of the fluid, the centre of the pressure is always on the same line E F, and at the same depth, however close the middle point E is to the extremities D, C—that is, however slender the parallelogram may be—it follows, that the centre of pressure of a straight line E F, having one extremity at the surface of the fluid, is at $\frac{2}{3}$rds the length of E F below E. The centre of pressure being the point about which all the pressing forces balance, it is, evidently, the point most in need of support, or where the opposing force should be more especially applied, to resist the pressure of the fluid on the surface, and thus to prevent rupture. The staves of vats and casks, which may be regarded as so many rectangles, should be each more especially strengthened at one-third of their lengths from the bottom.

SPECIFIC GRAVITIES OF BODIES.—When bodies are compared together, having the same specific gravity, any volume of one must of course have the same weight as an equal volume of each of the others; so that the weights of such bodies are to one another as their volumes. The volume of any irregular body may be ascertained by the bulk of water it displaces by being immersed (though more conveniently from its weight and specific gravity); or, for the purpose of comparing different volumes, we may merely observe the height to which the water rises in the two cases in a cylindrical vessel, upon the immersion of the bodies. The following is an example.

Example.—A mass of gold immersed in a cylinder containing water, caused the surface to rise a inches; a mass of silver of the same weight caused it to rise b inches; and a mass still of the same weight, but composed of gold and silver, caused it to rise c inches. What was the proportion of gold and silver in the compound mass?

Let x be the volume of the gold, and y that of the silver: then as the volumes immersed are as the elevations of the surface caused by the immersions, we have

$c : a :: x + y : \frac{a}{c}(x + y)$ the volume of the mass of gold.

$c : b :: x + y : \frac{b}{c}(x + y)$ „ „ „ silver.

The weights of these masses being equal, let W be the weight of each; then the weights being as the volumes when the specific gravities are the same,

$\frac{a}{c}(x + y) : x :: \mathrm{W} : \frac{c}{a} \cdot \frac{\mathrm{W}x}{x + y}$ the weight of gold in the compound,

$\frac{b}{c}(x + y) : y :: \mathrm{W} : \frac{c}{b} \cdot \frac{\mathrm{W}y}{x + y}$ the weight of silver in the compound.

$$\therefore \frac{c}{a} \cdot \frac{\mathrm{W}x}{x + y} + \frac{c}{b} \cdot \frac{\mathrm{W}y}{x + y} = \mathrm{W}$$
$$\therefore bcx + acy = ab\,(x + y)$$
$$\therefore (bc - ab)\,x = (ab - ac)y$$
$$\therefore x : y :: a\,(b - c) : b\,(c - a)$$

It is probable that in some such way as this Archimedes solved the problem proposed to him by Hiero, King of Syracuse, who having ordered a crown of gold to be made, suspected that the crown furnished to him was a mixture of gold and silver, and wished the truth to be ascertained without injuring the workmanship.

As the weight of one volume is to that of another of different specific gravity as the product of volume and specific gravity of the former is to the product of volume and specific gravity of the latter; therefore, if S, S′ represent the specific gravity of gold and silver respectively, the weights of x and y will be the one to the other as Sx to S′y; therefore, by the foregoing proportion,

wt. of the gold (x) : wt. of the silver (y)

$$:: a\,(b - c)\,\mathrm{S} : b\,(c - a)\,\mathrm{S}'$$
$$\text{or} :: \frac{a\,(b - c)}{b\,(c - a)} \cdot \frac{\mathrm{S}}{\mathrm{S}'} : 1$$

Consequently the weight of the compound is

$$\left\{\frac{a\,(b - c)}{b\,(c - a)} \cdot \frac{\mathrm{S}}{\mathrm{S}'} + 1\right\} \times \text{wt. of the silver} = \mathrm{W}$$

∴ the weight of the silver in the compound is

$$\mathrm{W} \div \left\{\frac{a\,(b - c)}{b\,(c - a)} \cdot \frac{\mathrm{S}}{\mathrm{S}'} + 1\right\}$$

PROBLEM.—Having given the volumes and specific gravities, or the weights and specific gravities of several bodies, to find the specific gravity of the compound.

1. Let the volumes V_1, V_2, V_3, &c., be given with the specific gravities S_1, S_2, S_3, &c.; and let S be the specific gravity of the compound; then since $\mathrm{W} = \mathrm{SV}g$, we have for the weight of $\mathrm{V}_1 + \mathrm{V}_2 + \mathrm{V}_3 + \&c.$

$$(\mathrm{S}_1\mathrm{V}_1 + \mathrm{S}_2\mathrm{V}_2 + \mathrm{S}_3\mathrm{V}_3 + \&c.)\,g$$
$$= \mathrm{S}\,(\mathrm{V}_1 + \mathrm{V}_2 + \mathrm{V}_3 + \&c.)\,g$$
$$\therefore \mathrm{S} = \frac{\mathrm{S}_1\mathrm{V}_1 + \mathrm{S}_2\mathrm{V}_2 + \mathrm{S}_3\mathrm{V}_3 + \&c.}{\mathrm{V}_1 + \mathrm{V}_2 + \mathrm{V}_3 + \&c.}$$

2. Let the weights W_1, W_2, W_3, &c., with the specific gravities S_1, S_2, S_3, &c. be given, S being the specific gravity of the compound as before: then since $\mathrm{V} = \frac{\mathrm{W}}{\mathrm{S}g}$, we have for the volume of $\mathrm{W}_1 + \mathrm{W}_2 + \mathrm{W}_3 + \&c.$

$$\frac{\mathrm{W}_1}{\mathrm{S}_1 g} + \frac{\mathrm{W}_2}{\mathrm{S}_2 g} + \frac{\mathrm{W}_3}{\mathrm{S}_3 g} + \&c.$$
$$= \frac{\mathrm{W}_1 + \mathrm{W}_2 + \mathrm{W}_3 + \&c.}{\mathrm{S}g}$$
$$\therefore \mathrm{S} = \frac{(\mathrm{W}_1 + \mathrm{W}_2 + \mathrm{W}_3 + \&c.)\,\mathrm{S}_1\,\mathrm{S}_2\,\mathrm{S}_3\,\&c.}{\mathrm{W}_1\,\mathrm{S}_1\,\mathrm{S}_2\,\&c. + \mathrm{W}_2\,\mathrm{S}_2\,\mathrm{S}_3\,\&c. + \mathrm{W}_3\,\mathrm{S}_3\,\mathrm{S}_4\,\&c.}$$

If m equal volumes are mixed, the specific gravity of the compound is

$$\mathrm{S} = \frac{\mathrm{S}_1 + \mathrm{S}_2 + \mathrm{S}_3 + \&c.}{m}$$

If m equal weights are mixed, the specific gravity of the compound is

$$\mathrm{S} = \frac{m\mathrm{S}_1\,\mathrm{S}_2\,\mathrm{S}_3 \ldots\ldots \mathrm{S}_m}{\mathrm{S}_1\,\mathrm{S}_2 \ldots \mathrm{S}_{m-1} + \mathrm{S}_2\,\mathrm{S}_3 \ldots \mathrm{S}_m + \&c.}$$

When there are only two bodies to be compounded, then for equal volumes, $\mathrm{S} = \frac{\mathrm{S}_1 + \mathrm{S}_2}{2}$; and for equal weights, $\frac{2\mathrm{S}_1\mathrm{S}_2}{\mathrm{S}_1 + \mathrm{S}_2}$, the former value being an arithmetic, and the latter an harmonic mean, between the specific gravities of the two substances.

PROBLEM.—To determine the volume of any substance, however irregular, of known specific gravity.

Let S be its specific gravity, and W its weight in ounces; then, since

$$\mathrm{W} = \mathrm{SV}g. \therefore \mathrm{V} = \frac{\mathrm{W}}{1000\,\mathrm{S}\ \text{oz.}}\ \text{cubic feet.}$$

In a similar way may the capacity of an irregular vessel be ascertained. Let the weight of the water that will fill the vessel be w ounces, then the capacity or volume of the vessel will be $\frac{w}{1000}$ cubic feet. If the result is to be in cubic inches instead of in cubic feet, the divisor 1000 must be replaced by the multiplier 1·728, because $\frac{1728}{1000} = 1{\cdot}728$: so that w being the number of the avoirdupois ounces in the weight, the volume or capacity will be $\mathrm{V} = 1{\cdot}728\,\frac{w}{\mathrm{S}}$ cubic inches.

Should w be the number of troy, instead of the number of avoirdupois ounces, then since

1 oz. troy : 1 oz. avoirdupois :: 480 : 437·5

$$\therefore 1 \text{ oz. avoirdupois} = \frac{437{\cdot}5}{480} \text{ oz. troy} = {\cdot}911458 \text{ oz. troy}$$

$$\therefore V = \frac{1728}{{\cdot}911458}\,\frac{w}{S} \text{ cubic inches} = \frac{1}{{\cdot}52746}\,\frac{w}{S} \text{ cubic inches.}$$

The divisor ·52746 is the troy weight in oz. of a cubic inch of water, as is obvious:—it is the value of w when $V=1$ and $S=1$. The troy weight of a cubic inch of water in grains is 253·1808 grains.

It is in general easier to ascertain the weight of a minute body than to measure accurately its dimensions; and thus the following is the method usually recommended for finding the diameter of a small sphere of known specific gravity and ascertained weight in grains troy. Let d be the diameter and w the weight in grains troy of the sphere, and S the specific gravity of the substance of which it is formed; then the volume of a sphere whose diameter is 1 inch being ·523598 inches, we have for the troy weight of an equal sphere of water

$$1 : {\cdot}523598 :: 253{\cdot}1808 \text{ grains} : 132{\cdot}5648 \text{ grains},$$

the weight of a sphere of water of 1 inch in diameter.

Now the volumes, and therefore the weights, of spheres of the same substance being as the cubes of their diameters, we have

$$1^3 : d^3 :: 132{\cdot}5648 \text{ grains} : 132{\cdot}5648d^3 \text{ grains},$$

the weight of the small sphere of water of diameter d; therefore the weight w of the proposed sphere is

$$w = 132{\cdot}5648d^3.\,S \text{ grains} \therefore d = {\cdot}19612\sqrt{\frac{w}{S}}$$

the *number* of grains being put for w.

When a body is wholly immersed in a fluid, the weight lost is to the whole weight as the specific gravity (S) of the fluid to the specific gravity (S′) of the solid.

The weight lost is the weight of the displaced fluid (page 754); and, from the general relation $W = SVg$, the weight of bodies of the same volume are as their specific gravities; therefore,

$$\text{wt. of displaced fluid} : \text{wt. of solid} :: S : S'$$
$$\text{that is, wt. lost} : \text{whole wt.} :: S : S' \ldots (1)$$

If the same body be immersed in another fluid whose specific gravity is S_1, then

$$\text{wt. lost} : \text{whole wt.} :: S_1 : S' \ldots (2)$$

The second and fourth terms being the same in the proportions (1) (2), it follows that the weights lost in the two fluids are as the specific gravities of those fluids; and hence may be ascertained the specific gravity of any fluid (obtainable in sufficient quantity for the experiment), when the specific gravity of any other fluid is known.

Also, the true weight of a body may be readily determined, from knowing what it weighs in each of two fluids of known specific gravities; for let W be the true weight and w, w' the weights in two fluids whose specific gravities are S, S′: then the weights lost are $W - w$ and $W - w'$ respectively.

$$\therefore W - w : W - w' :: S : S'.$$
$$\therefore S'W - S'w = SW - Sw',$$
$$\therefore (S' - S)W = S'w - Sw'.$$
$$\therefore W = \frac{S'w - Sw'}{S' - S}, \text{ true weight of}$$

the body.

And thus, from having the true weight of the body, and the weight lost in one of the fluids, we may, by the proportion (1) above, find also the specific gravity of the body.

By the true or absolute weight of a body is to be understood the weight of it in a vacuum, that is, free from the presence of even the air: the absolute weight, therefore, is equal to the weight of the body in air, increased by the absolute weight of a volume of air equal to that of the body; but for bodies of small volume this minute increase is inappreciable.

Example 1.—A piece of uniform substance, whose true weight is 64 grains, is found to weigh only 48 grains when immersed in distilled water: required the specific gravity (S) of the substance.

The weight lost is $64 - 48 = 16$ grains,

$$\therefore 16 : 64 :: 1 \text{ (specific gravity of water)} : 4.$$

Hence the specific gravity of the body is $S = 4$.

2. A body weighs 130 grains in one fluid, and 68 in another; but the true weight of the body is 240 grains: required the relative specific gravities of the two fluids.

The weights lost are 110 grains and 172 grains, and, as before, these are as the specific gravities of the fluids.

$$\therefore \frac{S}{S'} = \frac{110}{172}, \text{ or } S = \frac{110}{172}S'.$$

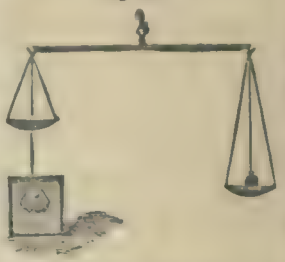
If one of the fluids be air in which the body is weighed, and the other water of specific gravity 1, then knowing the specific gravity S of the air, we have for the real weight W of the body, that is, for its weight in vacuo,

$$W = \frac{w - Sw'}{1 - S} = w + (w - w')S + (w - w')S^2 + \&c.$$
$$= w + (w - w')S \text{ very nearly,}$$

because S being a small fraction, S^2 is an equally small fraction of *it*.

The scales used in weighing bodies for the purpose of ascertaining specific gravities are called the *hydrostatic balance* (Fig. 169*). The body, after being weighed in the air, is suspended by a fine thread from one of the scale-pans, and immersed in distilled water, as in the margin; and when the weights in the other scale-pan bring the scale-beam into a horizontal position, the weight of the body in the fluid will be determined.

Fig. 169*



But in what has preceded, the solid is supposed to be heavier than an equal volume of the fluid in which it is immersed; when it is lighter than the fluid, the method of proceeding is this:—

Take a body sufficiently heavy to sink the lighter body with it, when both are united and immersed together in the fluid. Find the weight, in the fluid, of the heavier body by itself; then the weight, in the fluid, of the united mass: this latter weight will obviously be *less* than the former; as the lighter body displaces more than its own weight of water, the difference will show how *much* more. Call this difference between the two weights w', and the true weight of the lighter body w, then the weight of the fluid displaced by the lighter body will be $w + w'$. Consequently, $w + w' : w :: S$ (specific gravity of fluid) : S′ (specific gravity of the solid).

$$\therefore S' = S\frac{w}{w + w'}$$

The weight w', by which the weight of the displaced fluid exceeds that of the body, expresses the *buoyancy* of the body, or the upward pressure upon it, in virtue of which it would begin to ascend if left to itself.

If the specific gravity of a body in the form of powder is to be found, the preceding method may still be employed: the powder may be imbedded in wax, or some such yielding material, sufficiently heavy to cause the compound to sink in the fluid; the weight in the fluid, of the wax by itself, being found, and then the weight in the fluid, of the compound, the specific gravity of the powder, previously weighed in vacuo, will be given by the foregoing formula.

PROBLEM.—If in two fluids which do not mix, a solid be immersed, and rest partly in one fluid and partly in the other, to find the ratio of the two parts when the specific gravities of the solid and the fluids are known.

Let V′ be the volume immersed in the lower or heavier fluid, and V the volume immersed in the upper or lighter fluid; then from the condition $W = VSg$ we necessarily have

$$VS + V'S' = (V + V')S'',$$

where S′, S are the specific gravities of the two fluids, and S″ the specific gravity of the solid.

$\therefore V(S - S'') = V'(S'' - S')$ $\therefore \frac{V}{V'} = \frac{S'' - S'}{S - S''}$, the ratio.

Hence, adding 1 to each side,

$$\frac{V + V'}{V'} = \frac{S - S'}{S - S''}$$

If the solid float on *one* fluid, then in these results $S = 0$, that is, the upper portion V of the body is in vacuo; therefore $\frac{V}{V'} = \frac{S' - S''}{S''}$. Also $\frac{V + V'}{V'} = \frac{S'}{S''}$.

Consequently, if a body float on a fluid in vacuo, and then the air or any other lighter fluid be admitted, the body will rise, and leave a less portion of it immersed in the original fluid. Also, if a body float on a fluid, the part immersed V' is to the whole body $V + V'$ as the specific gravity S'' of the body to the specific gravity S' of the fluid.

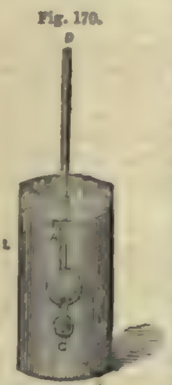
Consequently if the body float upon a second fluid of specific gravity S_1, and if V_1 be the part of the body immersed, then we have the two proportions

$$\left.\begin{array}{rl} V' : V + V' :: S'' : S' \\ \text{and } V_1 : V + V' :: S'' : S_1 \end{array}\right\} \therefore V'S' = V_1 S_1$$
$$\therefore V' : V_1 :: S_1 : S'$$

That is, the parts of the body immersed, or the volumes of the fluids displaced, are inversely as the specific gravities of those fluids. Upon this principle the instrument called the hydrometer, for measuring the specific gravities of different liquids, is constructed.

THE HYDROMETER.—There are several modifications of this useful instrument; in its simplest form, the hydrometer consists of two hollow spheres, usually of glass—a larger, and then smaller one below it, communicating with each other. Into the lower sphere mercury or small shot is introduced, in order that the spheres may sink in the liquid. From the upper sphere rises a cylindrical stem, the axis of which is in the straight line through the centres of gravity of the spheres; so that when the instrument rests in the fluid, the stem may be vertical. Let the instrument be placed in water, the stem will sink to some point A; let it then be placed in a liquid L that will cause the stem to sink to B; then, by the above-mentioned proposition, the specific gravity of L is to that of water (1), as the volume or magnitude of the body A C, to the volume or magnitude of B C.

Fig. 170.



$$\therefore \text{specific gravity of L} = \frac{\text{volume of A C}}{\text{volume of B C}}$$
$$= \frac{\text{volume of (D C} - \text{D A)}}{\text{volume of (D C} - \text{D B)}}$$

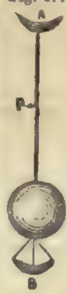
The whole volume of the instrument—that is, the volume of water it would displace if wholly immersed in it—is regarded as consisting of 4,000 parts, and the stem is divided so that each division is one of those parts. Suppose the stem to contain 50 of the parts, numbered from D downwards, and that it sinks to 30 in one liquid L_1, and to 20 in another liquid L_2: then

$$\frac{\text{Specific gravity of } L_1}{\text{Specific gravity of } L_2} = \frac{4000 - 20}{4000 - 30} = \frac{3980}{3970}$$

And in this way are the specific gravities of different liquids compared.

NICHOLSON'S HYDROMETER.—This differs from the common hydrometer chiefly in having a dish at each end, and in serving for measuring the specific gravities of solids as well as fluids. The stem in this instrument is a slender wire of hardened steel; and the adjustment is such that when a given weight—1000 grains for instance—is placed in the upper dish A (Fig. 171), the instrument will sink, in distilled water at the temperature of 60° Fah., to the point P in the middle of the stem. It is used as follows :—

Fig. 171.



To Compare the Specific Gravities of Two Liquids L, L′.—Let W be the weight of the hydrometer, w the weight which must be placed in the dish A to sink the instrument to the point P in the liquid L, w_1 the weight which must be placed in A to sink the instrument to P in the liquid L′: then

weight of the volume of L displaced $= W + w$
weight of same volume of L′ displaced $= W + w_1$

$$\frac{\text{specific gravity of L}}{\text{specific gravity of L}'} = \frac{W + w}{W + w_1}.$$

To find the Specific Gravity of a Solid.—Let w be the weight which, placed in the dish A, causes the instrument to sink to P in the water. Place the solid to be examined, or a fragment of it, in A, and let w' be the weight to be added to sink the instrument to P. Then remove the solid to the lower dish B, and let w'' be the additional weight to be added to the upper dish to sink the instrument to P.

It is plain that the weight of the solid in air, in $A = w - w'$
and that its weight in water, in $B = w - w''$

Hence the weight of water displaced by the solid $= w'' - w'$

$\therefore \frac{\text{specific gravity of the solid}}{\text{specific gravity of water}} = \frac{w - w'}{w'' - w'} =$ specific gravity of the solid, the specific gravity of water being 1.

Or, without placing any additional weight in the upper dish, observe to what depth the solid alone sinks the instrument in water; then remove the solid to the lower dish, and some additional weight w will be necessary to sink the instrument to *the same* depth; so that, calling the weight of the solid W, we shall have

$$\text{specific gravity of the solid} = \frac{W}{w}.$$

The weight W of the solid under examination is readily ascertained by finding what weight supplying its place in the upper dish will sink the instrument to the same depth.

It is evident that the instrument becomes more sensitive the slenderer the wire stem be made. If an additional small weight—a grain for instance—be placed in the dish A, an additional grain weight of the liquid must be displaced by the sinking of a suitable additional length of the stem; so that the finer this stem is, the greater must the additional length be. The diameter of the stem is in general $\frac{1}{40}$th of an inch; and the instrument will rise or fall nearly one inch by the abstraction or addition of $\frac{1}{10}$th of a grain. For the weight of a cubic inch of water is 253·1808 grains troy; and therefore the volume of $\frac{1}{10}$th of a grain is $\frac{1}{2531{\cdot}808}$ of a cubic inch. Now the area of a transverse section of the wire stem is $\frac{1}{40^2} \times {\cdot}7854 = \frac{7854}{16000000}$, and if the volume due to $\frac{1}{10}$th of a grain, namely $\frac{1}{2531{\cdot}808}$, be divided by this area, the quotient will be about $\frac{4}{5}$ths of an inch, for the length of wire that will rise or fall in water when the weight differs by $\frac{1}{10}$th of a grain. In a liquid lighter than water the length will of course be greater.

The hydrometer is the instrument used by officers of the Excise to ascertain the strength of spirituous liquors, or in what degree they are above or below proof. Proof-spirits consist of half alcohol, or pure spirit, and half water: when placed in this mixture, the exciseman's hydrometer sinks to the point marked *proof* upon the scale; if the liquor be below proof, or have more than half water, the instrument will not sink so far as proof; and if it be above proof, it will sink further, and the surface of the liquor will stand *above* proof.

But in all determinations of specific gravity, account must be taken of the temperature of the substance at the time of the experiment: all bodies expand by heat, and therefore become specifically lighter. Spirits more especially are susceptible of this increase of volume by increase of temperature: a cubic inch of brandy, for instance, will weigh about ten grains more in winter than in summer, unless the change of temperature is obviated by artificial means. It is necessary, therefore, in measuring the specific gravity of a liquid, to notice to what extent the temperature of it differs from the standard temperature of 60° Fahrenheit; and then, from knowing, by previous experiment, the amount of expansion or contraction of the liquid for different degrees of temperature, to reduce the specific gravity to what it would be at the temperature of 60°.

We shall now give a few examples in practical illustration of the preceding articles on specific gravity. The following examples will be useful in connection with Applied Mechanics.

Examples.—1. If a piece of stone weigh 10 lb. in air, and only 6¾ lb. in water, required the specific gravity of the stone.—Ans. 3·077.

2. A piece of elm weighs 15 lb. in air, and a piece of copper weighing 18 lb. in air, and 16 lb. in water, is affixed to it; the compound weighs 6 lb. in water: required the specific gravity of the elm.—Ans. 6.

3. A piece of cast-iron, of specific gravity 7·425, weighed 40 ounces in air, and 35·61 ounces in a fluid: required the specific gravity of the fluid.—Ans. 1.

4. Required the number of cubic inches in a block of stone of specific gravity 2·52, which weighs 1 cwt.—Ans. 1228⅘ nearly.

5. A composition of 1 cwt. consists of tin of specific gravity 7·32, and of copper of specific gravity 9; the specific gravity of the composition is 8·784: required the quantities of tin and copper in the mixture.—Ans. 100 lb. of copper and 12 lb. of tin.

6. The dimensions of one of the marble stones in the walls of Baibeck are, length 63 feet, and breadth and thickness each 12 feet; the specific gravity of the stone is 2·7: required the weight of the block.—Ans. 683⅖ tons nearly.

7. A solid, weighing 250 grains in air, weighs 147 grains in one fluid, and 120 in another: what is the ratio of the specific gravity of the fluids?—Ans. As 103 to 130.

8. A cubical iceberg is 100 feet above the level of the sea, the sides of it being vertical: given the specific gravity of sea-water 1·0263, and of the ice ·9214: required the number of cubic feet in the mass.—Ans. 936302452 cubic feet.

9. The weight of a common hydrometer is equal to that of a volume v of water; the part to which the stem is attached weighs a volume v' of water; the radius of the stem is r; and the specific gravity of a liquid, in which the instrument is immersed, is s: required the length l of stem immersed when in equilibrio.

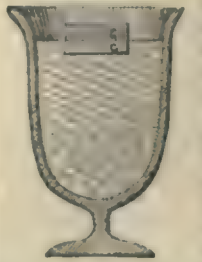
$$\text{Ans. } l = \frac{v - v'}{\pi r^2 s}.$$

EQUILIBRIUM OF A FLOATING BODY.—In order that a body may float on a liquid and remain at rest, two conditions are necessary:

1. The weight of the body must be less than the weight of a volume of the fluid of the same bulk as the body; it must be equal to the weight of the volume displaced by that portion of the bulk which is immersed in it.

2. The centre of gravity of the body, and the centre of gravity of the fluid displaced by the partial immersion, must both be situated in the same vertical straight line (p. 753).

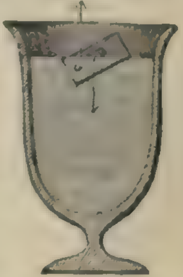
Fig. 172.



These are the only conditions necessary to secure the equilibrium of the floating body. If either of them be wanting, the body (though it may not sink) will move, and can come to a state of rest only when these two conditions are secured.

Suppose, for instance, a body floating at rest on the water, as in Fig. 172, the centres of gravity of the body and of the displaced fluid being in the same vertical line, to be disturbed from its position, as in Fig. 173. The fluid displaced then becomes changed in form and situation, though not in volume; its centre of gravity has shifted, and is no longer in the same vertical with the centre of gravity of the body. The body, therefore, is now acted upon by two forces tending to turn it round into the position from which it has been disturbed; namely, the force due to the weight of the body acting downwards through G, and the force due to the pressure of the displaced fluid acting upwards through G′.

Fig. 173.



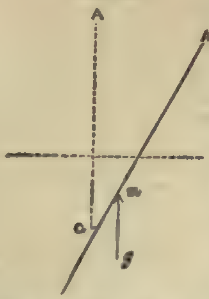
When a body thus slightly disturbed tends, as in this case, to return to its original position of equilibrium, that position is said to be one of *stable equilibrium*, in reference to the disturbance in question. If the disturbance were to act vertically on the body through its centre of gravity, and therefore tending either to depress the body lower in the fluid or to raise it further out; in the former case the additional upward pressure, and in the latter the additional downward weight, would bring the body into its original state of rest, the equilibrium being always stable in reference to disturbance in a vertical direction.

Unstable equilibrium is that position of the floating body, from which, if disturbed, it yields to the disturbance; and instead of recovering its original condition of equilibrium, departs from it more and more, till it finds either some new position of equilibrium, or upsets and sinks.

When a floating body is slightly disturbed from rest by being turned about its centre of gravity, the line through that centre, originally vertical, becomes slightly oblique; the downward pressure or weight is then in the direction of a new vertical line through the same centre; the upward pressure, too, in consequence of the change of figure and position of the displaced fluid causing a change in the centre of gravity of that fluid, is also in a new vertical line. The point, where this new vertical meets the slightly oblique line through the centre of gravity of the body, is called the *metacentre;* and the vertical itself is called the *line of support.* We have already seen that it is necessary for the line of support to pass through the centre of gravity of the body when the body is at rest (p. 753).

The position of the metacentre, in reference to the centre of gravity of the body when slightly disturbed, determines whether or not the disturbance will be counteracted, and the body right itself by returning to its former position of equilibrium; that is to say, whether or not this position of equilibrium is a *stable* position. If the metacentre be at a point on the oblique line, slightly turned out of its vertical position by the disturbance, which is *above* the centre of gravity on that line, then it is plain the upward pressure, acting along the vertical (line of support) through the metacentre, must re-establish the oblique line, or *axis* referred to, in its vertical position. For the centre of gravity is, as it were, a fixed point, round which the body turns; and

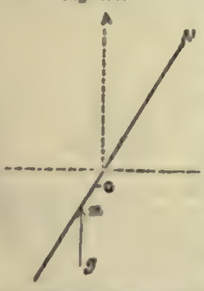
Fig. 174.



the upward force at the metacentre, *above* this centre, acting with a leverage, and unopposed, must restore to the axis its verticality. But if the metacentre be *below* the centre of gravity of the body, then the upward pressure has a contrary effect, and the oblique axis, on which it acts, is turned still more out of the vertical direction.

For instance, G (Fig. 174) being the centre of gravity of the floating body, if G A′ be the axis disturbed from its original vertical position G A, by any force which no longer acts, and if m be the metacentre, or point where the line of support gm, passing through the centre of gravity g of the displaced fluid, meets G A′, it is plain that the progress of the disturbance is arrested, and G A′ restored to its vertical position. If, on the other hand, the metacentre be situated, in reference to the centre of gravity G of the body, as in Fig. 175,—that is, below G, then the upward pressure upon it assists the deviation from the vertical; and thus G A′ goes on inclining more and more.

Fig. 175.



It is thus obvious, that when the metacentre is *above* the centre of gravity of the disturbed body, the disturbance will be rectified, and the equilibrium which has been disturbed is *stable.*

But when the metacentre is *below* the centre of gravity, the disturbance becomes aggravated; and the equilibrium thus disturbed is *unstable.* It is possible that the line of support gm may pass through G, the centre of gravity of the body: in this case, the body remains at rest in its new position, for the conditions of equilibrium are then as rigorously fulfilled as at first: the equilibrium in such circumstances is said to be *indifferent;* it is also sometimes called *neutral* equilibrium. This kind of equilibrium evidently has a place in a floating sphere and cylinder, and also in a body, of whatever shape, floating in a fluid of equal specific gravity as itself—that is, if it be allowed to call the equilibrium in this case *floating,* no part of the body being above the surface of the fluid.

From what has now been said, it is obvious how important it is, in the construction and loading of ships, to make the centre of gravity of the whole body so low that the metacentre may always be above that point, even for a considerable disturbance. The centre of gravity is sometimes elevated above its original position, in a gale of wind, by the shifting of the cargo: if the elevation be sufficient to bring it above the metacentre, the vessel must capsize.

Example.—A rectangular beam, the transverse vertical section of which is a square, and the specific gravity of which is one-half that of the water on which it floats, rests with one of its faces parallel to the surface of the water: it is required to determine whether the equilibrium is stable or unstable in reference to a slight transverse disturbance.

As the transverse vertical sections are all equal squares, it will be sufficient to consider merely the middle section A B C D (Fig. 176).

The centre of gravity of this is at G, the middle of the square; that is, G H = $\frac{1}{2}$ A B; and if g H = $\frac{1}{4}$ A B, then g will be the centre of gravity of the displaced fluid; for the body floats half in and half out of the water, as by hypothesis it is only half the weight of its bulk of water. E F is the plane of flotation, and H K the vertical axis through the centre of gravity G.

Let now the body be turned round its centre of gravity, through a small angle (Fig. 177), F G f = θ, causing the line of flotation to be ef, and the former vertical axis to become the oblique line H K; we have to find g', the centre of gravity of the displaced fluid $e\,f$ C B in this new position of the body, and thence the point O where the vertical g'O cuts the axis H K: this point O is the metacentre.

Fig. 176.

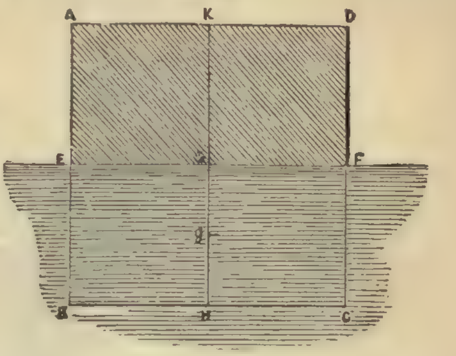


Fig. 177.

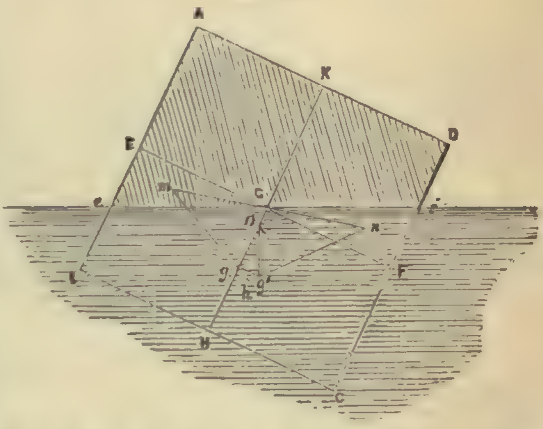


Let m, n be the centres of gravity of the portions E G e, F G f, and let h be the centre of gravity of the portion e G F C B.

Then by Statics, $hg : mg :: \text{EG}e : e\text{GFCB}$ and $hg' : ng' :: \text{FG}f : e\text{GFCB}$.

But E G e = F G f; consequently, $hg : mg :: hg' : ng'$ therefore gg' is parallel to mn

$$\therefore \frac{gg'}{mn} = \frac{hg}{gm} = \frac{\text{EG}e}{e\text{GFCB}}, \text{ by the first proportion,}$$

$$= \frac{\text{EG}e}{\text{EFCB} - \text{EG}e}$$

Now, as the angle of disturbance θ is considered as very small, the portion E G e must be insignificant in comparison with E F C B: hence

$$gg' = mn\frac{\text{EG}e}{\text{EFCB}} \quad . \quad . \quad . \quad . \quad (1)$$

Moreover, on account of the smallness of θ, sin. θ and θ may be regarded as equal; and we shall then have for the three quantities $m\,n$, E G e, E F C B, the values $m\,n = 2\,\text{G}\,m = \frac{4}{3}\,\text{G E}$, G E being the distance of the vertex G from the base, or from the *middle* of the base, the base being small in consequence of the minuteness of θ.

$$\text{EG}e = \tfrac{1}{2}\text{GE}^2 \times \theta,\ \text{EFCB} = 2\text{GE}^2$$

$$\therefore (1),\ gg' = \tfrac{4}{3}\,\text{GE} \times \tfrac{1}{4}\,\theta = \tfrac{1}{3}\,\text{GE} \times \theta = \tfrac{1}{3}\,\text{GE} \times \text{angle } gOg'$$

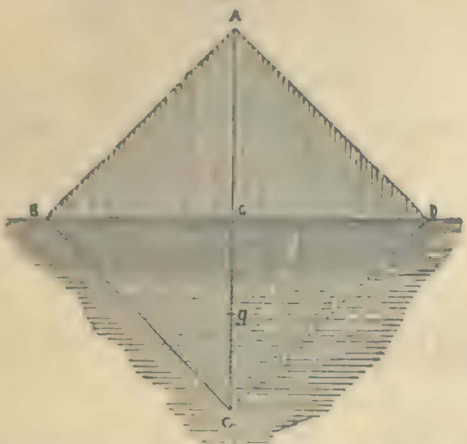
But $\quad Og \times \text{angle } gOg' = gg' \;\therefore \tfrac{1}{3}\,\text{GE} = Og$, that is

$$Og = \tfrac{1}{3}\,\text{GH}$$

$$\therefore \text{OH} = (\tfrac{1}{3} + \tfrac{1}{2})\,\text{GH} = \tfrac{5}{6}\,\text{GH} \;\therefore \text{GO} = \tfrac{1}{6}\,\text{GH}$$

Hence, the equilibrium is unstable, and therefore the beam will roll partly over, though displaced through only a very small angle. When such a position is reached that the diagonal A C becomes vertical, the body will slightly oscillate till the resistance of the fluid destroys its motion, when it will firmly settle in a position of stable equilibrium with the diagonal A C vertical. (Fig. 178). For it is plain, that when this position is arrived at, the centre of gravity G of the body, and the centre of gravity *g* of the displaced fluid, are again in the same vertical; but the inertia of the rolling mass will cause the axis C A to incline a little beyond the vertical position; the centre of gravity *g* of the displacement will thus move a little towards the right, as in the former case; and *g* being now nearer to G, the vertical form *g*′ will meet the slightly inclined axis above G, so that the new position of equilibrium into which the body finally settles will be stable.

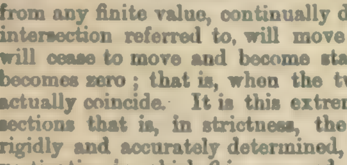
Fig. 178.



In reference to the foregoing investigation, it may be proper here to remark, that the student is not to infer that the resulting determination of the metacentre is merely a close approximation to its true position from our having regarded θ as deprived of appreciable value. The metacentre has been defined to be a point where certain two lines intersect: these two lines approach nearer and nearer to coincidence as θ diminishes. Now if θ, from any finite value, continually diminish, the point of intersection referred to, will move along the axis, and will cease to move and become stationary only when θ becomes zero; that is, when the two intersecting lines actually coincide. It is this extreme limit of the intersections that is, in strictness, the metacentre. It is rigidly and accurately determined, from any general investigation in which θ is assumed to be a small value, only in the extreme case of that hypothesis; that is, only when θ has diminished down to zero. It will be seen, by re-examining the operations above, that the final result strictly follows when θ becomes zero; or when O is the extreme limit of the intersections of the line of support with the axis H K. The metacentre, in reference to a displacement in a given direction, is thus a fixed point on the vertical, through the centre of gravity; and has nothing to do with extent of disturbance. When the body is at rest, the vertical through the centre of gravity of the body, and that through the centre of gravity of the fluid displaced, become one and the same line: if the equilibrium be disturbed, these verticals separate, and the point about which, in this separation, they *begin* to turn, is the metacentre.

FLUIDS COMMUNICATING THROUGH BENT TUBES.—In speaking of the Levelling Instrument at page 751, we have regarded it as a vessel of fluid; and from the proposition which suggested a reference to it, have inferred that the two surfaces of the bent tube were horizontal or level; but the following direct proof that the surfaces of the fluid in any bent receptacle are necessarily horizontal, is deserving of notice for its simplicity. We take it from the *Cours Elémentaire de Mécanique* of De Launay.

Fig. 179.



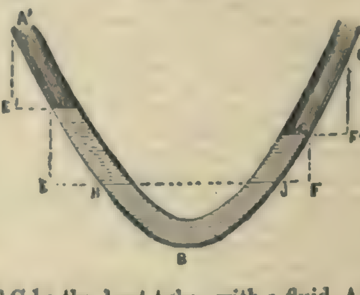
Let A B (Fig. 179) be two points taken in the interior of the fluid, and on the horizontal line wholly in the channel of communication A B, between the two ascending portions of the bent tube; these two portions being of any relative bulk whatever.

In order that the two points A and B may be at rest, the pressures at A and B must be equal, and must be the same as the pressure upon every point of the line A B. Now the pressure on A is equal to the weight of the vertical column of particles C A: the pressure on B, on account of the obliquity of the arm B M, is not so easily found. It may be obtained as follows:—The pressure on B is equal to the pressure on D, augmented by the weight of the column of particles D B. The pressure on D is the same as that on E; but the pressure on E is equal to the pressure on F, augmented by the weight of the column of particles F E: consequently the pressure on B is equal to the pressure on F, augmented by the weight of the two columns of particles D B, F E. Proceeding in this way, and observing that the pressure on M is nothing, we see that the pressure on B is equal to the weight of the five columns of particles D B, F E, H G, K I, M L. And since the pressures on A and B are equal, it follows that the five vertical lines D B, F E, H G, K I, M L, are together equal to the vertical line C A. Consequently every point in the surfaces at C and M is at the same vertical distance from the horizontal plane passing through the two points A, B: these surfaces are therefore horizontal.

In order that the foregoing phenomenon may always be exhibited, it is of course necessary that the fluid introduced into the tube be of uniform density, or that equal vertical columns of it press with equal weights. When two distinct fluids, which do not intermix, balance in a bent tube, or in any two vessels having a channel of free communication with each other, the proportion becomes modified, as follows:—

If two fluids which do not intermix are in equilibrio in a bent tube, the heights of their surfaces above the horizontal plane, where the one fluid rests upon the other, are inversely as their special gravities.

Fig. 180.



Let A B C be the bent tube, with a fluid A H of specific gravity S resting upon another fluid H B C of specific gravity S′, the horizontal plane of their separation being at H.

The pressure of the fluid A H on the horizontal plane H is H × A E × S*g*; the pressure of the fluid C J, upward on the same plane, is H × C F × S′*g*; and the plane H sustains only the upward pressure communicated by C J, since, H J being horizontal, if C J were removed, there would be no upward pressure on H.

Hence, as the fluids are at rest, the pressures on H must be equal.

$$\therefore \text{H} \times \text{A E} \times \text{S}g = \text{H} \times \text{C F} \times \text{S}'g$$

$$\therefore \text{A E} \times \text{S} = \text{C F} \times \text{S}', \text{ or } \frac{\text{A E}}{\text{C F}} = \frac{\text{S}'}{\text{S}}$$

that is, the heights of the surfaces A, C, above the horizontal plane of separation H J, are inversely as the specific gravities of the fluids A H, C J.

If S′ = S, we then have the case of a single uniform fluid before considered, and the result gives A E = C F;

that is, the surfaces are at the same height above a horizontal plane, or are level. Suppose above A and C, two other fluids of specific gravities S″, S‴, to be introduced into the tube, and that the equilibrium remains undisturbed; then the new fluid in C′ C communicates to the horizontal plane A the only upward pressure it receives, and this by hypothesis is balanced by the downward pressure of the new fluid in A′ A. Hence, as before,

$$\mathrm{A'E'} \times \mathrm{S''} = \mathrm{C'F'} \times \mathrm{S'''} \quad \therefore \mathrm{A\,E} \,.\, \mathrm{S} + \mathrm{A\,E''} \,.\, \mathrm{S''} = \mathrm{C\,F} \,.\, \mathrm{S'} + \mathrm{C'F'} \,.\, \mathrm{S'''}$$

and so on for any number of superposed fluids in equilibrio. Hence, if any number of fluids be in equilibrio in a bent tube, the sum of the products of the vertical heights into the specific gravities of the fluids in one branch of the tube, will be equal to the sum of the corresponding products in the other branch. The vertical height of each fluid is estimated from the horizontal plane on which it rests; the height of the lowest fluid H B C is estimated from the lowest point B; the vertical distance of B from H is the height in one branch of the tube; and the vertical distance of B from C, is the height in the other branch.

In illustrations such as the above, the tubes are always represented as circular; but, as the reasoning shows, the shape of the channel which connects the two upper surfaces of a fluid together does not enter into consideration. A pool of water connected by underground open passages, however tortuous, with an adjacent river, will, on the above principle, have its surface on the same level as that of the river. Also, water conveyed by pipes from a reservoir can never deliver a supply to any place, on a higher level, than the surface of the source, without the application of mechanical force or pressure.

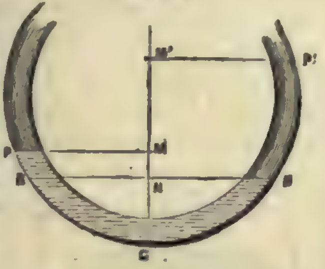
The student must be apprised, that in discussing the circumstances of the equilibrium of fluids in tubes, though the shape of the tube is of no moment, nor are the sectional area of the branches at any height, provided only that these exceed a certain amount of smallness; yet, if the section at any part be so small as to bring into operation what is called capillary attraction, the fluid surfaces in the two branches will not stand at the same level. If the section be circular, the diameter of it should exceed $\frac{1}{16}$th of an inch, in order that capillary attraction may not oppose that of gravity, and thus lessen downward pressure. We shall devote a short article to this curious subject presently.

Problem.—Equal lengths of two fluids which do not intermix, and whose specific gravities are as m to 1, are poured into a uniform circular tube; required the position in which they will rest.

Let P C H (Fig. 181) be the heavier fluid, and P′ H the lighter, the lengths of the arcs P H, P′ H being equal; let a represent each of these lengths; and draw P M, P′ M′ each perpendicular to the vertical diameter, as also H N R.

Then the lighter fluid P′ H is upheld entirely by the pressure of the portion P R of the heavier fluid; hence the downward pressure of the lighter fluid on the horizontal plane H must be equal to the upward pressure of the portion P R of the heavier fluid, transmitted to that plane. The heights of these equilibrating portions of fluid are respectively M′ N, and M N; and as these are inversely as their specific gravities, from what is shown above, we have

Fig. 181.



$$\mathrm{M'N : MN} :: m : 1 \;\therefore\; \mathrm{M'N} = m \,.\, \mathrm{MN} \;\ldots\ldots\ldots (1)$$

Let the arc C P be represented by x ∴ C H $= a - x$, and C P′ $= a - x + a = 2a - x$, then M′ N and M N may be found in terms of a and x as follows, observing that

$$\mathrm{M'\,N = M'\,C - N\,C}$$
$$\text{and } \mathrm{M\,N = M\,C - N\,C.}$$

$$\mathrm{M'\,C} = \text{ver. sin. } (2a - x),\ \mathrm{N\,C} = \text{ver. sin. } (a - x),\ \mathrm{M\,C} = \text{ver. sin. } x;$$

$$\therefore \mathrm{M'N} = \text{ver. sin. } (2a - x) - \text{ver. sin. } (a - x),$$
$$\mathrm{M\,N} = \text{ver. sin. } x - \text{ver. sin. } (a - x);$$
$$\therefore (1) \text{ ver. sin. } (2a - x) - \text{ver. sin. } (a - x) = m \text{ ver. sin. } x - m \text{ ver. sin. } (a - x) \;.\,.\; (2).$$

Or, since ver. sin. = R — cos., where R is the radius of the circle, we may use cosines instead of versed sines; and reduce the geometrical to the ordinary trigonometrical cosines; that is, to the scale R = 1; we shall only have to regard a and x as standing, not for lengths of arc, but for the *degrees* in those lengths; we shall thus have from (2)

$$1 - \cos.\ (2a - x) - 1 + \cos.\ (a - x) = m - m \cos.\ x - m + m \cos.\ (a - x);$$

that is, $\cos.\ (a - x) - \cos.\ (2a - x) = m \cos.\ (a - x) - m \cos.\ x$;

$$\therefore \cos.\ (2a - x) + (m - 1) \cos.\ (a - x) = m \cos.\ x;$$

that is, $\cos.\ 2a \cos.\ x + \sin.\ 2a \sin.\ x + (m - 1)(\cos.\ a \cos.\ x + \sin.\ a \sin.\ x) = m \cos.\ x$;

$$\therefore \cos.\ 2a + \sin.\ 2a \tan.\ x + (m - 1)(\cos.\ a + \sin.\, a \tan.\ x) = m;$$

$$\therefore \tan.\ x = \frac{m - \cos.\ 2a - (m - 1) \cos.\ a}{\sin.\ 2a + (m - 1) \sin.\ a} \;\ldots\ldots\ldots (3)$$

From this expression the trigonometrical tangent of the arc x may be found from the tables; and thence the number of degrees in that arc, or the angle which C P subtends at the centre of the circle.

Let $a = \frac{\pi}{2}$, then $\cos.\ a = 0$, $\cos.\ 2a = -1$, $\sin.\ a = 1$, $\sin.\ 2a = 0$, and the expression in these circumstances becomes

$$\tan.\ x = \frac{m + 1}{m - 1} \;\ldots\ldots\; (4)$$

If $m = 1$, that is, if the two fluids be the same, then (3) gives

$$\tan.\ x = \frac{1 - \cos.\ 2a}{\sin.\ 2a} = \frac{1 - (1 - 2 \sin.^2 a)}{2 \sin.\ a \cos.\ a}$$
$$= \frac{\sin.\ a}{\cos.\ a} = \tan.\ a.$$

that is, the arcs a and x are equal, as we otherwise know they must be.

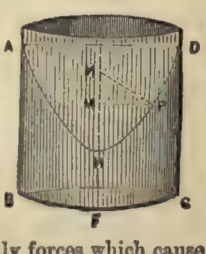
EQUILIBRIUM OF A ROTATING FLUID.—In all the preceding investigations, the only force supposed to act on the fluid is the force of gravity; we shall give an illustration of a case in which the equilibrium is due to the united effects of gravity and centrifugal force.

Problem.—A cylindrical vessel, containing water or any other liquid, revolves round its axis, perpendicular to the horizon, with a given angular velocity; to determine the form assumed by the internal surface of the fluid.

The rotation of the vessel necessarily puts the contained fluid in motion, and this motion continues till all the forces balance and the fluid attains a fixed form and position; it is in this state of equilibrium that we have to consider it.

Suppose A H D (Fig. 182) to be the form assumed by the surface of the fluid when the state of equilibrium is attained, and P any particle on that surface. From P draw P M perpendicular to the axis of the cylinder, and P N perpendicular to the curve at P. The forces which keep P in equilibrio are—1. Gravity, acting in the vertical direction N M; 2. The centrifugal force, acting in the horizontal direction M P; and 3. The pressure or reaction of the particle in the direction P N perpendicular to the surface; for it is plain that the vertical and horizontal forces acting on P are the only forces which cause

Fig. 182.



the normal pressure of P on the surface H P D; so that this normal pressure is the resultant of the other two, and therefore, taken in the opposite direction P N, neutralises the former, and keeps P at rest.

Let a be the angular velocity of rotation, that is, the angle turned through by M P or F C in a second of time; then the circular arc turned through by P in a second will be ay, putting y for P M; that is to say, the velocity v, of the point P, is $v = ay$.

Now the centrifugal force acting on P is

$$\frac{v^2}{y} = \frac{a^2y^2}{y} = a^2y. \quad \text{(Dynamics, page 741).}$$

Also (STATICS, Prop. IV., page 696),

N M : M P : : gravity : centrifugal force . . . . (1)

$$\text{that is, N M} : y :: g : a^2y \therefore \text{N M} = \frac{g}{a^2}.$$

The line N M, thus determined, is called the subnormal to the curve A H D at the point P; and we see that the curve is such that the subnormal at any point is a constant quantity. This property belongs exclusively to the *parabola*. Hence the surface of equilibrium is that generated by the rotation of a parabola about its axis; that is, it is a *paraboloid*.

In reference to the foregoing investigation, it may be useful to the student to attend to the following remarks:—

It will have been perceived that the problem proposed is of a mixed character—partly dynamical and partly statical. The forces first generate motion in P, which point continues to move till these forces become balanced, and P takes a position of rest. The force of gravity g, and the centrifugal force a^2y, both act dynamically, and are therefore to be expressed in *feet*. The symbol a, representing the angular velocity of rotation, is an abstract number—it is not an *angle*. Here, as in all dynamical inquiries, angular velocity is estimated thus:—A circle, whose radius is represented by 1, is imagined to be described about the centre of motion (about M in the present case); the semicircumference of this circle is 3·1416; and the extent of arc of the same circle, turned through in a second, is a, the angular velocity of the rotation, which is therefore 3·1416 multiplied by some number, whole or fractional. If, therefore, y or M P be measured in inches, the velocity of P is ay inches; if in feet, it is ay feet. As g is measured in feet—viz. $g = 32{\cdot}2$ feet, it is necessary that M P or y should also be measured in feet; otherwise the proportion (1) would be incongruous. The final result, namely, N M $= \frac{g}{a^2}$, gives the length of N M in feet: it is 32·2 feet divided by the abstract number a^2. Suppose the vessel performed 10 rotations in a second; then the angular velocity would be

$$a = 3{\cdot}1416 \times 20 = 62{\cdot}832 \therefore a^2 = 62{\cdot}832^2 = 3947{\cdot}86$$

$$\therefore \text{N M} = \frac{32{\cdot}2}{3947{\cdot}86} \text{ feet} = \frac{386{\cdot}4}{3947{\cdot}86} \text{ inches.}$$

We see that, with the same angular velocity of rotation, the curve is the same whatever be the magnitude of the vessel: it is further obvious that, as the cylindrical shape of the vessel is no item of consideration in the above solution, the conclusion remains the same whatever the shape may be, provided that the horizontal sections be circles, and the vertical axis of revolution pass through their centres.

Suppose the vessel to be itself in the form of a paraboloid: then the velocity of rotation, necessary to cause all the fluid to run over, may be easily determined. For the vessel will be emptied as soon as every point P has, through the intensity of the centrifugal force, reached the side of the vessel; that is, when the subnormal N M at any point P is identical with the subnormal at the point where the horizontal line M P meets the side of the vessel.

Calling, then, the constant subnormal of the given parabola l, we have $l = \frac{g}{a^2} \therefore a = \sqrt{\frac{g}{l}}$, the angular velocity per second at which the vessel must rotate in order that the empty paraboloid, formed by the rotation, may coincide with the concavity of the vessel itself.

From this expression for the angular velocity, the time in which each complete revolution must be performed may be ascertained thus:—

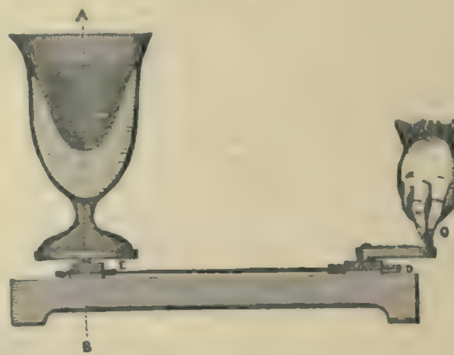
$$a : 3{\cdot}1416 :: 1 \text{ sec.} : \frac{3{\cdot}1416}{a} \text{ sec.} = \text{time of a semi-rotation}$$

$$\therefore \text{time of a rotation} = 2\frac{3{\cdot}1416}{a} = 3{\cdot}1416 \times 2\sqrt{\frac{l}{g}} \text{ seconds}$$

the subnormal l being measured in feet, and g being 32·2 feet. It appears, therefore, that with this rate of rotation, the fluid will rise and run over the vessel, till only what covers and adheres to the sides is left.

The following figure will illustrate the manner of communicating rapid rotatory motion to a vessel of water. D and E are two pulleys, round which passes an endless cord; by means of a winch C, the vessel may be made to rotate round its vertical axis A B as rapidly as we please.

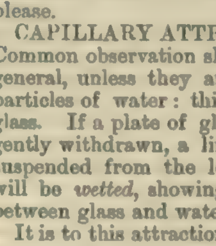
Fig. 183



CAPILLARY ATTRACTION AND REPULSION.—Common observation shows that the surfaces of solids in general, unless they are unctuous surfaces, attract the particles of water: this is more especially noticeable in glass. If a plate of glass be dipped in water, and then gently withdrawn, a line of fluid particles will be seen suspended from the lower edge, and the whole surface will be *wetted*, showing that there exists an attraction between glass and water.

It is to this attraction that the rise of water in a capillary tube is attributed: the bore of such a tube being very minute, from $\frac{1}{30}$th to $\frac{1}{50}$th of an inch in diameter, the thread of water is so slender that the surface of glass, above its upper extremity, may exercise attractive force sufficient to raise the upper particle, when the contiguous particles must follow to fill up the vacuum: this lengthening of the thread increasing till gravity, or the weight of the little column, counterbalances this capillary attraction. It is observed that the height to which the water is raised in a capillary tube, is inversely as the diameter of the tube. And this fact is sufficient to teach us the form of the curve which the upper surface of water assumes, when acted upon by the two glass plates which embrace it.

Fig. 184.



For the distance between the plates at B (Fig. 184), is to the distance between them at C, as the height of the liquid at C, to the height at B. Hence, putting A B $= x$, and A C $= x'$, and the corresponding heights y and y', and remembering, from Euclid, Prop. II., Book VI., that the distances between the plates at B and C are as A B to A C, we have

$$x : x' :: y' : y \therefore xy = x'y';$$

that is, the rectangle xy is a constant quantity, wherever B may be within the limits of capillarity. As this is the distinguishing property of the hyperbola, the axes of reference being the asymptotes, we infer that the curve presented by the upper surface of the fluid interposed between the plates, is an hyperbola. The curve ceases, of course, to be that of the hyperbola beyond the limits of capillarity. At a distance from the junction of the plates, at which the interval between them exceeds about $\frac{1}{50}$th of an inch, the curve will terminate: there will still be an elevation of the liquid up the side of each plate, but the line traced by its surface will become a straight line.

Where the distance between the plates is $\frac{1}{200}$th of an inch, the fluid, if water, is observed to rise 5 inches; and therefore where the distance between the plates is $\frac{1}{100}$th of an inch, the rise of the water is $2\frac{1}{2}$ inches. The elevation of the liquid is found to be quite independent of the thickness of the glass: if the bore of the tube, or the distance between the interior surfaces of the plate, be the same, the elevation is unaffected by the thickness, so that the quantity of matter in the glass does not contribute to the ascent of the fluid; and if the interior surfaces of the plates, or the bore of the tube, be coated with a film of oil, the capillary attraction is destroyed. On this account, it has been inferred that the attraction is exerted entirely by the surface of the glass, and that the liquid must be in complete contact with that surface, for the phenomenon to take place: the attractive energy, it would seem, has no penetrating power, it being stifled and rendered inoperative by the interposition of even the thinnest lamina of oil or grease.

It may be remarked, too, that the elevation of the fluid is not near so great between plates, as in a tube whose diameter is equal to the distance of the plates: the rise is something less than half as great in the former case as in the latter. But this might be expected, as in the tube, the thread of fluid is completely surrounded by the glass surface; the same law, however, namely, that the height of the fluid is inversely proportional to the distance between the plates, is observed to have place.

The fluids which exhibit the phenomena here noticed are exclusively the watery fluids, all of which rise to different heights in the same tube; and some of the heavier rise higher than the lighter: spirits of wine, for instance, rises only about $\frac{2}{5}$ths as high as water, which of all liquids rises to the greatest height. Mercury, however, does not rise at all; on the contrary, the tube and the plates seem to exercise a repellant energy, and cause the mercury to descend: this is called *capillary repulsion.*

The diameter of a capillary tube is not found by actual measurement; the method recommended is this:—Put a known weight w of grains of mercury into the tube, and let the length of tube it occupies be l inches; then representing the diameter of a transverse section of the tube by d, we have for the volume of the mercury $d^2l \times \cdot 7854$; and as a cubic inch of mercury, when pure, weighs 3443 grains, we have

$$1 : d^2l \times \cdot 7854 :: 3443 \text{ grains} : w \text{ grains};$$

$$\therefore d = \sqrt{\left(\frac{w}{l} \cdot \frac{1}{3443 \times \cdot 7854}\right)} = \cdot 09123 \sqrt{\frac{w}{l}} \text{ inches.}$$

Whatever the force called capillary attraction and repulsion may be, it is plain that it cannot be analogous to that so universally diffused throughout the material universe, and called the force of gravitation; because the intensity of *this* influence increases with the mass of the body exercising it: whereas the capillary influence is more like that of *electricity*, which, when in a state of equilibrium, seems to be confined to mere surfaces. It appears not improbable, therefore, that capillarity may be a peculiar manifestation of electric force exerted by the surface of the glass on the particles of liquid in its immediate neighbourhood.

CHAPTER V.

HYDRODYNAMICS.

Hydrodynamics treats of the motion of incompressible fluids, and, as the name implies, more especially of *water.* The consideration of compressible or elastic fluids, whether in a state of equilibrium or of motion, comes under the head of *Pneumatics*, a subject to which the next chapter will be devoted. But, from our limited space, we are precluded from discussing these remaining topics at any great length. This, however, is scarcely to be regretted, for the physical laws which regulate the motions of fluids are so imperfectly ascertained, that, except in those few particulars which constitute the mere elements of the subject, the investigations of hydrodynamics, founded on hypothetical data, are of little practical value; and sometimes even lead to results clearly contradicted by experiment. We shall, therefore, confine ourselves, in this brief summary, to those elementary portions of the mathematical theory which actual experiment confirms, or where the practical obstacles to such confirmation are clearly ascertained, and may be estimated and allowed for.

If water run through a pipe or other channel, always filling it, the velocity of the fluid at any part will be inversely as the area of the transverse section of the channel at that part. For let A, A′ represent the area of any two transverse sections, the water being supposed to run from A towards A′; then whatever quantity passes through A in a given time, the same quantity must pass through A′ in that time; since if a less quantity passed through, then the fluid between the sections, always remaining full, would be condensed; and if a greater quantity passed through, the fluid between the sections would be expanded, as the channel is always full. As each consequence is incompatible with an incompressible fluid, it follows that equal quantities of fluid must pass through A and A′ in the same time.

If, therefore, the velocity of the stream through A be v feet per second, and the velocity through A′, v' feet per second, we shall have

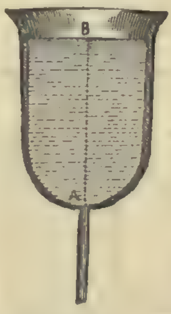
$$Av = A'v' \;\therefore\; A : A' :: v' : v;$$

that is, the velocities are inversely as the areas of the sections.

SPOUTING OF FLUIDS.—The velocity with which a fluid issues from a small orifice in the bottom or side of a vessel, kept constantly full, is equal to the velocity that would be acquired by a heavy body falling freely through the height of the surface of the fluid above the hole.

Suppose the orifice A (Fig. 185) to be at the bottom of the vessel, then the thin lamina of fluid covering the orifice A is forced out by the action of gravity upon it, and by the superincumbent pressure of the column of fluid whose base is A and altitude A B. Conceive the column A B to consist of n such laminæ, thus supposed to be acted upon at A; that is, calling the thickness of the lamina 1, let A B $= n$; then before motion, the statical forces or pressures on A are its own weight, and the weight or pressure of the column A B, and these are as 1 to n; consequently the dynamical effect of these forces, when motion takes place, must be also as 1 to n. Now the dynamical effect, that is, the velocity generated in the lamina A, in the time of falling through its own thickness 1, regarding this time as the unit of time, is 2 (Dynamics, page 736): hence

Fig. 185.



$$1 : n :: 2 : 2n;$$

therefore $2n$ is the velocity generated in the lamina A by the column of fluid in the assumed unit of time; and as this time is indefinitely small, it must be the velocity which the fluid has at the orifice itself, or that with which it actually spouts out. As the vessel is kept constantly full, the initial circumstances continue invariable, so that the fluid is discharged with the same uniform velocity.

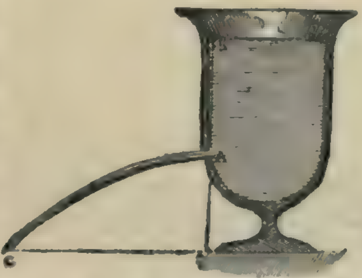
Now, if a heavy body fall freely through a height h by the action of gravity it acquires during the time of fall, a velocity $v = 2h$; that is, a velocity that would carry it through $2h$ in the same time (DYNAMICS, page 736). Consequently the fluid issues from the orifice A with a constant velocity equal to that which a heavy body would acquire in falling through the height B A.

If this height be h feet, the accelerating force of gravity being $g = 32{\cdot}2$ feet, we have, for the constant velocity of the spouting fluid, $v = \sqrt{2gh}$, the velocity per second.

The fluid spouts out with the same velocity whether the small orifice be in the side or in the bottom of the vessel, provided only that in both cases the hole be at the same depth below the surface of the fluid, since the pressure of a fluid is the same in all directions at the same depth.

The stream being, as it were, thus projected with a uniform velocity v, the curve it will describe in issuing from the side of a vessel (as in the margin) will be a *parabola*, of which the directrix is the horizontal line through B (Fig. 186), the surface of the fluid (DYNAMICS, page 739). The hole through which the fluid spouts must be so small as to render the pressures at different parts of it insensibly different from that at the centre of the orifice.

Fig. 186.



QUANTITY OF FLUID DISCHARGED PER SECOND.—As the velocity is constant, the quantity of fluid discharged per second is found by multiplying the area of the orifice by the length $\sqrt{2gh}$; thus, if a be the area of the orifice, the discharge per second is $a\sqrt{2gh}$ cubic feet. Let $h = 20$ inches, and $a = 1$ square inch, then $a\sqrt{2gh} = \sqrt{(2 \times 32{\cdot}2 \times 12 \times 20)} = \sqrt{15456} = 124{\cdot}3$ cubic inches.

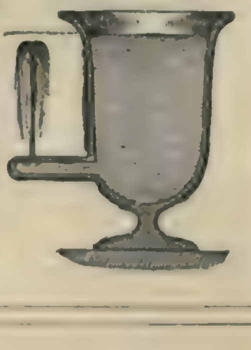
Since $a\sqrt{2gh}$ is the discharge per second, in t seconds a quantity Q will be discharged, such that

$$Q = at\sqrt{2gh} \;\therefore\; t = \frac{Q}{a\sqrt{2gh}} \quad . \quad . \quad . \quad . \quad (1)$$

This, therefore, expresses the time in which a proposed quantity Q of the fluid will be delivered, Q being expressed in cubic feet.

THE VENA CONTRACTA.—The foregoing conclusions respecting the velocity with which a fluid spouts from a small hole in the vessel containing it, and the quantity of the fluid delivered in a given time, have been compared with many carefully conducted experiments. The most satisfactory way of ascertaining practically the velocity of the discharge, is by observing the altitude to which the fluid spouts when forced to take an upward direction, as in the accompanying figure. If the uniform velocity of the issuing fluid be that due to the fall of a heavy body from the surface to the orifice, the fluid ought to spout up as high as that surface; and such is found to be very nearly the case. We might expect that the theoretical result would not be rigidly fulfilled, but that the height reached would fall a little short of the surface of the fluid in the vessel; because friction and the resistance of the air would act as opposing forces. But there is another cause in operation which must now be noticed

Fig. 187.



When a passage is made in a vessel for the exit of the fluid contained in it, the equilibrium of the entire mass is disturbed, and motion takes place among all the particles. The instant that the plug is removed, the velocity is due to the direct pressure upon it; but as lateral and oblique pressures all round the hole, cause the neighbouring fluid to flow sideways towards the main stream, when this surrounding fluid reaches the aperture, it does so with a certain velocity transverse to the direction of the main stream, which, in consequence, becomes slightly contracted a little beyond the opening. This contraction of the fluid vein is called by Newton the *vena contracta*; and it is through the section of the vena contracta that the fluid flows, as we have supposed it to flow through the orifice itself. The distance of this section from the orifice is nearly equal to the radius of the orifice, and its area about $\frac{5}{8}$ths of that of the orifice.

If, therefore, the orifice be small—as, for instance, a gimlet-hole in a cask—the confounding the orifice with the vena contracta can occasion but very little error in the height or distance to which the fluid spouts; but a considerable departure from the truth will result from calculating the quantity of fluid delivered in any time, on the supposition that the sectional area of the spouting stream is A instead of $\frac{5}{8}$ A; for instance, in the example above, the quantity of fluid discharged per second, instead of being 124·3 cubic inches, is only 77·7 cubic inches.

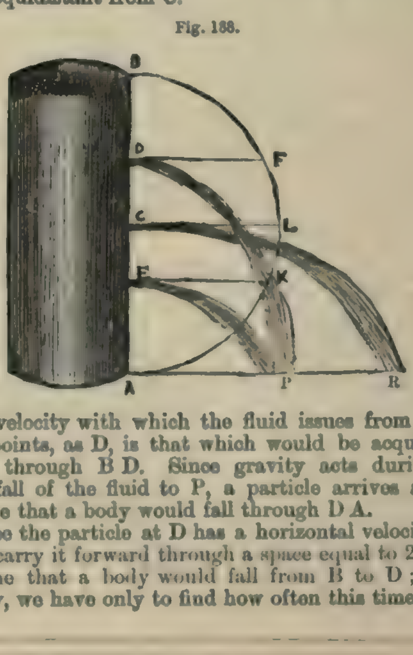
If the vessel be not kept full, and the surface be therefore allowed to descend, the velocity with which the descent commences will be, to the velocity with which it passes through the vena contracta, as the area of the section at the latter to the area of the surface (page 763).

Since the curve, which the fluid spouting from a small hole in the side of the vessel assumes, is that of a parabola—the same curve, in fact, that is described by a projectile impelled in the same direction and with the same velocity as the fluid at the vena contracta—everything connected with the extent of range, time of describing it, greatest altitude, &c., may be determined as in the theory of projectiles. The following are a few illustrations:—

If the fluid spout from a point in the middle of the upright side of a full vessel, the horizontal range will be the greatest; and from points at equal distances above and below the middle point, the ranges will be equal.

Let A B (Fig. 188) be the upright side of the vessel perforated at the middle point C, and also at two points D, E, equidistant from C.

Fig. 188.



The velocity with which the fluid issues from one of these points, as D, is that which would be acquired in falling through B D. Since gravity acts during the whole fall of the fluid to P, a particle arrives at P in the time that a body would fall through D A.

Hence the particle at D has a horizontal velocity that would carry it forward through a space equal to 2 B D in the time that a body would fall from B to D; consequently, we have only to find how often this time is contained in the time of falling from D to A, and to multiply 2 B D by the resulting number, in order to get the horizontal range A P. Now the times of falling through any spaces are as the square roots of those spaces (DYNAMICS, page 736); therefore the required multiplying number is $\sqrt{\frac{\mathrm{DA}}{\mathrm{BD}}}$: consequently,

$$\text{Range AP} = 2\mathrm{BD} \times \sqrt{\frac{\mathrm{DA}}{\mathrm{BD}}} = 2\sqrt{\mathrm{BD} \cdot \mathrm{DA}}.$$

If, therefore, with centre C a semicircle be described upon A B, and the perpendicular D F be drawn, the range of A P will be twice the length of this perpendicular. (Euc., XIII., Book VI.)

In like manner, the range of the fluid spouting from E will be twice the length of the perpendicular E K; and as these perpendiculars are equal, being equidistant from C, the ranges from D and E are equal.

As the perpendicular C L from the centre C is the longest that can be drawn from A B to the arc of the semicircle, the range A R = 2 C L, of the fluid spouting from C, is the greatest of all ranges.

These theoretical results are fully confirmed by experiment, when the orifices in the vessel are small, so that the vena contracta may be sufficiently near the vessel to be regarded, without sensible error, as at the orifice itself.

As the perpendicular D F is the sine of the arc B F, we see that the horizontal range from any orifice, is twice the sine of the arc of a circle whose diameter is the depth of the fluid, and whose versed sine is the depth of the orifice. By the depth of the fluid may be understood the depth of the horizontal plane on which the range is measured below the upper surface of the fluid; for whether the bottom of the vessel be in this plane, or be raised above it, makes no difference. The range from any orifice, measured on any horizontal plane, is the same, provided the distance between that orifice and the surface be the same, whether the fluid extend down to that plane or not.

PROBLEM.—A fluid issues from the side of a vessel through an oblique jet: to determine the horizontal range.

Let a be the angle of direction of the jet above the horizontal line, and h the height of the surface of the fluid above the orifice: then (DYNAMICS, page 739) the range r on the horizontal plane through the orifice will be $r = 2h \sin. 2a$. This is the greatest when $\sin. 2a$ is greatest; that is, when $a = 45°$, the range then being $\mathrm{R} = 2h$.

The velocity with which a fluid spouts from a small orifice, as the surface of the fluid descends, varies as the square root of the height of the surface above the hole.

For the velocity, at any instant, is always equal to that acquired by falling from the surface to the orifice; and this velocity varies as the square root of the space fallen through: hence the velocity varies as the square root of the height of the surface above the hole. The velocity, therefore, is retarded as the surface descends, but not uniformly retarded, unless the horizontal sections of the vessel are all equal in area; for the more extensive the section—or the surface of the fluid—at any instant of the descent, the more slowly will it increase its distance from the top of the vessel, and the less, therefore, will the velocity of the issuing fluid be retarded.

But if the horizontal sections of the vessel be all equal, then the velocity of the issuing fluid, as likewise the velocity of the descending surface, will be uniformly retarded.

For let V be the velocity of the descending surface at any instant, and v that at the orifice: let also the areas of the surface and orifice be A and a: then (page 763)

$$\mathrm{V} : v :: a : \mathrm{A} \therefore \mathrm{V} = \frac{a}{\mathrm{A}} v.$$

Now, as shown above, v varies as the square root of the space s between the descending surface and the orifice: we may put, therefore, $c\sqrt{s}$ for v, and write

$$\mathrm{V} = \frac{ac}{\mathrm{A}}\sqrt{s} = \sqrt{\frac{a^2c^2}{\mathrm{A}^2} s} = \sqrt{2fs}$$

by putting $2f$ for $\left(\frac{ac}{\mathrm{A}}\right)^2$. As this agrees with the general expressions for the velocity in uniformly accelerating or retarding forces (DYNAMICS, page 736), we infer that the velocity V is uniformly retarded; and since v is V multiplied by an invariable number, we conclude that v, the velocity of the spouting fluid, is also uniformly retarded. Consequently, the volumes or quantities of fluid discharged in equal times, decrease as the numbers 1, 3, 5, 7, &c., taken in reverse order. (DYNAMICS, page 736).

If a vessel of uniform horizontal section be kept constantly full, then twice the quantity which the vessel holds, will run out from a hole in the bottom, in the same time that the vessel would empty itself.

For the surface of the descending fluid is uniformly retarded as the fluid runs out; and when it arrives at the bottom, the velocity is destroyed: the space which the surface *would* describe in the same time, with the first velocity of it uniformly continued, would be twice the actual space described; and the quantity discharged in any time when the vessel is kept constantly full, is the same as what *would* be discharged if the surface descended uniformly with the first velocity: hence the quantity discharged in the one case is double that discharged in the other.

PROBLEM.—To find the time in which a vessel of uniform horizontal section will empty itself through a small orifice in the bottom.

Let A be the area of any horizontal section of the fluid, h the height of the vessel, and a the area of the orifice. Then the quantity of fluid that would be discharged in the time t of emptying, if the first velocity were to continue uniform, would be twice the contents of the vessel; that is, the quantity would be $2\mathrm{A}h$; so that if v be the velocity with which the fluid would then uniformly issue, we should have

$$atv = 2\mathrm{A}h \therefore t = \frac{2\mathrm{A}h}{av}$$

$$\text{But (page 764) } v = \sqrt{2gh} \therefore t = \frac{\mathrm{A}}{a} \times 2 \frac{h}{\sqrt{2gh}} = \frac{\mathrm{A}}{a}\sqrt{\frac{2h}{g}}$$

which therefore expresses the number of seconds occupied in emptying the vessel through the orifice.

It follows from this expression for t, that the times of emptying cylinders or prisms through equal orifices in their bases, vary as $\mathrm{A}\sqrt{h}$. If the bases of the vessels be equal in area, then the times vary as $\sqrt{h}$. If the altitudes are equal, the times vary as the bases. The time of emptying any altitude $h - h'$ of the vessel, is found by substracting from the time of emptying the whole height h, the time of emptying the height h': thus, since

$$\left.\begin{array}{r} t = \frac{\mathrm{A}}{a}\sqrt{\frac{2h}{g}} \\ \text{and } t' = \frac{\mathrm{A}}{a}\sqrt{\frac{2h'}{g}} \end{array}\right\} \therefore t - t' = \frac{\mathrm{A}}{a}(\sqrt{h} - \sqrt{h'})\sqrt{\frac{2}{g}} \quad \ldots (1)$$

the number of seconds elapsed during the descent of the surface of the fluid from the height h to the height h'.

The time in which the surface would descend from the height h to the height h', or the time in which the fluid occupying this interval would run out, if the vessel were kept constantly full, by equation (1), page 764, is

$$\frac{\mathrm{Q}}{a\sqrt{2gh}} = \frac{\mathrm{A}(h - h')}{a\sqrt{2gh}} \quad \ldots \ldots (2).$$

Hence the time of discharging the proposed quantity Q, when there is no supply from without, is to the time of discharging the same quantity when the vessel is kept constantly full, as

$$\frac{A}{a}(\sqrt{h}-\sqrt{h'})\sqrt{\frac{2}{g}} : \frac{A}{a}\times\frac{h-h'}{\sqrt{2gh}}, \text{ or as}$$

$$2(\sqrt{h}-\sqrt{h'}) : \frac{h-h'}{\sqrt{h}},$$

$$\text{or as } 2 : \frac{\sqrt{h}-\sqrt{h'}}{\sqrt{h}}, \text{ or } 2 : 1-\sqrt{\frac{h'}{h}}.$$

If the quantity Q be the whole contents of the vessel—that is, if h' be zero—then the times of discharging the vesselful of fluid in the two cases are as 2 to 1, as already inferred at page 765.

In order to test the accuracy of the theory by experiment, (1) is the most suitable formula for the purpose, since the time occupied by the surface in descending from one level to another, can be correctly observed; but the instant when the last portion of fluid escapes cannot be accurately noted; for when the vessel is near exhaustion, the fluid ceases to fill the orifice, and is discharged in drops from the edges of the hole. The time occupied by the surface descending through a certain space, is found to agree very closely with the theoretical expression for it.

THE CLEPSYDRA.—The clepsydra, or water-clock, is a contrivance for measuring time by the descent of the surface of water in a vessel, the water flowing through an orifice at the bottom. The most convenient form for the vessel is that in which the surface descends through equal vertical spaces in equal times. This form may be determined as follows:—

Let the altitude of the surface at any instant be x, and the radius of the surface—that is, the corresponding ordinate of the generating curve—y. Then the velocity at the orifice at that instant is $\sqrt{2gx}$ (page 764), and the area of the descending surface πy^2, where $\pi=3{\cdot}1416$. The velocity V of the descending surface is found by the theorem at page 763, which gives

$$\pi y^2 : a :: \sqrt{2gx} : V = \frac{a}{\pi y^2}\sqrt{2gx}$$

where a is the area of the orifice.

Since the surface is to descend uniformly, V must be a constant quantity, which can be suitably assumed in reference to the whole time of emptying: putting c for this constant, we have

$$c=\frac{a}{\pi y^2}\sqrt{2gx} \therefore y^4=\frac{2a^2g}{\pi^2c^2}x.$$

This, therefore, is the equation of the curve, the rotation of which about its vertical axis x will generate the surface of the vessel. This generating curve is a parabola of the fourth order.

But the surface need not be a surface of revolution, or one having all its horizontal sections circles. They may all be rectangles. Let the sides of the rectangular section, at the altitude x from the base, be y and p, then the area of the section is py, and we have

$$c=\frac{a}{py}\sqrt{2gx} \therefore y^2=\frac{2a^2g}{p^2c^2}x,$$

so that if p be the same for every section—that is, if the rectangular sections have all the same breadth—the curve bounding the vessel towards the lengths of these rectangles will be the common parabola.

THE RESISTANCE OF FLUIDS.—All bodies moving in a fluid are impeded in their progress by the resistance of the fluid, which must itself be moved, in order that motion may take place in the immersed body. The resistance to motion in the fluid is of course mainly due to its inertia; friction and the tenacity of the fluid, add somewhat to the resistance; but the retarding influence of these is too inconsiderable to render the consideration of them of much practical consequence.

It may safely be assumed that the resistance on a plane surface, moving with a given velocity through stagnant water, is the same as when, the plane being at rest instead of the water, a stream moving with the same velocity acts against *it*.

If a stream act perpendicularly against a plane surface, or if the surface act against the quiescent fluid by moving perpendicular to its surface through the fluid, the resistance will be as the area of the plane, the density of the fluid, and the square of the velocity conjointly.

For the velocity v of the stream being regarded as uniform throughout the whole depth of the plane, the resistance is the same at every point of the plane; and therefore, other circumstances being the same, it is proportional to the area A of the plane.

But the quantity of fluid matter striking against the plane, in a given time, is proportional to the density and velocity of the fluid conjointly; and this quantity of matter strikes with a velocity v, and therefore with a momentum equal to

quantity of matter × v.

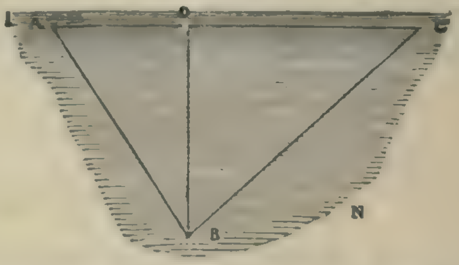
Hence, D being the density of the fluid, the resistance of the area A varies as A Dv^2.

If a body were to fall by the force of gravity till it acquired the velocity v of the stream, the space fallen through would be $s=\frac{1}{2}\frac{v}{g}$ (DYNAMICS, page 736); this, therefore, would vary as the square of the velocity; so does the resistance A Dv^2; hence the resistance varies as the weight of a column of the fluid, whose base is the area of the plane, and the altitude equals the space through which a heavy body must fall to acquire the velocity of the stream or of the moving plane.

The force with which a stream acts perpendicularly upon a plane opposed to it obliquely, varies as the square of the sine of the inclination of the plane to the stream.

Let A B (Fig. 189) and L N be sections of the plane and stream, moving in the direction of the latter; draw A C in that direction, meeting B C perpendicular to A B in C; draw also B D perpendicular to A C.

Fig. 189.

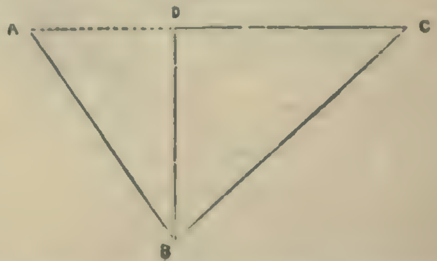


Now the quantity of fluid acting against A B is the same as that which acts perpendicularly against D B; it varies, therefore, as the length of B D; that is, as the sine of the angle A. If the velocity with which this quantity moves in the direction of the stream be represented by A C, then B C will represent the velocity with which it moves perpendicular to A B; and just as B D varies as the sine of the angle A, so does B C vary as the sine of the angle A; hence the force with which the stream acts perpendicularly upon the plane varies as sin.² A.

The force impelling the plane in the direction of the stream, varies as the cube of the sine of the inclination of the plane to that direction.

Let B C (Fig. 190), perpendicular to A B, represent the force on A B perpendicular to it; this may be resolved into two forces B D, D C, the latter D C in the direction of the stream, and the former B D perpendi-

Fig. 190.



cular to that direction. Now D C, the force in the direction of the stream, varies as B C sin. D B C; that is, as B C sin. A: but, as shown above, B C itself varies as $\sin.^2 A$; therefore, the force in the direction of the stream varies as $\sin.^3 A$.

This, of course, is on the assumption that the other component of the force of the stream in its own direction —namely, the component represented by B A, in the direction of the plane itself—is of no effect.

The force B D, perpendicular to the stream, is as B C cos. D B C = B C cos. A; hence the force with which the stream impels an oblique plane upwards, in a direction perpendicular to the stream, varies as $\sin.^2 A$ cos. A.

It must be observed, that in the foregoing propositions the plane is regarded as fixed while receiving the force of the stream, or else the fluid is regarded as quiescent, and the plane as moving through it. If both be regarded as moving in the same or in opposite directions, then the velocity spoken of above must be considered as the relative velocity; that is, it is the difference of the velocities if the plane and stream move in the same direction, and the sum of the velocities if they move in the opposite direction. Thus, if V be the velocity of the stream, and v the velocity of a float-board of an undershot water-wheel, then the perpendicular pressure on the float-board will vary as $(V-v)^2$.

The student has already been apprised, at the commencement of the present brief chapter on the motion of incompressible fluids, that the results of the mathematical theory often require considerable modification to render them accordant with actual experiment. This arises from the difficulty of assigning correct values to all the circumstances attending that motion. We have seen, in treating of fluids spouting from an orifice, that observation has discovered the orifice not to be the narrowest channel through which the stream uniformly flows, and consequently that the velocity there, is less than at the vena contracta, which ought therefore to be regarded as the true orifice.

It was found by Newton that the velocity at the vena contracta is, to the velocity of the orifice, as $\sqrt{2}$ to 1; and since, in falling bodies, the spaces passed through are as the squares of the velocities acquired, it follows that the space to be fallen through to give a body the velocity with which the fluid spouts from the *orifice*, is only half the space necessary to give the velocity at the vena contracta; that is, the velocity at the orifice would be acquired by a body falling through only half the altitude of the surface above the orifice.

In like manner, in treating of fluid resistances, the commonest observation shows that a stream impinging upon a plane surface cannot have the full effect which theory assigns. The velocity of the stream is, to a certain degree, impeded by what may be termed the backwater; moreover, the velocity is not in general the same at all depths. Yet the results of theory may usually be applied with safety in the *comparison* of different similar cases: for instance, the comparative results as to quantity of fluid discharged, time of emptying, &c., from equal orifices in two different vessels, disregarding the vena contracta, would accord very nearly with experiment. And, in like manner, fluid-pressures may be relatively estimated and computed from theory: for instance, though theory may assign an erroneous value for the effect of a stream upon the rudder of a ship, yet the position of *greatest* effect, as deduced from theory, may very well accord with actual observation; so the effect of a stream of water upon the floats of a water-wheel may be incorrectly assigned by theory, and yet the degree in which the velocity of the wheel should fall short of that of the stream, in order that the *greatest* effect may be produced, is found to be verified pretty closely by practical experience.

To determine particular values for the unknown, or arbitrary quantities, which enter into a general expression, so that for those values the expression may be a maximum or a minimum, requires the aid of the differential calculus. But in the two cases mentioned above, the principles to be employed are so elementary, and the knowledge required of that science so trifling, that although in general we are interdicted from using the calculus, we shall give the two problems adverted to as a conclusion to the present portion of our subject. We may premise, however, that in order to determine x so that any expression of the form

$$A + Bx + Cx^2 + Dx^3 + \&c. \quad . \quad . \quad . \quad . \quad (1)$$

may be a maximum, all we have to do is to disregard the term independent of x—that is, the term A—to write down all the other terms, first converting each *exponent* of x into a factor, and writing each exponent a unit smaller; thus

$$B + 2Cx + 3Dx^2 + \&c.,$$

and then to equate this expression to 0: that is, to solve the equation $B + 2Cx + 3Dx^2 + \&c. = 0$. The value of x, necessary to render (1) the greatest possible—if it *can* be made the greatest possible for any value of x—will be found by solving this equation.

Problem.—To find the angle at which the rudder of a ship must be inclined to the stream, so that the effect, in the direction perpendicular to the stream, may be the greatest possible.

It has been seen above that the effect varies as

$$\sin.^2 A \cos. A, \text{ or as } (1 - \cos.^2 A) \cos. A = \cos. A - \cos.^3 A = x - x^3$$

where x is put for the cosine of the required inclination.

$$\text{Since } x - x^3 = \text{a maximum}$$
$$\therefore 1 - 3x^2 = 0 \quad \therefore x = \sqrt{\tfrac{1}{3}}$$

hence the angle whose cosine is $\sqrt{\frac{1}{3}}$ will be the inclination necessary.

Problem.—The velocity V of the stream being given, to determine the velocity v of an undershot-wheel, so that the greatest possible effect may be produced.

The pressure upon the same area of float-board will vary as $(V - v)^2$. As this pressure moves with the velocity v, the effect will be greatest when

$$(V - v)^2 v = V^2 v - 2Vv^2 + v^3 = \text{a maximum};$$

in order to which, the unknown quantity v must satisfy the condition

$$V^2 - 4Vv + 3v^2 = 0$$

The solution of this quadratic gives

$$v = V, \text{ and } v = \tfrac{1}{3}V$$

The first value of v renders the proposed expression a minimum: that is, the least quantity of work is performed by the wheel when it moves with the same velocity as the stream—which is obvious: the other value of v is that which renders the expression a maximum; and shows that the greatest amount of work is performed when the wheel moves with a velocity equal to one-third the velocity of the stream. But, for the practical effects of water-power, acting through the medium of water-wheels, and other hydraulic machines, the student is referred to the section on Applied Mechanics, in the present volume.

[In the preceding chapters, the theories of momentum in dynamics, and the equal pressure of liquids in all directions as a fact in hydrostatics, have been investigated. Presuming the student to have become acquainted with the principles involved in each of these subjects, we shall now illustrate their application in pile-driving and pile-removing. In the construction of bridges, &c., it is often desirable to obtain a more solid foundation than the earth at the surface affords. This is especially the case when a bridge has to be built over a river, and the arches of which must be divided so as to be supported by their base on the bed of the stream. By means of the *momentum* of a mass of metal, piles are driven into the earth, forming the bed, and for this purpose the pile-driving machine is used. The following is a description of one of these machines, as represented in the annexed plate, Figs. 1 and 2.

Fig. 1 gives an end view of the machine. A A are two upright supports, generally about eighteen feet high. B is the base on which they are fixed. C is a fly-wheel for equalising the motion; and *k k* are winches turning G, a cylinder on which a rope is wound. By means of the rope, the "monkey," E, a heavy mass of metal attached to it by the head F at *f*, is raised by a pulley to the top of the uprights at *m*. The mode of detaching the monkey, after its being raised to the top, is thus managed:—In *e* (Fig. 1) we notice an arrangement like a pair of pincers. The same may be seen in Fig. 3, in which F, a cross-bar, receives the axis of these clamps. In Fig. 4, *n n* represents two rings, from each of which a cord is hung, so that they may be held in the hands of the workmen beneath. Now, supposing the "monkey" to have been raised to the top of the machine, and that its lower part is vertically over a pile, the men in attendance pull the cords stretched from *n n* (Fig. 4), and the clamps at once open and let fall the monkey. The separated clamp is represented in Fig. 5, with the cord as stretched from the hand of the person holding it. The "monkey," falling a height of some sixteen or twenty feet, acquires a velocity of nearly forty feet per second;* and being of great weight, its momentum† is sufficient to drive the pile receiving it with great force into the earth. The "monkey" is then again attached to the clamps, *e*, and raised to the top of the machine, again to fall. The operation is repeated until the pile has been driven sufficiently into the soil. Fig. 2 is a side view of the same machine, with the exception that an arrangement of teethed wheels is employed, as shown at G *g*. C is a block fixed to the uprights A for the sake of giving it additional support. Sometimes the flooring is extended, as at *a a*, and these joists are bolted firmly into a platform on which the machine stands.

Fig. 6 illustrates an application of hydrostatic laws. The principle of the hydrostatic power has already been explained at page 750. In this case, it is applied for the purpose of removing piles, which have been driven into the earth by the pile-driving machine. A is a bed of piles requiring to be removed, B being one of them. C D is a block of timber, which acts as a lever, whose fulcrum is E. This lever belongs to the second order,‡ the resistant or weight being in the lines *l*, *m*, *a*. The latter letter shows the chain by means of which the pile is attached to the lever: *d* is the head of the piston, and moves through a collar *b*. The piston is inside the cylinder F. The pump which works the press may now be described:—*h* is its handle, working on a pivot *g*; *f* is the plunger, which works in the cylinder *k*. Water is thus driven through the pipe *e* into F; and the power thus produced effects the removal of the sunken pile B by the action of the lever, &c. It will be seen that the principles of the lever, and the pressure of liquids, are both employed in this ingenious arrangement. A similar arrangement is adapted to hoists, cranes, &c.—Ed.]

CHAPTER VI.

PNEUMATICS.

THE fluids treated of in the foregoing chapter are all regarded as inelastic or incompressible: it remains for us to devote a few pages to the consideration of those of an elastic or compressible nature. The most important of these is the atmosphere with which we are surrounded: and it is in especial reference to this, that the examination of the mechanical properties of elastic fluids is said to belong to the science of *Pneumatics*—derived from a Greek term signifying, the air we breathe.

TRANSMISSION OF PRESSURE: COMPRESSION.—The mechanical properties of elastic and inelastic fluids are in many important particulars the same: the fundamental principle in Hydrostatics, for instance—namely, that a pressure applied to the surface of a fluid, is transmitted undiminished in all directions throughout the entire volume of the fluid—holds equally whether the fluid be elastic or inelastic; and in both cases may be put to the test of experiment in the same way. If the piston A, shown at page 748, play in a metal cylinder projecting into the interior of the vessel, and be forced inwards along the tube by a pressure or weight of 1 lb. say, it will advance under this pressure along the tube, and then stop: and it will be found that an additional pressure of 1 lb. must be applied to the piston B to prevent its being forced out.

In the case of a liquid, the only effect of the pressure on A is the transmission of it to every portion of the surface of equal area. In the case of the air, there is another and a distinct effect observably produced—namely, the compression of the fluid into smaller volume; and it is found by experiment that the volume diminishes just as the pressure increases: in other words, that the space into which any quantity of air is forced to compress itself, is inversely as the pressure applied. How this truth was ascertained we shall explain presently: it is necessary first to establish the fact that air has weight. It is possible to conceive that a substance like air may have the property of transmitting pressure, yet that it may not itself be a pressing or weighty substance.

EXPERIMENTAL PROOF OF ATMOSPHERIC PRESSURE.—But that the air exercises pressure, may be proved by many easy experiments: the boys' sucker is familiar to everybody. This toy consists of a piece of leather with a string passing through a perforation in the middle: upon being wetted so as to exclude the air, when it is pressed close to a smooth surface, it is found that considerable force must be applied to the string to detach the sucker; and if the surface of it be large, a stone of considerable weight may be thus lifted. What is it that thus presses the sucker and stone so firmly together? We are compelled to answer, the *air*, which surrounds them both as if they were one body. Before the sucker was applied, the air surrounded *it*: the pressure, if any, was alike on its upper and under surface: but when affixed to the stone, the pressure on the under surface of it was excluded, while that on the upper surface remained the same; and as an equal pressure is exerted on the corresponding area of the under surface of the stone, the two are, as it were, thus pinched or pressed together.

Again: take a glass tube, a foot or two long, open at both ends, and therefore full of air; plunge one end into a vessel of water: then we know from the first principles of Hydrostatics, that the level of the water will be the same both outside and within the tube. Let, now, the air in the tube be drawn out by the mouth, or pumped out by a machine fitted for the operation:—the water will be seen to rise within, and at length to fill the tube; and if the thumb be quickly applied to the top, so as to prevent the readmission of the air, the water thus filling the tube will remain suspended, just as it would do if an additional column of water of the same height as the unimmersed part of the tube pressed upon the surface of the water in the vessel. In the absence of this additional column of water, what is it that sustains the water in the tube? We are again compelled to answer, the pressure of the air which supplies its place.

We have here supposed the tube to be only a foot or two long, for convenience; but careful experiment has proved, that with a tube of sufficient extent, exhausted of air, the water would not cease to rise till it had attained the elevation of about 32 feet; which limit attained, it would remain stationary. On this large scale

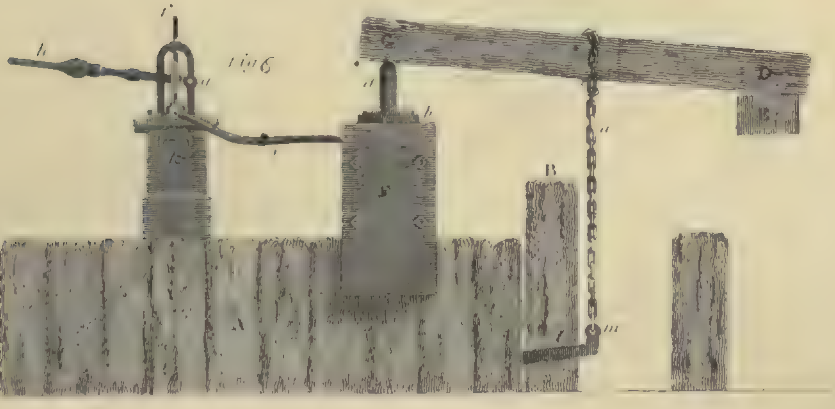
Fig. 6



the experiment was actually performed, in 1647, by the celebrated Pascal: he procured glass tubes closed at one end, of forty feet long, and found, that when filled with water in a deep river, and then raised vertically with the open end downwards, the fluid ceased to fall when water in the tube stood about 32 English feet 2½ inches from the surface of the river. This experiment clearly proved that the pressure of the whole atmosphere on any surface was equal to the pressure of a column of water 32¼ feet high on the same surface. And thus was satisfactorily shown not only that air has weight, but what amount of weight was sustained by a given area of the surface of the earth pressed upon by the atmospheric column resting upon it: the weight sustained would be equal to that of a column of water, on the same area, about 32¼ feet high.

The same conclusion is obtained with a more manageable length of tube by using mercury instead of water. And in this way the experiment had been tried previously by Torricelli, and it is hence called the Torricellian experiment: it led to the invention of the barometer. When a tube about three feet in length, and closed at one end, is filled with mercury, and then inverted in a basin of that fluid, the column of mercury held suspended in the tube is found to be about 29 inches above the surface; and as mercury is about 13½ times the weight of the same volume of water, we arrive at the same result—namely, that the pressure of the atmosphere on any area, is the same as the pressure of a column of water on that area of about the height

$$29 \times 13\tfrac{1}{2} \text{ inches} = \text{about } 32\tfrac{1}{4} \text{ feet.}$$

An exact correspondence between the results of such experiments made at wide intervals of time must not be expected, because the weight of the atmosphere fluctuates, like the other changes in its condition. The average height of the mercurial column is about 30 inches, the ordinary range being between 28 inches and 31 inches; and as 30 cubic inches of mercury weigh about 15 lbs., every square inch of the surface of the earth, at the level of the sea, sustains, on the average, 15 lbs. of atmospheric pressure.

WEIGHT OF A VOLUME OF AIR.—Besides the foregoing methods of proving that the whole atmosphere exerts a pressure, upon the globe of the earth, equal to that which would be exerted by a sea of mercury 30 inches deep, covering its entire surface, a definite portion of the air about us may be taken, and, like any other material substance, be actually weighed in a balance.

Let a vessel containing a cubic foot, that is, 1000 ounces, of water be provided with a stop-cock screwed upon its neck. This vessel may be exhausted of its air by aid of the air-pump, a machine which will be hereafter described. Thus emptied, and the stop-cock closed so as to prevent the readmission of air, let the vessel be accurately weighed in a very sensible balance. (See STATICS, page 723).

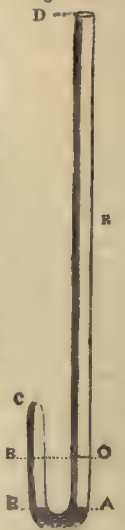
When the exact counterpoise is thus ascertained, let the stop-cock be opened and the air admitted into the vessel; the vessel thus filled, with the stop-cock again closed, to cut off all external pressure, will be seen at once to preponderate, and we shall find it necessary to put about 523 grains of additional weight in the other scale-pan to restore the equilibrium; thus showing that a cubic foot of air, at the surface of the earth, weighs about 523 grains.

We cannot, of course, speak accurately as to a few grains more or less, but it will be always found that at least an ounce more weight will be required to counterpoise the vessel when full of air, than was required before the air was admitted.

It is in this way ascertained, that when the barometer stands at 30 inches, and the temperature of the air is 52° of Fahrenheit's thermometer, the weight of water is to the weight of an equal volume of the air around us as 840 to 1.

LAW OF MARRIOTTE.—Having thus established the truth of the proposition that air has weight, we may now proceed to explain the way in which the law of Marriotte, namely, that the volumes into which air may be compressed are inversely as the pressures applied, is arrived at.

Fig. 191.



Let DAC (Fig. 191) be a bent tube of equal bore throughout, or at least equally wide throughout, the shorter vertical leg. Conceive this tube to be at first open at both ends C and D, and let a little mercury be poured in, so as to fill the bend of the tube; the level of the mercury at A and B will be at the same height AB in each tube, however dissimilar the two portions of the tube may be (HYDROSTATICS, page 751). Now let the end C be closed, and let such a quantity of mercury be poured in at D as will cause the surface, originally at C, to rise to B′, half-way between B and C. Upon measuring the additional column of mercury thus introduced into the tube—that is, having previously marked the level O of B′—if we now mark the level E when the surface B has risen to B′, we shall find that the length of the mercurial column O E is exactly equal to that of the mercurial column (as shown by the barometer) which represents the weight of the atmosphere. The inference is this: when the surface A sustained the pressure of only the column of air above it, the air in the shorter leg occupied the space B C; the air in B C was thus compressed into the volume it then had, simply by the weight of the atmosphere applied upwards to the surface B.

But when the weight of *two* atmospheric columns pressed on the surface B, that is, the weight of the barometric column of mercury in addition to the atmosphere, then the volume of air in B C occupied only half the space—namely, B′ C; that is, the original volume was compressed by the double pressure into *half* its former bulk. Again, if another column of mercury be poured into the tube at D, till the air in the other leg occupies only one-third of its original volume, we shall find that the height of the entire column of mercury, measuring the difference of the levels in two legs, is twice that of the barometric column; so that the air in B C, when pressed upwards by the weight of *three* atmospheres—the atmosphere itself pressing on the upper surface of the mercury and the double barometric column—is compressed into *one-third* of its original volume. Results in harmony with these are always found to follow whatever fractional portion of the whole atmospheric pressure be applied; and thus the law is experimentally established, that the volumes into which air is compressed by pressures are inversely as the intensities of those pressures. And this is only saying that the densities are directly proportional to the pressures.

As it is the elastic force of the condensed air that thus balances the additional pressures, we further infer that the elastic force is proportional to the density or to the force of compression.

A form somewhat more mathematical may be given to the foregoing account as follows:—

The mercury, at first poured into the tube at D, standing at the same level A B in both legs, and the end C of the tube being then closed, the space B C is occupied by the air in its existing state of atmospheric pressure at the time of the experiment, which pressure is indicated by the column of mercury in the barometric tube at that time. Fresh mercury is now poured in at D; its surface reaches the level E in one leg, and some lower level B′ O in the other, showing that the pressure of the air originally occupying C B, by now being forced to contract itself into C B′, exercises an increased pressure; so that now it not only balances the pressure of the atmosphere, in its original state at D, but also the column of mercury O E.

Let H be the height of the mercury in the barometer; then the pressure on the original volume of air B C is that of a column of mercury of base B and height H, while the pressure on the condensed volume, B′ C, is that of a column of mercury of the same base and of the height H + E O. Now, wherever B′ may be, it is found by actual measurement that

$$\mathrm{H + E\,O : H :: B\,C : B'C;}$$

and the pressures and volumes being as these linear dimensions, it follows that

Pressure on B′ C : Pressure on B C : : Volume B C : Volume B′ C.

And the same proportion is found to hold whatever be the original density of the air experimented upon ; and it equally has place for all elastic fluids.

The foregoing law, although generally called the law of Marriotte, is equally entitled to be called Boyle's law ; as it was announced, independently, by the latter philosopher, at nearly the same time. It was discovered by Boyle in the year 1662.

Since the force of compression on the air near the surface of the earth is that due to the weight of the superincumbent atmosphere, it follows that the air must be rarer the higher we ascend ; rarer, for instance, at the top of a mountain than at its base—a truth that has been turned to practical account in the way of measuring the height of a mountain by observing, with the barometer, the difference of atmospheric pressure at top and bottom.

With the general theoretical principles and the practical construction of this useful instrument, we here presume the reader to be already acquainted ; for although some account of the theory of the barometer might reasonably be expected in a treatise on Pneumatics, yet, as the subject appertains chiefly to METEOROLOGY, and as the space now at our disposal is limited, we must refer for the requisite information, upon what concerns the barometer and thermometer, to that section.

DENSITY OF THE ATMOSPHERE AT DIFFERENT HEIGHTS.—Since the density of air varies directly as the pressure sustained by it, the higher regions of the atmosphere having a less superincumbent load than the lower, must be proportionally less dense. This weight or pressure, as already noticed, will be affected by temperature : and moreover, the same particle, or volume of air, will weigh less, the higher it is situated above the surface of the earth, on account of the diminution in the force of gravity. But, leaving these comparatively unimportant modifying influences out of consideration—unimportant, at least, for moderate altitudes—and regarding both the temperature and the force of gravity as uniform, we may prove that—The density of the atmosphere at different heights above the surface of the earth, varies thus—namely, when the heights increase in arithmetical progression, the densities decrease in geometrical progression.

Conceive a uniform slender column of the atmosphere to be divided by horizontal sections into n equal parts ; the number n being so great, that each thin stratum of air may be regarded as of uniform density : then commencing at the bottom, or first stratum a_1, the several strata may be denoted by

$$a_1,\ a_2,\ a_3,\ a_4,\ \ldots\ a_n\ \ldots \quad (1)$$

and their densities by

$$d_1,\ d_2,\ d_3,\ d_4,\ \ldots\ d_n\ \ldots \quad (2)$$

It has been sufficiently explained (HYDROSTATICS, page 750) that, in speaking of the density of any substance, we always have reference to some assumed unit of density, and that the weight of the unit of volume (the unit of weight) of the standard substance, multiplied by the numerical expression (D) for the density of any other substance, gives the weight of a unit of volume of that other substance. The abstract numbers (2) therefore will equally express the number of units of weight of the volumes (1), provided we take the magnitude of a_1 or a_2, &c., for that of the unit of volume : and this we are of course at liberty to do, for in all investigations our unit of measure may be chosen at our convenience.

It may be well, however, in order to prevent confusion, to write the numbers (2), when regarded as so many units of weight, thus, namely :—

$$w_1,\ w_2,\ w_3,\ w_4,\ \ldots\ w_n.$$

Then, as the density of any stratum of air varies with the weight or pressure it sustains, we have

$$\left.\begin{array}{l} d_1 : d_2 :: w_2 + w_3 + w_4 + \ldots + w_n : w_3 + w_4 + \ldots + w_n \\ d_2 : d_3 :: w_3 + w_4 + w_5 + \ldots + w_n : w_4 + w_5 + \ldots + w_n \\ d_3 : d_4 :: w_4 + w_5 + w_6 + \ldots + w_n : w_5 + w_6 + \ldots + w_n \\ \qquad \&c. \qquad\qquad \&c. \qquad\qquad \&c. \end{array}\right\} (3).$$

But

$$\left.\begin{array}{l} d_1 : d \ :: w_1 : w_2 \\ d_2 : d_3 :: w_2 : w_3 \\ d_3 : d_4 :: w_3 : w_4 \end{array}\right\} (4).$$

Hence, putting w for d, in the foregoing proportions, alternating and compounding the ratios (ALGEBRA, page 477), we have

$$\begin{array}{l} w_1 : w_1 + w_2 + w_3 + w_4 + \ldots + w_n :: w_2 : w_2 + w_3 + w_4 + \ldots + w_n \\ w_2 : w_2 + w_3 + w_4 + w_5 + \ldots + w_n :: w_3 : w_3 + w_4 + w_5 + \ldots + w_n \\ w_3 : w_3 + w_4 + w_5 + w_6 + \ldots + w_n :: w_4 : w_4 + w_5 + w_6 + \ldots + w_n \end{array}$$

Consequently, alternating, and having regard to the proportions (3) and (4), we have

$$d_1 : d_2 :: d_2 : d_3 :: d_3 : d_4,\ \&c. ;$$

therefore the densities of the strata a_1, a_2, a_3, a_4, &c., of which the heights are in arithmetical progression, are themselves in geometrical progression ; and consequently the pressures sustained at different altitudes are also in geometrical progression.

DETERMINATION OF ALTITUDES BY THE BAROMETER.—Let A be the altitude in feet of any spot above the surface of the sea ; then measuring downwards from that spot, the distances 0, 1, 2, 3, &c., feet, the pressures upon each foot will form a geometrical increasing progression, by what is proved above. The relation, therefore, between the numbers expressing this progression, and the numbers 0, 1, 2, 3, &c , is the same as that between any numbers in geometrical progression, and their logarithms. The numbers 0, 1, 2, 3, expressing the distances downwards from the highest point, must therefore be the common logarithms of the numbers expressing the corresponding pressures, multiplied by some constant factor or modulus, which constant factor we may call K.

Hence, a expressing any lower altitude in feet, and P, p the pressures at the altitudes A, a, we shall have

$$\mathrm{A} - a = \mathrm{K} \log. \mathrm{P} - \log. p = \mathrm{K} \log. \frac{\mathrm{P}}{p}$$

If the lower station be at the level of the sea, then $a = 0$; and since the pressures P, p are indicated by the heights of the mercurial column in the barometer at the two stations, we have for A, the number of feet in the altitude of the upper station above the lower,

$$\mathrm{A} = \mathrm{K} \log. \frac{\mathrm{P}}{p} = \mathrm{K} \log. \frac{\text{height of barometer at upper station}}{\text{height of barometer at lower station,}}$$

But before this formula can be turned to practical account, we must be able to assign the numerical value of the constant multiplier K.

Let H be the height of the barometer at the level of the sea, and H′ the height at some known altitude A′; then

$$\mathrm{A'} = \mathrm{K} \log. \frac{\mathrm{H}}{\mathrm{H'}} = \mathrm{K} \log. \frac{\mathrm{P}}{p}$$

Let A′ = 1 foot, then

$$K = 1 \div \text{log. } \frac{H}{H'}, \text{ or } K = 1 \div \text{log. } \frac{P}{p}.$$

Now when the barometer stands at 30°, and the temperature of the air is 55° Fah., the weight of a volume of air is to that of an equal volume of mercury as 1·22 is to 13568 : hence the pressure of the 30 inches of mercury is equal to the pressure of a column of $\frac{13568 \times 30}{1{\cdot}22}$ inches of air of the same uniform density as that in which the barometer is placed—that is, of the air at the level of the sea. The height of this equiponderant column of homogeneous air is therefore

$$\frac{13568 \times 30}{1{\cdot}22 \times 12} \text{ feet} = 27803 \text{ feet ;}$$

and, therefore, the height of the column measured from a foot above the level of the sea, is 27802 feet.

$$\therefore K = 1 \div \text{log. } \frac{27803}{27802} = 1 \div \text{log. } (1 + \frac{1}{27802}).$$

But log.

$$(1 + \frac{1}{27802}) = {\cdot}43429448 \left\{ \frac{1}{27802} - \frac{1}{2} \frac{1}{27802^2} + \&c. \right\}$$

(MATHEMATICAL SCIENCES, page 519), therefore, neglecting the powers of so small a fraction,

$$K = 1 \div \frac{43429448}{27802} = \frac{27802}{{\cdot}43429448} = 64020 \text{ feet ;}$$

or dividing by 6, K = 10670 fathoms. Consequently the formula for the computation of any altitude A above the level of the sea, is

$$A = 10670 \text{ log. } \frac{\text{height of bar. at alt. A}}{\text{height of bar. at the sea-level.}} \text{ fathoms.}$$

The constant factor 10670 has been determined on the supposition that the temperature of the air is 55° Fah. The more convenient multiplier 10000 may be employed instead, by a suitable alteration of the temperature ; that is, by assuming the air to be in a different state. Experiment has shown that the altitude of a place, as deduced from the foregoing formula, will vary by $\frac{1}{435}$th of its whole value, for every degree by which the mean of the temperatures at the two stations differs from 55° ; the variation to be added when the mean exceeds 55°, and subtracted when the contrary is the case.

Now, the difference between 10670 and 10000 is 670, and the difference between 10670 and the value it would have for one degree less of temperature is $\frac{10670}{435} = 24{\cdot}5$: hence, to find for how many degrees less of temperature the difference is 670, we have the proportion

24·5 : 670 : : 1° : 27°.

Consequently 55° — 27° = 28° is the temperature of the air for which the altitude A in fathoms is

$$A = 10000 \text{ log. } \frac{\text{height of bar. at alt. A}}{\text{height of bar. at the sea-level.}}$$

And this value must be increased or diminished by the $\frac{1}{435}$th part of itself for every degree shown by the mean temperature of the two stations above or below 28°.

In taking the logarithms, we may employ only five figures for each, including the index 1. Regarding these as whole numbers, we take their difference ; then if E be the excess of the mean temperature of the two stations above 28°, we must multiply this difference by $\frac{E}{435}$, and add the result to the said difference to obtain the altitude in fathoms. This fraction of the difference must be subtracted if E be negative. The following is an example :—

Required the height of a mountain when the barometer at the bottom stands at 29·68 inches, and at the top at 25·28 inches, the mean temperature, that is, half the sum of the temperatures at the two stations, being 47°. The excess of the mean temperature above 28° is 47° — 28° = 19°

$$\begin{array}{lr} 10000 \times \begin{cases} \text{log. } 29{\cdot}68 \;.\;.\;.\;. \\ \text{log. } 25{\cdot}28 \;.\;.\;.\;. \end{cases} & \begin{array}{r} 14725 \\ 14028 \\ \hline 697 \end{array} \qquad \frac{E}{435} = \frac{19}{435} \\ \qquad\qquad 697 \times \frac{19}{435} = & 30 \\ \cline{2-2} \therefore \text{the height is} \;.\;.\;.\;.\;. & 727 \text{ fathoms} = 4362 \end{array}$$

feet.

Where minute accuracy is required, certain particulars, here disregarded, must be taken into consideration ; as, for instance, the latitude of the place of observation, and the dilatation of the mercurial column, which lengthens to the extent of $\frac{1}{10000}$th of the whole for every additional degree of temperature : but the determination of altitudes by the foregoing formula will, in general, differ from the truth only by a fathom or two, and will therefore be sufficiently accurate for most practical purposes. (See Chapter V.—Section, Meteorology.)

The higher we ascend into the regions of the atmosphere, the colder does it become. There are two reasons for this : in the first place, the direct rays of the sun pass through the air without being arrested, as it were, as in the case of a solid body, which absorbs a great portion of the heat poured upon it ; and, in the next place, experiment proves that air by rarefaction loses part of its original heat, so that when air of a certain temperature is relieved of part of the pressure upon it, and allowed to expand (as the air in the receiver of an air-pump), it is found that the temperature becomes less and less as the pressure diminishes ; so that if the original temperature is to be maintained, fresh heat must be communicated. As there is no external source for the supply of such heat in the more elevated regions of the atmosphere, the superior coldness of those regions becomes sufficiently accounted for.

WEIGHT OF THE WHOLE ATMOSPHERE.—We have already seen that the weight of the atmosphere surrounding the earth is equal to the weight of a surrounding coating of mercury, on the average 30 inches thick : the amount of this weight may be found by multiplying the volume of the mercurial shell by the specific gravity of the mercury, and the product by g = 1000 ounces (HYDROSTATICS, page 752). Let R = radius of the earth in feet, r = height of the mercury in feet, and s its specific gravity : then subtracting the volume of a sphere of radius R from that of a sphere of radius R + r, in order to get the volume of the spherical shell of mercury, we shall have for the weight W of that shell

$$W = \left\{ \frac{4\pi(R + r)^3}{3} - \frac{4\pi R^3}{3} \right\} sg$$

$$= \frac{4\pi}{3} \left\{ 3R^2r + 3Rr^2 + r^3 \right\} sg$$

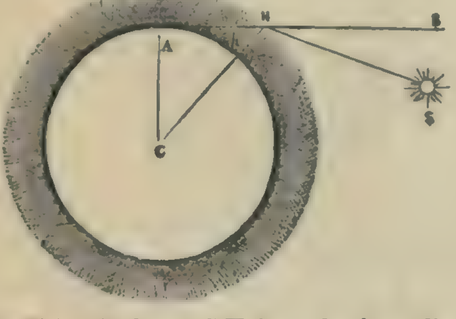
$$= \pi r \left\{ R^2 + Rr + \tfrac{1}{3}r^2 \right\} s + 1000 \text{ oz.}$$

This weight the celebrated Cotes calculated to be equal to that of a globe of lead of 60 miles in diameter, or upwards of 77,670,000,000,000,000 tons.

The weight of the atmosphere can be much more accurately estimated than its height, since the former can be submitted to experimental examination, while the latter is beyond our reach. But there are many cogent reasons which preclude the notion that the atmosphere is illimitable. Thus, we have seen that it has weight ; that is, that it is a material substance, like all other material substances, operated upon by the attraction of gravitation. There must be an elevation, therefore, at which its elasticity, or its tendency to expand further upwards, is just balanced by its gravitating tendency downwards, and which must therefore mark the limit of its altitude. Again, if its extent were boundless, the moon and all the other planets would each, by its attraction, appropriate a share of it ; and, as in the case of our earth, the density of it would increase towards the surface of each planet; and, more especially as regards the moon, its presence would become manifest by astronomical observation. But astronomers find the moon to be quite destitute of an atmosphere: it has no clouds, no rain; and some of the planets seem to be in the same predicament. That the moon has no atmosphere, and consequently can have no breathing inhabitants, is a fact interesting in itself; and it involves this other fact, equally interesting, that our atmosphere has its limits. Accurately to assign these limits is beyond the power of science; but the phenomenon of the refraction and reflection of light leads to the conclusion that it extends to the height of about forty or fifty miles. The average between those, namely, forty-five miles, is usually regarded by philosophers to be the height of our atmosphere. But that this conclusion may rest upon something better than mere conjecture, we shall give the reasonings by which it has been arrived at.

Atmospherical refraction is caused by the bending of the rays of light from a luminous body upon entering our atmosphere: till the outer boundary of the atmosphere is reached, nothing diverts the direction of a luminous ray. This refraction of the rays of the sun adds intensity to the twilight, or the light we enjoy after sunset. The twilight is found to continue till the sun is 18° below the horizon. Let, therefore, A H (Fig. 192) be the horizon of an observer at A, who will continue to have twilight till the ray S H from the descending sun makes with B H the angle S H B = 18°, and therefore the angle A H S is 162°.

Fig. 192.



The last glimmer of twilight is due, no doubt, mainly to the reflection of the ray S H from the particles of the atmosphere at H; and the radius C H being perpendicular to the reflecting surface at H, the angles A H C, S H C must be very nearly equal, and therefore each equal to about 81°. Now taking the radius C A of the earth at 4,000 miles, we have by Trigonometry,

$$CH = CA\,\text{cosec.}\,H = \frac{CA}{\sin.\,H} = \frac{4000}{\sin.\,81^\circ} = 4050 \text{ nearly.}$$

So that, according to this calculation, the height h H of the atmosphere is 4,050 — 4,000 = 50 miles.

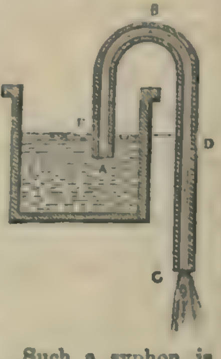
The height of an homogeneous atmosphere that would press, as the actual atmosphere is found to do, may be readily ascertained. Thus, if we take the specific gravity of air to that of water as 1 to 850, when the barometer stands at 30 inches, and the specific gravity of water to that of mercury as 1 to 14, we shall have the specific gravity of air to mercury as 1 to 11,900.

$\therefore$ 1 : 11,900 : : 30 inches : 357,000 inches = 5·63 miles. This, therefore, would be the height of an atmosphere pressing with the same weight as ours does, and of which the density is uniformly the same as the air at the surface of the earth. If the specific gravity of the air at the surface to that of mercury, when the barometer stands at 30 inches, be taken as 1 to 12,000, the height of the homogeneous atmosphere will be 12,000 × 30 inches = 10,000 yards = 5⅔ miles nearly. Hence the height of the equiponderant homogeneous atmosphere would be about 5⅔ miles.

THE SYPHON.—The weight of the atmosphere, like all the other forces spontaneously offered to us by nature, has, by the ingenuity of man, been made subservient to his wants and conveniences in a great variety of ways. Next to the force of gravitation, of which, indeed, the weight of the air is only a particular manifestation, atmospheric pressure is perhaps the most important of terrestrial phenomena; and it is not easy to estimate the amount of extra toil and privation to which mankind would be subjected, if the air we breathe, like the light we see, had no appreciable weight. It is our business now to give a short account of some of the contrivances by which atmospheric pressure has been turned to advantage in the practical affairs of life, and to explain the principles upon which these contrivances accomplish the purposes intended by them. The least complicated of these is the Syphon.

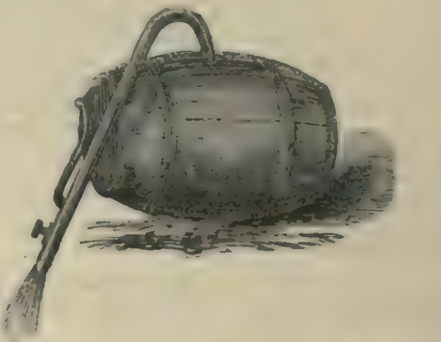
This instrument is simply a bent tube A B C (Fig. 193), employed for the purpose of exhausting a vessel of the liquid it may contain, or of transferring it to another vessel without the practical inconvenience—often the practical impossibility—of actually pouring the liquid from the one vessel into the other.

Fig. 193.



There are two ways of bringing the instrument into operation: the end of the shorter leg A may be inserted in the liquid, and then the air in the tube withdrawn by the mouth through a small pipe communicating with the tube near the extremity C of the longer leg. In this case there must be a stopcock between the pipe and C to cut off communication with the atmosphere pressing through C. Such a syphon is called the distiller's syphon: it is exhibited in operation in Fig. 194. In the second way the tube is inverted and filled with the fluid, and the ends A, C closed; the shorter end is then immersed, and both ends are opened.

Fig. 194.



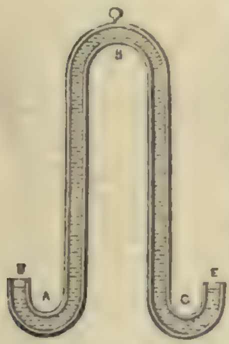
Suppose, as in the first way, that the tube, with the end A (Fig. 193) in the liquid and the end C stopped, has been exhausted of air: the pressure of the atmosphere on the exposed surface of the fluid in the vessel acts upwards at A, and forces the fluid into the vacant space with an energy sufficient, if it were water, and the tube were straight, to carry it to the height of thirty-two or thirty three feet; and to a greater height if it were a fluid lighter than water. As, however, the tube bends at a moderate height B, the ascending column is forced to accommodate itself to the course of the tube, and descends into the leg B D C. Arrived at B, the highest point, its descent down B C is expedited by the direct influence of gravity upon it; and C being opened, the liquid flows out.

Now it must be observed, that when the column has attained the height E B, it is not forced forward by the whole of the atmospheric pressure at E, but only by that pressure diminished by the weight of the column E B; so that when the column had extended itself to D, if the atmospheric air were admitted, the upward pressure on D, like that on E, would be equal to the whole atmospheric pressure diminished by the weight of the column D B; the two pressures, therefore, balance. But as soon as D is passed, and the column in B C lengthens, the equilibrium is destroyed, the downward pressure prevails, and the liquid falls through C upon finding a passage there: and the longer the part D C of the syphon below the surface D of the liquid, the greater will be the velocity with which it will issue, since the greater will be the preponderating pressure downwards.

In the second way of preparing the syphon, that is, by first filling it with the fluid, it is brought, in another manner, into the same circumstances as when it is filled, as above, through the pressure of the air on the surface of the liquid. The liquid will evidently cease to flow as soon as the surface of it descends to a level with the rising surface in the vessel to which it is transferred; at this stage, however, the syphon will remain full, as there will be a complete equilibrium.

In the syphon just explained, it is necessary that the legs be of unequal length; but there is another kind of syphon called the Wurtemburg syphon, in which the two legs are of the same length. In this instrument (see Fig. 195), the extremities of the equal legs are turned upwards so that the two open ends D, E may be on the horizontal level when the syphon is held upright. The instrument is kept constantly filled with water, which remains suspended in the two legs D A B, E C B, because the equal atmospheric pressures at D and E place them in a state of equilibrium; but if the leg terminating in D be immersed in water, the end D will sustain the additional pressure of the water reaching from D to the surface, and consequently E being free from such additional pressure, the fluid is forced out at that end. When the surface of the water in the vessel has descended to D, the stream from E stops, but the syphon remains full, and, thus filled, is taken out and hung up by a loop at B till again wanted.

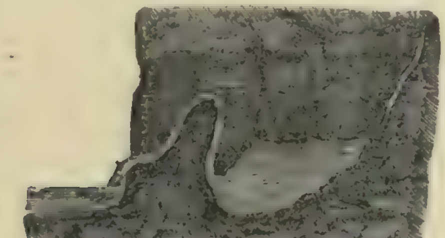
Fig. 195.



INTERMITTING SPRINGS.—The curious phenomena of intermitting springs, are referable to the foregoing principles. These springs, issuing from a fissure in a mountain side, flow for a certain period and then stop; after awhile the water flows again, and so on. These effects are produced through the operation of one of Nature's syphons. Fig. 196 exhibits a section of the mountain and the stream. A cavity exists in the former, as here represented; this is filled by gradual infiltrations, or by slender fissures communicating with the upper surface.

Suppose, now, that there is a syphon-like communication between the reservoir of water, supplied by these channels from above, and the mountain side; as this syphon is not artificially exhausted of air, it will not deliver the water in the reservoir till the surface of that water rises as high as the bend of the syphon B; after which it will begin to flow, pouring out a continued stream till the reservoir is emptied, or at least till the level reaches the immersed end of the syphon; the stream will then stop, and will commence to flow again only when, by a fresh accumulation of water from above, the level of B is again reached.

Fig. 196.



It is, of course, a condition necessary to the production of these results that the surface of the reservoir be subjected to the pressure of the atmosphere; but through the fissures which supply the cavity with water, air must have previously found its way; and, indeed, from the principle of the equal transmission of fluid-pressure, the weight of the atmosphere acting on the upper surface of the water in a single downward column, as on the water in the slender perforation to the right in the foregoing figure, acts equally on every part of the surface of the water in the reservoir.

THE HOUSEHOLD PUMP.—The common suction-pump is another important contrivance, which owes its usefulness entirely to the pressure of the atmosphere, although its dependence upon this agency was little suspected for many ages after its invention. As already noticed (page 769), Torricelli, a pupil of Galileo, early in the seventeenth century, was the first who fully recognised the influence of atmospheric pressure. He accounted for the ascent of water in the pump, and of mercury in an exhausted tube; and the invention of the barometer naturally followed.

Fig. 197.

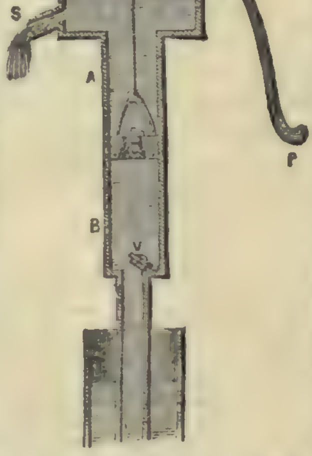


Fig. 197 represents a section of the suction-pump; A B is the tube, or working pump-barrel, communicating with the water in the well. In this barrel, an air-tight piston C, moved by the lever or pump-handle P, freely plays. At the lower extremity of the working barrel there is a valve V opening upwards: this valve separates the barrel from, and completely covers, what is called the suction or feeding-pipe, which is usually of smaller bore. In the piston C there is also a valve similarly opening upwards. The piston C is called the *sucker*.

Now, imagine the piston C to be at first at the bottom V of the barrel, and then to be raised by the action of the pump-handle. As the piston is air-tight, the pressure of the air in the barrel upon the ascending valve C keeps it closed, so that that air, having no escape below, is forced up and pumped out at the spout S. The vacuum thus produced in the barrel is immediately filled up by the ascent of the water through the feeding-pipe, for the water in the well sustains the pressure of the atmosphere on its surface—all except that portion of the surface which the feeding-pipe covers; and from *this* portion, as just explained, the air has been withdrawn. The barrel is thus filled with the water forced up by the pressure of the atmosphere on the exposed surface of that in the well; but no water escapes through the spout S, since all that has been raised is below the closed valve C; but it is retained suspended in the barrel, though the valve V still remains open, the upper surface of the water, immediately below the piston, being, of course, not more than 32 or 33 feet above the surface of the water in the well (page 769).

Upon now lowering the piston, the valve C opens by the resistance of the water confined in the barrel; for the downward pressure communicated to the confined water, and exercised through the lever P, closes the valve V, and prevents the water from being, by this extra pressure, forced back again into the well. Hence, upon again raising the piston, the upward resistance of the water above it closes the valve C, and the fluid is forced out of the spout S, while another vacuum is forming below the piston, and fresh water rising in the barrel. Thus every time the piston is raised, the lower valve opens and the upper one closes; while, on the contrary, every time the piston descends, the lower valve closes and the upper one opens; and in a well-made pump the barrel is kept constantly full.

It will of course be understood, in all that is said above, that the pressure of the atmosphere on the surface of the water in the well, or reservoir, need not be sufficiently great to cause the water in the pump to ascend as high as the spout, when, by the action of the handle, the air is withdrawn from the tube: if the length of the suction-pipe be 28 or 29 feet, or rather, if the valve at the top of it be at this height above the water in the well, the exhaustion of the air will be followed by the ascent of the water, through the suction-pipe, to some distance up the barrel of the pump. The subsequent raising of the water, thus introduced into the barrel, to the spout, is the sole result of the mechanical force applied to the pump-handle.

QUANTITY OF WATER DISCHARGED, AND FORCE APPLIED TO RAISE IT.—The quantity of water discharged at each stroke of the handle, supposing the barrel to be constantly full—that is, supposing the spout not too high—is a column of water whose base is the horizontal section of the piston, and of the height to which the piston is raised, called the length of the stroke: thus, if r be the radius of the section in feet, and l the length of the stroke in feet, we shall have

$$\text{Quantity discharged} = 3{\cdot}1416r^2l \text{ cubic feet};$$

or, since a cubic foot of water weighs 1000 ounces, or about 62½ pounds avoirdupois, and since an imperial gallon contains 10 lb. of water, we have

$$\text{Quantity discharged} = 3{\cdot}1416r^2l \times 6{\cdot}25 \text{ gallons}.$$

But the force necessary to raise this quantity, will be that required to raise the entire column of water extending from the surface of the reservoir to the surface of the water in the pump, the base of the column being the section of the piston. For let a be the number of linear feet of water above the piston, and b the number of feet below it, to the surface of the reservoir; let also p be the length of the column of water equal to the atmospheric pressure: then since, in raising the piston, the downward pressure of the atmosphere has to be overcome, the height of the equivalent column of water lifted is $a + p$; but the upward pressure against this, is equal to the weight of a column of water of height $p - b$: hence

$$(a + p) - (p - b) = a + b$$

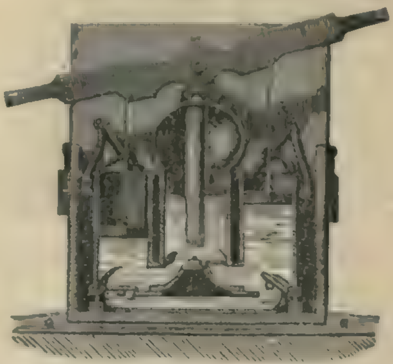
Consequently, the force necessary to lift the piston is that necessary to lift a column of water having the same section as the piston, and the height $(a + b)$, of the water in the pump, from the surface of that in the reservoir; and, in fact, additional force must be applied to pump out the water, on account of friction, and the weight of the piston and rod.

In the returning stroke of the pump-handle, the piston descends by its own weight, which is sufficient to overcome the friction, and the slight resistance of the water.

FORCING-PUMP AND FIRE-ENGINE.—As the pressure of the atmosphere varies, pumps are not constructed to raise water to a height above 28 or 29 feet; but the water thus raised may, by an additional contrivance, be forced upwards as much higher than this as we please. A pump for this purpose is called a *forcing pump*. In this pump there is no valve C in the sucker or piston; so that, after the exhaustion of the pump-barrel of air, and the consequent filling of it with water, no downward pressure on the piston could cause its descent, since the water is incompressible. A pipe, therefore, is inserted in the side of the barrel near the bottom, with a valve at the insertion opening outwards; the downward pressure on the solid piston forces open this valve, and drives the water into the tube, which may be carried upwards to any height, and be made to deliver the water there, provided only sufficient downward pressure act on the piston.

The fire-engine (Fig. 198) is essentially the combination of two forcing-pumps, the pistons of which are worked by a lever whose fulcrum is at its middle, and the power is applied at each end alternately; the water from the fire-plug is forced into the central receptacle, called the air-vessel, the air in which is thus condensed the more, the more water is forced in; the elastic force of this compressed air drives the water up the leathern hose, from which it issues through the delivery-pipe with a velocity proportionate to the pressure applied, or the condensation produced in the confined air. If the pistons be worked with sufficient energy to supply the air-vessel with water as rapidly as it is thus delivered, the stream will be invariable; if more water be forced into the vessel than can escape out of the delivery-pipe, the air-vessel will be in danger of bursting, by the increased pressure of the condensed air.

Fig. 198.

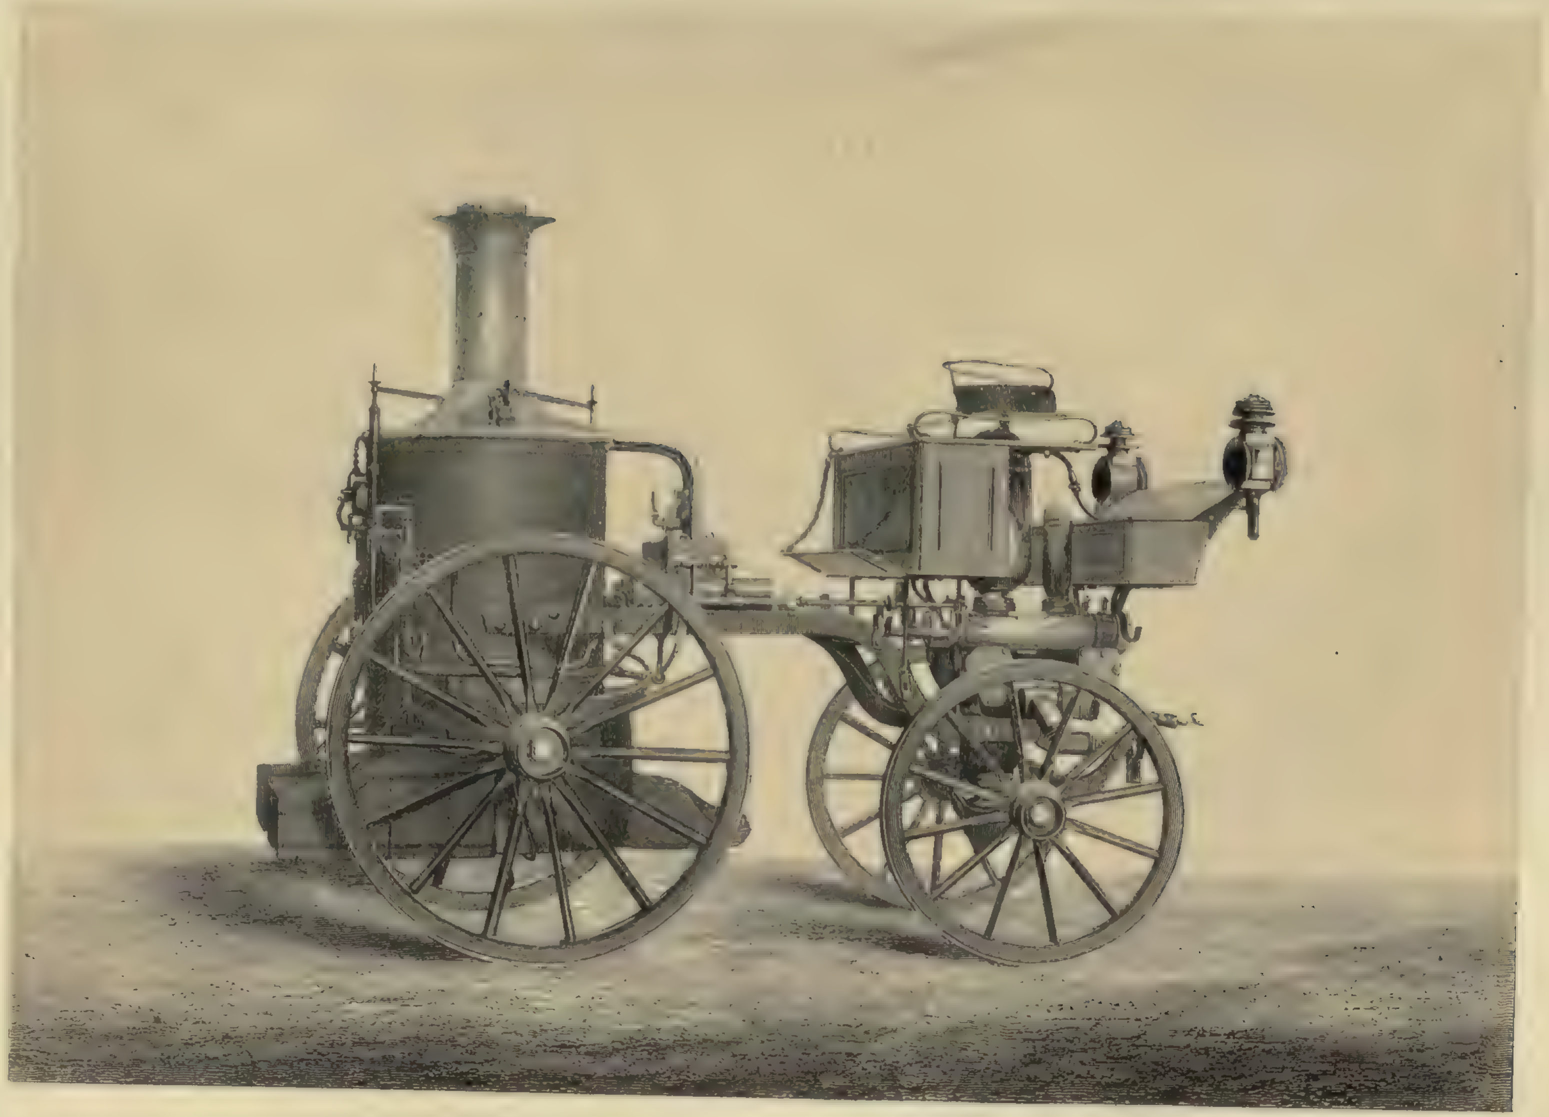


The intention of the air-vessel will be readily perceived by the student: the force applied to the two ends of the lever, which works the double pump, is necessarily an intermitting force; and without some contrivance to render the effect continuous, the water would issue from the delivery-pipe in jerks, by the separate impulsions given to it; but the continuous pressure of the condensed air in the air-vessel, causes a continuous flow of water along the hose, up to the point of issue. If the supply of water to the air-vessel vary, the velocity of the issuing stream will, of course, vary likewise; but there will be, nevertheless, no interruption in the continuousness of the discharge.

In fact, the air-vessel performs an office a good deal like that performed by the fly-wheel in ordinary machinery: it gives continuity to intermittent action, tends to equalise the effects of it, and prevents that strain on the structure which irregularities of action are apt to produce.

The metal pipe, from which the stream of water issues, is considerably smaller in bore than the leathern hose along which the fluid flows to it. A double purpose is accomplished by this disparity. In the first place, the friction in the hose is diminished, as a comparatively smaller portion of water comes in contact with the interior surface; and in the next place, the contraction of the stream, at the outlet, gives to it a proportional increase of velocity, so that the water is driven out of the narrow pipe with much greater force (page 764). It may be observed here, that the common syringe, or boys' squirt, is a miniature forcing-pump, or embryo fire-engine; the great contraction of the tube near the outlet, is the cause of the velocity with which the water issues, being so much greater than that with which the piston moves. In the syringe there is certainly no air-vessel, as in the fire-engine; but the pressure on the water is continuous, so long as the tube contains any.

THE DIVING-BELL.—The diver's bell is a heavy iron chest open at the bottom; it is called a *bell*, because, in its original construction, a bell-form figure was given to it. The interior is furnished with seats, sufficiently



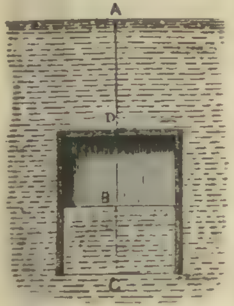
"THE SUTHERLAND" STEAM FIRE ENGINE.

BY MERRYWEATHER & SONS

high above the mouth to enable the persons sitting on them to keep their heads free from the water, which rises in the bell, in virtue of the upward pressure, as it descends into the sea, and to breathe the air which is thus forced up and condensed, above the rising water. By means of a flexible tube, communicating with the upper atmosphere through the top of the bell, fresh air can be pumped in, and the air unfit for respiration let out.

It is easy to find the space into which the air, originally in the bell, will be compressed when the chest is sunk to any depth below the surface.

Fig. 199.



Let A B (Fig. 199) be the distance between the surface of the water above, and the surface of the water in the bell. Let also h be the height of a column of the water, the pressure of which is equal to that of the atmosphere: then the original air in the bell sustained a pressure equal to that of a column of water, of the same horizontal section and height h; but when condensed by being forced up to B, it sustains a pressure equal to the same column h, and the additional column of water that is above B; that is, the pressure now sustained is equal to that of a column of water of height $h + \mathrm{A\,B}$.

$$\therefore \frac{\text{vol. of condensed air}}{\text{vol. of original air}} = \frac{\mathrm{D\,B}}{\mathrm{D\,C}} = \frac{h}{h + \mathrm{A\,B}} \text{ (page 769).}$$

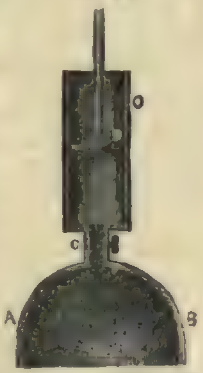
Putting, therefore, x for D B, the depth of the compressed air between the roof of the bell and the surface of the water within it, we have

$$\frac{x}{\mathrm{D\,C}} = \frac{h}{h + \mathrm{A\,D} + x} \quad \therefore x^2 + (h + \mathrm{A\,D})x = h\,\mathrm{D\,C}.$$

Hence, by solving this quadratic equation, which has but one positive root, the depth D B of the compressed air may readily be ascertained when the height D C of the bell, and the depth A D, to which its upper surface is sunk, are given.

THE CONDENSER.—The condenser consists of a strong vessel A B (Fig. 200), called the *receiver*, into which atmospheric air is forced and condensed by means of the following apparatus:—

Fig. 200.



A cylindrical barrel, opening into the receiver, and having a valve opening downwards at C, is furnished with a piston D, having a valve also opening downwards. As the piston descends, the valve D closes by the resistance of the air in C D, and the pressure opens the valve C, the compressed air passing into the receiver A B.

This piston having thus forced all the air originally in the barrel into the receiver, is raised up; and the superior pressure of the condensed air in A B immediately closes the valve C, while the downward pressure of the external atmosphere opens the valve D; so that the barrel becomes again filled with common air, and the operation is repeated.

In some condensers the piston D is made solid, and a small orifice is made at O near the top of the barrel, through which, upon raising the piston above it, the barrel is supplied with fresh air from without.

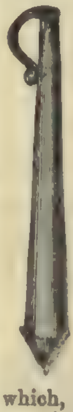
The density of the compressed air in the receiver, after n descents of the piston, may be ascertained thus:—Let R and B be the respective capacities of the receiver and the barrel, and let D be the density of the atmospheric air: then, R being the volume of this air in the receiver at first, and R + B the volume of it in the receiver after the first descent of the piston, the entire mass of air then in A B will be D . R + D . B; as the additional mass D . B is forced in at the second descent, A B will then contain the mass D . R + 2D . B; and a fresh mass D . B being thus forced in at every descent, we have for the whole quantity of air, after n descents,

$$\text{Quantity of air} = \mathrm{D}\,(\mathrm{R} + n\,\mathrm{B}) \;\therefore \text{ its density}$$
$$= \mathrm{D}\left(1 + n\frac{\mathrm{B}}{\mathrm{R}}\right)$$

which increases in arithmetical progression.

THE WINE-TASTER.—We may here notice, as among the minor contrivances by which the pressure of the air has been made available for practical purposes, the convenient little instrument called the wine-taster, which is much used in wine and ale cellars to draw out, through the bung-hole of a cask, a specimen of its contents. The marginal representation (Fig. 201) will give a sufficiently clear idea of the form of this contrivance, which is hollow, and has a small perforation at each end. When dipped into any liquid, the upper orifice being kept open to the atmosphere, the fluid rises through the lower orifice, till the level is the same inside and outside; the thumb is then pressed on the upper orifice, and the vessel withdrawn. The air previously within—the common atmospheric air, reaching from the surface of the liquid to the upper hole—expands and fills the enlarged space which the descent of the liquid leaves as the vessel is raised. The pressure within is thus diminished, while the external pressure upwards, on the lower orifice, is that of the unrarefied atmosphere; so that a portion of the liquid remains suspended in the tube, under which, if a glass be held, and the thumb removed, the sample will run out by its own weight.

Fig. 201.



THE AIR-PUMP.—The office of the air-pump is the opposite of that of the condenser, the purpose of it being to exhaust a receiver of the air contained in it. There are several forms of this machine; one of the best known is represented in Fig. 202, and is called Hawksbee's air-pump. The receiver, containing the air to be withdrawn, communicates, by means of a pipe, with two barrels, generally of polished brass, in which two closely-fitting pistons move by rack-work, as in the sectional outline exhibited in Fig. 203, where it will be observed that the descent of one piston compels the ascent of the other. The four valves, marked a, b, e, f, all open upwards. As one of the pistons descends, its valve opens, and the air in the barrel passes through, and rests above the piston when it has arrived at the bottom. During this operation the other piston ascends, with its valve closed, emptying the barrel in which it is fitted, of its air, the vacuum being supplied from the air in the receiver with which the barrel is in communication. The first piston is now raised, and *its* barrel emptied in

Fig. 202.

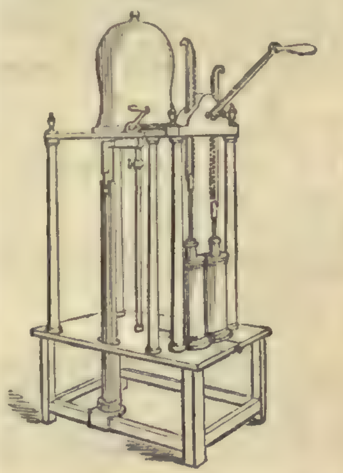


Fig. 203.

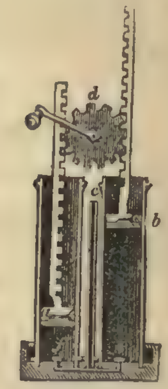


like manner, fresh air rushing in from the air in the receiver communicating with it. And these alternate ascents and descents of the piston render the air in the receiver so rarefied, that at length its pressure is inadequate to open the valves and pass into the barrels. It is plain that each turn of the toothed wheel, driving one piston to the bottom of the barrel and raising the other to the top, withdraws one barrel full of air; so that the air in the receiver, previously to this turn of the wheel, now occupies both the receiver and one of the barrels.

Let R be the capacity of the receiver, and B that of each barrel; and the density of the atmospheric air being D, let D_1, D_2, D_3, &c., be the densities of the air in the receiver after 1, 2, 3, &c., strokes or turns of the wheel: then since, at every turn, the volume of air R is dilated into R + B, we have

$$D_1\ (R + B) = D \, . \, R \ \therefore D_1 = D \frac{R}{R + B}$$

$$D_2\ (R + B) = D_1 \, . \, R \ \therefore D_2 = D \left(\frac{R}{R + B}\right)^2$$

$$D_3\ (R + B) = D_2 \, . \, R \ \therefore D_3 = D \left(\frac{R}{R + B}\right)^3$$

And generally $D_n = D \left(\frac{R}{R + B}\right)^n$, the density after n turns. Hence the density decreases in geometrical progression. As the mass, or quantity of air, is equal to its volume multiplied by its density (page 742), therefore after n strokes, the quantity of air in the receiver is

$$D_n \, R = \left(\frac{R}{R + B}\right)^n R = D \frac{R^{n+1}}{(R + B)^n}$$

The quantity of air in the receiver decreases, therefore, in geometrical progression; but as a decreasing geometrical progression may be continued indefinitely, it follows that the quantity can never be actually exhausted in any number of strokes of the air-pump.

As the pressure of the atmosphere on the receiver becomes very great after the pump has long worked, it is necessary that it possess considerable strength; and the bell-form, as exhibited in Fig. 202, is given to it to secure this condition, the glass of which it is formed being also very thick. The valves are usually of strong oil-silk, in little brass frames, traversed by a grating.

PROBLEM.—To find the number of strokes necessary to reduce the air in the receiver to a given density.

Let d be the given density: then D being the original density,

$$d = D \left(\frac{R}{R + B}\right)^n$$

$$\therefore \log. d = \log. D + n \ \{ \log. R - \log. (R + B) \}$$

$$\therefore n = \frac{\log. d - \log\ D}{\log. R - \log. (R + B)}$$

And if, as is usual, the original density, or that of the atmosphere in its ordinary state, be represented by 1, we shall have

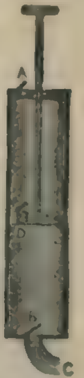
$$n = \frac{\log. d}{\log. R - \log. (R + B)}$$

The density d is here, of course, a proper fraction, and therefore log. d is negative, but the denominator being evidently negative also, the expression is positive; and here, as inferred above, if $d = 0$, that is, if the receiver be absolutely exhausted of air, log. d, and therefore n, is infinite.

Although two barrels are connected with the receiver in Hawksbee's air-pump, but only one barrel is exhausted at each stroke; yet the working of the two pistons simultaneously, at each turn of the wheel, considerably diminishes the labour of the operation; for the atmospheric pressures on the upper surfaces of the two pistons being the same, the force required to work the pump is only that necessary to overcome the difference of the pressures on the under surfaces of the pistons, and the friction of the pistons themselves. If only one barrel were employed, the ascent of its piston would be opposed by the difference, constantly augmenting, between the pressures on its upper and under surfaces, in addition to the friction. If, however, the ascending single piston could be relieved from the pressure of the atmosphere, a single exhausting barrel would answer every purpose, and the machine would be simplified.

SMEATON'S AIR-PUMP.—Such a simplification is given to the pump constructed by Smeaton, and called after his name. A B (Fig. 204) is the barrel or cylinder communicating with the receiver by means of the pipe B C. In this construction the barrel is closed at top, but furnished with a valve A opening upwards; the piston also has a valve D opening upwards; and a third valve B, likewise opening upwards, covers the pipe B C.

Fig. 204.



As the piston ascends from the bottom of the barrel, forcing up the air above it, and leaving a vacuum below, D is the only valve that closes; the atmospheric air originally in the barrel is forced out at A, and the exhausted cylinder is instantly supplied with air from the receiver through the pipe B C. Upon the descent of the piston, the valve A closes, the pressure from without exceeding that from within the cylinder, so that in its next, and in every succeeding ascent, the piston is relieved from the pressure of the atmosphere upon it.

If, as before, R, B represent the capacities of the receiver and barrel respectively, D the density of the atmospheric air, and D_n the density of the air in the receiver after n strokes of the piston, we shall have, as in the former case,

$$D_n = D \left(\frac{R}{R + B}\right)^n, \text{ the density after } n \text{ strokes.}$$

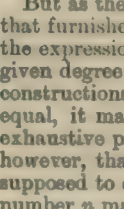
In this pump the exhaustion may be carried on to a much greater extent than in the common pump before described, because the valve D, being relieved from the downward pressure of the atmosphere, will open for a very slight pressure upwards, and consequently will allow of the passage of air in a more rarefied state.

But as the foregoing expression for D_n is the same as that furnished by Hawksbee's machine, and consequently the expression for n, the number of strokes producing a given degree of exhaustion, must be the same in both constructions, provided only that the barrels are all equal, it may seem that there is no difference in the exhaustive powers of the two. It must be remembered, however, that in the former investigation the valves are supposed to open at even the nth stroke, however high a number n may be; but as, in the former construction, the valve of the descending piston sustains the pressure of the atmosphere, which in the present contrivance is removed, a greater elasticity in the air below the valve is necessary to open it; so that, in Smeaton's pump, a greater degree of rarefraction will be ultimately attained.

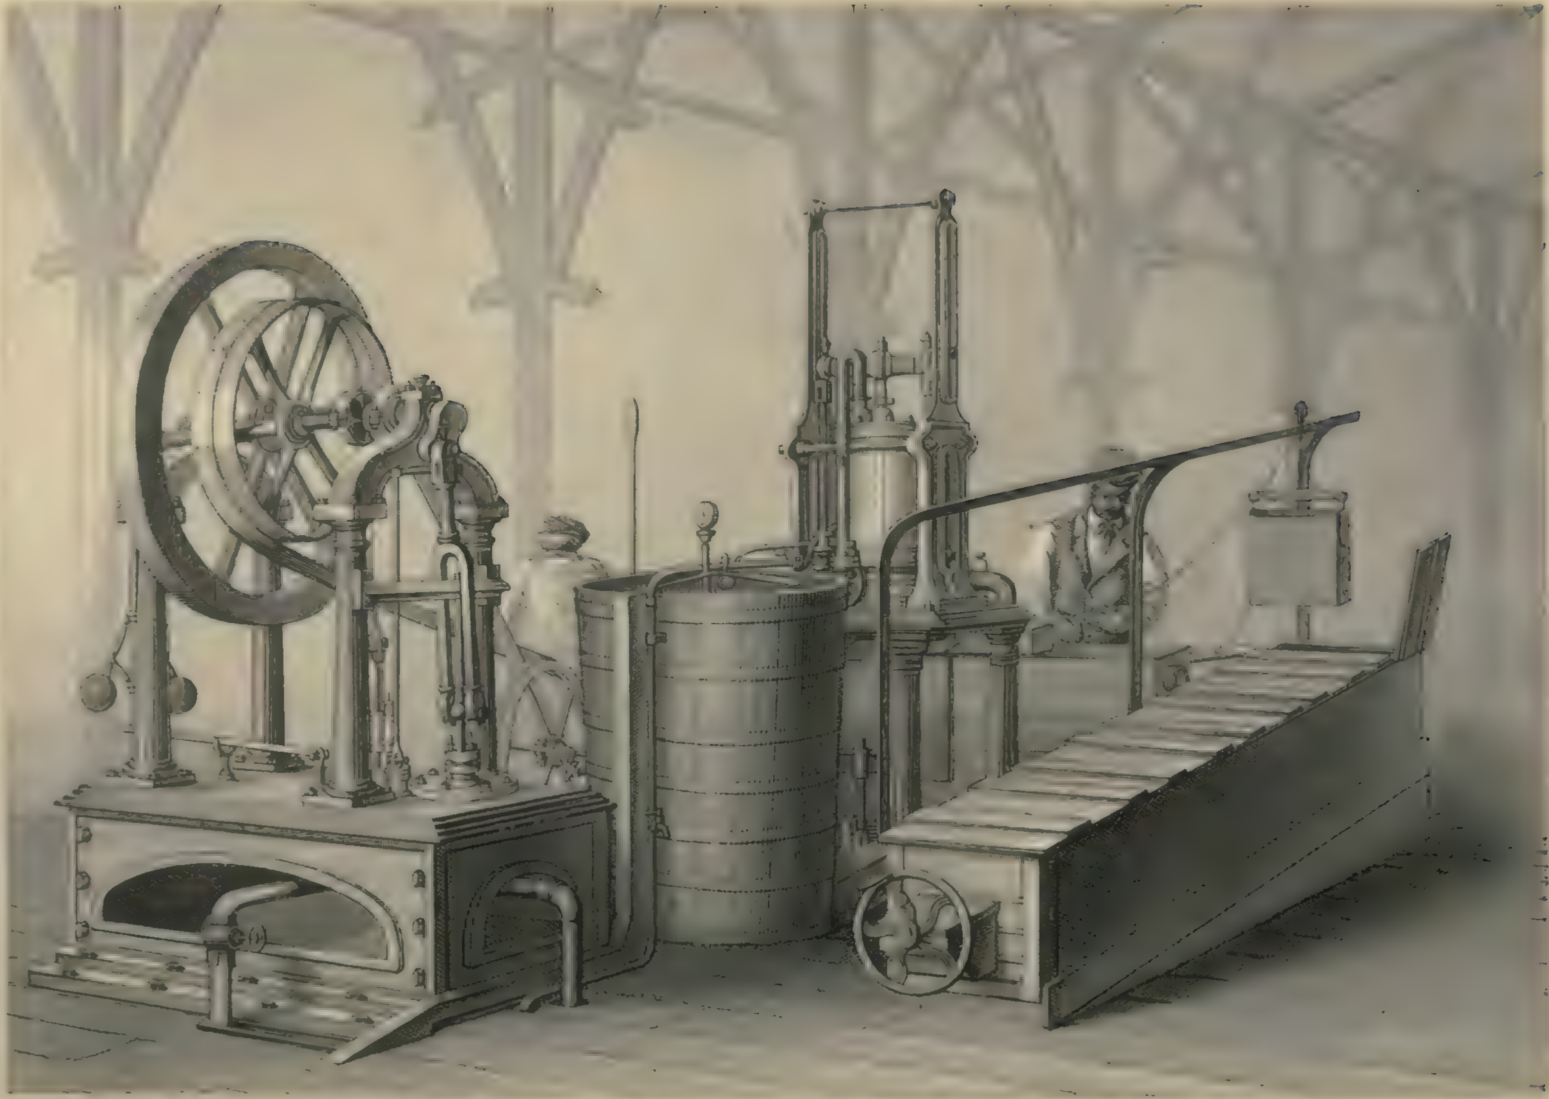
TATE'S AIR-PUMP.—This pump was first described by the inventor in the *Philosophical Magazine* for April, 1856. Its chief peculiarity is, that while it has, like Smeaton's pump, only a single cylinder or barrel, it has a double piston. This double piston performs the work of the two pistons in the ordinary double-barrelled air-pump, and that with only half the motion.

In the annexed diagram (Fig. 205), C D is the cylinder or barrel; A and B are solid pistons, rigidly connected by a rod K, and moved by the piston-rod A H, passing through a stuffing-box S. V and v are valves opening outwards; and R an open pipe, at the middle of the cylinder, leading to the receiver from which the air is to be exhausted.

Fig 205.



The distance between the extreme faces of the pistons is about ⅜ths of an inch less than one-half the length of the cylinder; this ⅜ths of an inch being the space requisite for clearing the exhausting-pipe R. The pistons are each about 1⅛ inch in thickness, and the rod K connecting them may be of any section consistent with strength. The effective length of the stroke is equal to the space between one side of the pipe



PATENT ICE MAKING MACHINE

[illegible]

[illegible]

R and the corresponding end-face of the cylinder, or it is very nearly equal to one-half the length of the cylinder.

In an upward stroke, the air above the piston A is propelled through the valve V into the atmosphere, while a vacuum is being formed beneath the piston B. When the piston A strikes against the top of the cylinder, the air from the receiver rushes through the pipe R, and diffuses itself through the lower half of the cylinder. In a downward stroke, the air beneath the piston B is propelled through the valve *v* into the atmosphere, while a vacuum is being formed above the piston, A, and so on. It will be observed that the double piston performs a double duty at every single stroke; for while a vacuum is being formed in one half of the cylinder by one piston, the other piston is propelling the air from the opposite half, into the atmosphere; hence much time and labour are saved.

ADDENDA.

THE PATENT ICE-MAKING MACHINE.—In temperate climes, sufficient ice is produced for summer consumption during the winter season; but in tropical countries, where it is unknown as a natural production, and its value is often at a high price, a method of producing it at pleasure has long been a desideratum.

In our Section on Heat we have given a list of freezing mixtures: these, however, can only be employed on the small scale.[*] It has, therefore, been frequently attempted to apply the air-pump to refrigerating purposes; and, perhaps, the most successful machine of the kind, is one which was shown in the Exhibition of 1862, and of which we shall give a short description.

It has been already stated, that ether boils at a very low temperature in a vacuum, and that if a little be placed in a watch-glass, resting in another containing water, the latter may easily be frozen in the receiver of an air-pump, whilst the air is being exhausted in the usual manner.[†] On the large scale, however, other arrangements for applying this principle must be adopted, both on account of speed and economy; for the attenuated atmosphere, being but a poor conductor of heat, would freeze but slowly any quantity of water exposed to its action; and the ether, which is an expensive material, must be recovered if possible, so as to be used repeatedly for the same purpose. The latter difficulty is overcome by permitting the restoration of the atmospheric pressure, when the ether regains its liquid form, which it had lost in the vacuum. To effect the rapid congelation of the water, strong brine is employed, being first cooled by the evaporation of ether in a receiver, from which the air is pumped by a steam-engine. The brine is a good conductor of heat; and, when thus cooled, it is caused to run round square cells containing the water to be frozen. The cells are placed at a little distance from each other, in a long trough, as represented in the folio engraving; and one of them is seen suspended over the trough on the right hand of the plate. The circulation of the brine is constantly kept up; fresh cold liquid being driven in by a pump, as that which has cooled the water is withdrawn. In a short space of time the water in the square cells is frozen, through the abstraction of its latent heat by the brine, and it may then be removed in solid flat cakes of ice. Fresh water is then introduced into the emptied cells; and thus the freezing process can be kept up without intermission, so long as the steam-engine is kept at work.

Comparatively speaking, in this climate the above is an expensive process; but when employed in hot countries, it produces ice in large quantities, at a price which is much lower than that hitherto charged. The machine has the advantage of requiring no chemical salts, as in the old method: in fact, the whole process is one of a purely mechanical nature.

BALLOONS.—In connection with the subject of Pneumatics, a few remarks on balloons may prove interesting to many of our readers. The ascent of a balloon in the air, is owing to the fact, that the contents, bag, car, &c., weigh less than the bulk of air they occupy. In other words, the balloon and its appendages, taken together, have less specific gravity than the atmosphere in which they float. This would, at first sight, appear paradoxical, but it is easily explained. Balloons may be raised by either of two means. If a large bag of paper, closed in all parts, except at a small orifice in its lower end, have the air it contains rarefied, by holding it over a gas flame, so that the air inside shall become heated; then, a less *weight* of hot air having the same *bulk* as cool air, will fill it. If the difference of weight between the heated air and that of the external atmosphere, bulk for bulk, equal that of the bag containing it, the bag will float in the air. On this principle the common fire-balloon is made to ascend. A piece of cotton wool, wetted with spirits of wine, is hung at the orifice of a large bag of tissue paper; and the spirits being inflamed, the internal air becomes rarefied, and the balloon ascends. The earlier attempts at aerostation, made by Montgolfier and others, were carried on in a similar manner. We need scarcely state that such a plan was highly dangerous. Large quantities of straw were burnt beneath the opening of a silk bag of considerable size, and thus the air it contained became rarefied. Occasionally, however, the machine caught fire, and fatal results occurred to those who had made the ascent.

The use of hydrogen was subsequently suggested; and it is a familiar lecture-table experiment to fill small balloons with that gas, when they immediately ascend in the air.[‡] Now, as pure hydrogen has a specific gravity of only, in round numbers, 0·07, whilst air (the standard of gases) = 1·00, it follows, that any bulk of hydrogen will only weigh one-fourteenth part of the same of atmospheric air. Hence, if a light and air-tight material be shaped into any hollow form, so that when filled with hydrogen, its weight, and that of the contained gas, shall be less than that of an equal bulk of air, of course it will at once fly upwards on being set free.

On the large scale, coal gas is always employed in filling balloons, because it is much cheaper, and almost always readily obtained. The external skin forming the balloon, consists of fine silk, which has been well varnished, to render it air-tight. A car is attached beneath it, by means of netting and cords. And such arrangements have been made of sufficient size to permit of the ascent of several persons.

Many attempts have been made to steer balloons, but all such have proved failures. At the present time, their use is confined to occasional ascents for scientific and military purposes, and as an attraction at places of public amusement. Balloons were frequently employed during the civil war in America, in 1862-'63: the British government have instituted experiments to test their value for reconnoiting purposes. Some account of the ascents of Mr. Glaisher, for meteorological observations, will be found in Chapter V., in the Section on Meteorology, p. 1174, *t. seq.*—EDITOR.

SECTION IX.

PRACTICAL OR APPLIED MECHANICS.

CHAPTER I.

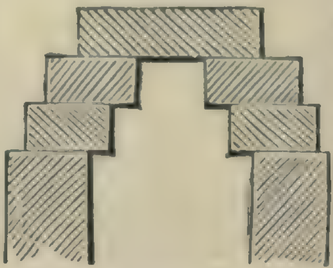
INTRODUCTORY.

Contents.—MECHANICS OF ANTIQUITY—MODERN MACHINERY—MECHANICS AND CHEMISTRY—STATICAL AND DYNAMICAL MECHANICS—STRENGTH OF MATERIALS—POWER—STANDARD OF POWER—SOURCES OF POWER—APPLICATION OF POWER—FRICTION—GOVERNING POWER—NATURE OF MACHINES—MECHANICAL EDUCATION.

PRACTICAL MECHANICS is the art of applying the theoretical principles of mechanical philosophy to materials, so that they may be fashioned, arranged, and combined in the various forms required by man. It is difficult in any case to draw an exact line of separation between the theoretical and the practical: for all true theory is founded on practice, and all skilful practice is the application of true theory. In the case of Mechanics, the separating line between the theory and the practice is eminently difficult to be traced; for the development of principles depends at every step upon practical experiment, and the improvements in mechanical arts are generally the results of extended research into the principles. It is true, indeed, that a great range of mechanical theory can be investigated by abstract reasoning upon a few simple principles, just as mathematical science is built upon a few definitions and truths; but it is remarkable that little progress was ever made in mechanical science until men began to translate the actual results of experiment. In Mathematics, which is certainly the science of all others requiring the least amount of experimental proof, the ancients made considerable progress, because the minds of men in former times were quite as well fitted for the investigation of abstract truths as those of modern mathematicians; but in the sciences which demand experimental proof—such as Chemistry, Optics, Astronomy, and Mechanics—little progress was ever made until philosophers began to observe facts, and thence reasoned to their causes. For many ages of the world's history, it was the custom of men pretending to science to start in their own minds a hypothesis or conjecture about some law of nature; to build upon this slippery foundation a vast scheme of nature; and then to wonder that natural phenomena did not suit their arrangement. In some such way as this the astronomers of old, with a few illustrious exceptions, took it for granted that an enormous, in their notions a boundless, mass, such as the earth, could not move; and, therefore, that the sun, moon, planets, and stars, revolved in daily cycle round it. And it was not until observations had been carried on for many centuries—until the records of these observations had been compared and digested, and until instruments had become so far perfected as to enable astronomers to observe with accuracy—that the true theory of the celestial phenomena was developed.

MECHANICS OF ANTIQUITY.—In respect of mechanical science, the ancients appear to have been very deficient. They had, indeed, tolerably true notions respecting the construction of buildings in such a manner as to ensure permanence and stability; but for these qualities they seem to have depended almost entirely on rude strength and massiveness, instead of skilful arrangement. Among the gigantic remains of Egyptian architecture, there is not found a single arch; the only approach to it is the vault of a passage hollowed like an an arch, but made of two or three immense blocks of stone cut to the vaulted form. Again, among the ruins of Central America, remarkable for their enormous extent and elaborate decoration, the passages of such buildings as remain tolerably entire are found to be covered by blocks of stone, arranged as in Fig. 1. The beautiful and stable arrangement of materials in the form of an arch does not seem to have occurred to the architects of antiquity, until the comparatively recent era of the Roman Empire. It is difficult to ascertain whether the ancients were acquainted with any of the forms of roofs now in use, on account of the perishable nature of the materials: but it is probable that they knew no such method of covering large spaces; and for covering apartments of more limited extent, they had no resource but the use of large masses of stone.

Fig. 1.



In respect of machinery, the ancients appear to have been extremely deficient, for we have records of no apparatus except certain implements of war and of the chase, and a few rude contrivances for irrigating and cultivating the ground. But, indeed, even in modern times, the mechanical arts had made little advance until the genius of Watt had given to man a power applicable alike to manipulation of the most delicate character, and to labour demanding the most gigantic strength. Could a man who lived in England but a hundred years ago now revisit his country, he would in mechanical art find a change far greater, an advance more astonishing, than the whole progress made from the creation of the world up to the time at which he lived.

MODERN MACHINERY.—That a man seeing all the wonders of modern art, as they have been seen of late years at the great Exhibitions, should endeavour to attain a knowledge of their nature and construction, may at first sight appear presumptuous, because of the vast extent and variety of the objects which we would have to study; and, indeed, unless one were prepared to devote his lifetime to mechanical art, he could scarcely hope to know accurately the details of modern machinery, much less to attain the skill of a master in all its varied departments. But, with a fair knowledge of some simple first principles, and an introductory glance at a few of the leading details that are common to all mechanical arrangements, we believe it would not be difficult to attain a good general knowledge of mechanical art, and a readiness at comprehending any mechanical arrangements that may be brought under our notice. Few will be inclined to dispute the advantages of possessing even such a moderate knowledge of Mechanics as this implies, for in modern times but little advance can be made in any useful pursuit without that aid. Practical Mechanics may indeed be called the handmaid of the other arts. The sculptor, the architect, the musician, the chemist, the astronomer, the surgeon, the merchant, the manufacturer, the builder, the military man, the civilian, the traveller, and the emigrant, all require her services—all reap the benefit of her labours.

It is generally supposed that inventors in the arts, as well as discoverers in the sciences, owe their success to some fortunate accident. We think it may, in most cases, be shown that such is not the fact. Almost every famous discovery, or useful invention, has been the result of long, often painful and laborious, thought and research; and success has often followed repeated failures; accuracy has succeeded repeated errors. That there is a natural genius for invention peculiar to some minds, cannot be doubted; but that genius alone, without labour and study, has ever led to brilliant results, may as firmly be denied. Mechanics, as an art, in a peculiar manner demands concentrated thought; there should be no waiting for some inspiration to bridge over a mechanical difficulty. Let a man gird himself to his task, and determine thoroughly to think out the subject he may have on hand, and we venture to predict that he will find few difficulties insurmountable.

MECHANICS AND CHEMISTRY.—The two sciences that deal with matter in its various affections and modifications are Chemical and Mechanical Philosophy. The former treats of the influences affecting its minute particles, and the combination of these particles; the latter has reference to masses of matter, and the forces and motions of masses, or aggregations of particles. Each of these two sciences frequently encroaches upon the other's domain, for there are many similar phenomena developed by the action of natural laws on masses as well as on particles, and thus it is often difficult to draw a line of separation between the subjects of the two sciences. Questions relating to heat, light, electricity, and magnetism, form part of both sciences alike, and can scarcely be said to belong to the one more than to the other. There are questions, however, which are purely chemical, and others as distinctly mechanical.

The chemist, examining a piece of matter, tries its specific gravity, its solubility or fusibility; analyses it, and finds the different elementary substances which compose it, and the precise quantities in which they are combined.

The practical mechanic, examining a structure or a machine, sees, feels, and measures the parts of which it consists, traces the laws that govern its equilibrium or its movements, and determines the principles which have been adopted in its construction.

STATICAL AND DYNAMICAL MECHANICS.—The objects of Practical Mechanics may be divided into Statical and Dynamical. Statical mechanics has reference to the formation and arrangement of materials intended to remain in a state of rest; its principal objects are permanence and stability. It has to consider the strength, elasticity, flexure, weight, and durability of the materials with which it deals. It has to employ the proper substances for its purposes, put them in their right places, make them of suitable forms, and unite them firmly together, or so arrange them, that the tendency to change their relative position when affected by external forces shall be the least possible. The civil and the naval architect, or the builder, whose business it is to make large fabrics by putting together numerous small pieces, is indebted for the durability and strength of his structure to the application of statical mechanics. So, also, the miner or the civil and military engineer, who has to form extensive excavations, erect embankments, bridges, tide-works, or fortifications, requires, an intimate knowledge of statical mechanics.

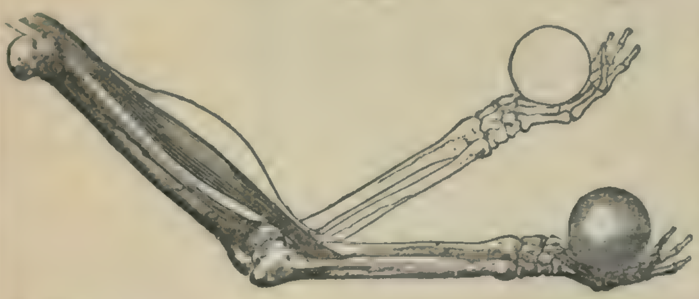
Dynamical mechanics, on the other hand, has reference to the forms and combinations of materials with a view to motion. Its principal objects are the generation, communication, and application of power and force, in order to change the forms or arrangements of materials. Its products are tools, implements, machines, engines, or apparatus; it teaches us how to choose the most suitable materials, produce the strongest and most serviceable forms, arrange their respective motions so as to secure regularity and diminish resistance, with a view to economy of labour and durability of structure. The farmer, brickmaker, and stone-worker, the carpenter and the smith, the spinner and weaver, the worker in pottery and metals, are all employed in changing the forms and arrangement of the materials submitted to them; and they have all to use the apparatus provided by the machinist, and the machinist practises the art of dynamical mechanics in devising and executing the implements suitable for their and his own use.

In statical and dynamical mechanics, the chief study is economy of material, labour, and cost. In any structure, whether for stability or movement, by an unsparing use of materials, it may generally be possible to secure the necessary strength. But it frequently happens that the usefulness of a construction would be seriously diminished by a rude accession of mere strength; and, in all cases, elegance of construction is manifested by the careful and ingenious arrangement of materials, and not by their absolute mass. Accordingly, we find, that as mechanical art advances, lightness and neatness of structure take the place of magnitude and weight; and improvements in existing constructions or arrangements are made to depend for their merits on the saving of material and labour which they effect. Perhaps the most stable structures that mankind have ever formed are the pyramids; and as works of enormous magnitude, of great age, and mysterious purpose, they excite admiration and wonder. But when one considers their form and the arrangement of their parts, their durability is not to be wondered at. A hill of mere sand, not blown upon by strong winds or washed by heavy rains, would retain for ever its pyramidal form, and would be an object of as great beauty and utility as the pyramid itself. The sovereigns of Egypt had probably at their command an enormous amount of human power, and knew no better object on which to employ it, than the erection of some immense pile, to gratify their pride while living, and contain their bodies when dead. We, living thousands of years after them, do not see the pain and labour of their slaves, and scarcely know how much misery might have been spared mankind, had their labour been applied to better uses. In the mere paving of the metropolis, we have more material and labour applied to a useful purpose than the amount required for the largest of the pyramids. In our harbours and docks, our canals and railways, we have works far more stupendous; and in our steam vessels and manufactories, we have power at work exceeding the capabilities of the whole ancient world. But with all this, it is the object of the engineer and machinist to study the greatest possible economy of material and of labour.

STRENGTH OF MATERIALS.—Whatever be the elements which constitute beauty, in works intended for ornament, we see beauty in things made for use, just in proportion to their fitness for their purpose. Parts out of place, deficiency or redundance of material, elaboration not called for, and deviation from just proportion, become glaring defects in any structure or apparatus formed for useful purposes; and no amount of decoration or finish can reconcile us to a disproportioned or unskilfully designed fabric. It is, therefore, most important that the practical mechanic should form an intimate acquaintance with the strength of the various materials with which he deals; their powers to resist strains in various directions, and the arrangements suitable for making use of these qualities to the greatest advantage. In the theoretical portion of this subject, there is much that is abstract and mathematical, yet nothing so difficult, but that the fair exercise of judgment may lead to very sound conclusions respecting it. All the main facts, however, respecting the strength of materials, are the result of experiment and observation; and the true use of theory in a subject like this, is to analyse and classify these results. If it be found, for instance, that several beams of timber, of known dimensions, are capable of sustaining certain strains applied to them in certain directions, it is not difficult to form general rules by which the strength of other beams differing in dimensions, or their strength to resist strains in certain other directions, may be computed. The careful mechanical designer either makes experiments for himself, or accepts the observations of others, and devises his structures in such a manner as to take advantage of these results. Practice in design, and frequent observation of successful works, do much to form the eye of a designer, so that the mere appearance of a thing, whether drawn or executed, satisfies his sense of just proportion, or the reverse. It is indeed a wonderful, as it is a most valuable property of the mind, that it can readily recognise and prefer the useful and suitable; and, as the just and the true recommend themselves to the mental and moral sense, so does the fitting in design recommend itself to the eye. Some individuals are gifted by nature with a keener sense and readier power of discriminating these qualities, and can therefore criticise more truly, or design more skilfully than others. But where there is a love for mechanical pursuits, or a desire to study mechanical works, we believe much of this power may be readily acquired.

POWER.—In the dynamical branch of Mechanics there are subjects of great interest and extensive application which demand the utmost attention; we allude to the means of deriving and communicating power. If we ask ourselves what power means, we can scarcely define it by any simple term; we may say that it is the capability of doing work or producing change. We start with the idea, which is a true one, that all matter is inert, incapable of receiving motion, of being brought to rest, or of undergoing any kind of change whatever of its own accord; some extraneous force or power has to be impressed upon it, and the quantity of change effected is the work done. When we lift a weight from the ground, the hand exerts a certain amount of power, and produces a certain amount of work; an act of mental volition communicates through the nerves, in some way unknown to us, an influence to the muscles of our arm, which causes them to contract. The muscles are attached at both ends to the bones, which are rigid levers jointed together. One end of such a bone or lever being fixed, as at the elbow-joint, and the muscle being contracted, the other end of the lever, to which is attached the hand holding the weight, is caused to move through a certain space, and thus to lift the weight a certain height (Fig. 2).

Fig. 2.



This is a case of power employed in producing motion; but, after the weight is lifted, power must still be exercised in retaining it in its position, for were the muscles for one instant relaxed, the hand and weight would drop downwards. If such be the case, we may at first sight imagine that our notion respecting the inertness of matter is incorrect, otherwise the hand and weight would of themselves remain where our muscular power had placed them. But, looking a little more closely into the facts, we find that while the matter with which we deal is really inert, there is a constant power acting upon it in opposition to our muscular power—the power of gravitating attraction, by which all bodies near the earth's surface are drawn down to it.

This power has been found, by extended experiment and observation, to act equally on all bodies and all parts of every body; and the measure of the force with which it acts on any body is the weight of that body. In estimating power, therefore, weight is the measure of one important element; and if we know the weight which any given power can lift from the earth, we have correct data for calculating its amount: in fact, we know the quantity of matter on which the power has effected a change. But there is another element of power quite as important as the quantity of matter acted on,—we mean the quantity of change produced upon it. If we find a certain amount of exertion necessary to lift a weight one foot from the ground, we shall find greater exertion necessary to lift it two feet. The change in both cases effected by the power applied, is a change of position; but the amount of change—that is, the distance through which the weight is moved—is in the one case double that in the other. Experiment and observation, as well as reasoning, prove distinctly, that the force required to lift a given weight, is exactly proportional to the distance through which it is lifted. We thus acquire the means of computing another element of power; and can combine this element, expressive of the amount of change effected, with the former, which expresses the quantity of matter upon which the change is produced.

In comparing numerically one power with another, we are therefore warranted in multiplying the weight lifted in each case, by the distance through which it is lifted, and comparing the results. Thus, if one man lift 20 lbs. 1 foot high, and another lift 30 lbs 1 foot high, we say that the powers exerted by the two men are as 20 to 30, or as 2 to 3; or if one lift 20 lbs. 2 feet high, and the other lift 20 lbs. 3 feet high, the powers they exert are as 20 multiplied by 2 (that is, 40), to 20 multiplied by 3 (that is, 60); or as 2 to 3. Again, let the one lift 20 lbs. 2 feet high, and the other 30 lbs. 3 feet high, their powers are as 20 multiplied by 2 (that is, 40), to 30 multiplied by 3 (that is, 90); or, more simply, as 4 to 9.

But, recurring to our definition of power as being the capability of effecting change, we must see that there is yet another element of calculation necessary for estimating different capabilities; as yet we have reckoned only the amount of work done, and have paid no regard to the time required for doing it. A few coral insects, labouring continuously for centuries, may form an island, which it would require thousands of workmen to raise in a short period; but yet the power of each workman far exceeds that of the insect, and the two powers can only be compared by supposing them to be exerted during equal times. Now, it is clear that a certain work being done, the shorter the period required for doing it, the greater is the power exerted; and conversely. In comparing powers numerically, we must therefore divide the work done by the time occupied in performing it. Suppose one man lifts 20 lbs. 12 feet high in 3 minutes, and another lifts 30 lbs. 10 feet high in 2 minutes, the work done by each is 20 lbs. × 12 feet, or 240, and 30 lbs. × 10 feet, or 300, respectively; but 240 divided by 3 minutes give 80, and 300 divided by 2 minutes give 150: the powers of the two are therefore in the proportion of these numbers, 80 to 150; or, more simply, 8 to 15.

STANDARD OF POWER.—We have now found means of measuring all the elements of power, and so determining its amount. For the sake of convenience, we fix upon some standard power with which we can compare others, just as we fix on a standard weight, such as a pound, or a standard length, as a foot; and knowing the value of several powers as compared with this standard, we can estimate their values as compared with one another. The standard power usually adopted in practical mechanics is a horse-power, which has been defined to be 33,000 lbs. lifted 1 foot high in 1 minute. The weight lifted, 33,000 lbs., was determined from the average of numerous experiments made with horses at work. Whether it be an accurate expression of the power of an average horse or not, is of little consequence, provided it be generally accepted and understood as a standard measure of power. Were there no such standard, each mechanic might make an estimate of his own: one might compute the work of a very strong horse, the other of a very weak one. Thus, steam-engines or other apparatus might be supplied of all different strengths and sizes, and yet purporting to be of equal powers; or apparatus of like strengths and dimensions might be stated to be of very different powers. But, this standard once fixed, it is the duty of a mechanic to estimate, by experiment or calculation, the weight which the engine he makes can lift through a given height in a given time, or the weight which moving through a given height in a given time, can work efficiently some apparatus which he may have fabricated; and he can then state the power which his engine furnishes, or which his apparatus requires, in terms intelligible to all the world. It is clear from what has preceded, that a horse-power does not mean precisely 33,000 lbs. lifted one foot in one minute, but a power equivalent to that; as, for instance, 330 lbs. lifted 100 feet in one minute, 3,300 lbs. lifted one foot in one-tenth of a minute; or, in fact, any weight such that, on multiplying it by the distance moved and dividing the product by the time occupied in the motion, the result shall be 33,000.

These considerations may be somewhat simplified by combining the distance and time into one term, which we call velocity or speed. Velocity is directly proportional to the distance passed over, and inversely proportional to the time occupied in the transit. A railway train that passes over 50 miles in an hour, has double the velocity of one that travels 25 miles an hour, because 50 is double 25. Again, a train that travels 25 miles in one hour has double the velocity of a train that passes over the same distance in two hours. To compare the velocities numerically, we divide the distances by the times of each.

In estimating powers, since our standard is given in feet for distance, and minutes for time, we divide the distance in feet by the time in minutes, and thus get the velocity. The weight in pounds lifted, multiplied by the velocity thus reckoned, gives a product which, being divided by 33,000, shows the number of horses'-power. Suppose an engineer were required to furnish a steam-engine capable of pumping 165,000 gallons of water every hour, to a height of 120 feet, he would reckon thus:—An hour contains 60 minutes; and 120 divided by 60, gives two feet per minute as the velocity with which the required volume of water must be lifted. A gallon of water weighs 10 lbs.; therefore, 165,000 gallons weigh 1,650,000 lbs.; this weight moved at the velocity of 2 feet per minute is equivalent to 1,650,000 × 2, that is 3,300,000 lbs. lifted 1 foot in 1 minute. Dividing this by 33,000, the quotient is 100 horse-power as the actual force required to do the work in the time given. He would, therefore, proceed to make an engine which, after providing for all mechanical losses in the operation, should be capable of producing this effect.

SOURCES OF POWER.—The principal sources of power are, the muscular forces of men and animals, the natural motions of air and water, the weight and elasticity of materials, and the changes effected in bodies by the action of heat, and by electrical and chemical action. It is the business of the mechanic to utilise these forces, to regulate and control them, to change or modify their directions, velocities, or intensities, so that they may be made to do certain work in the best, most economical, and expeditious manner. In addition, therefore, to his knowledge of the materials on which, or through which, these forces have to act, he must have an intimate acquaintance with the nature and laws of the forces themselves, as discovered by experiment, or investigated abstractly. It is a fortunate circumstance for man, considering the brief period allotted for individual research, that the laws of nature are of the most simple character, and that he is gifted with faculties that enable him to communicate the results of his investigations through great distances and over lengthened periods. Every successive discovery in natural science throws additional light over all that has preceded, opens up new fields for research, and suggests new modes of practical action. In the arts, likewise, an ingenious invention simplifies much that formerly was rude and cumbrous, facilitates operations formerly deemed impracticable, and furnishes the means of practising new and unheard-of branches of art. Let one but compare the state of mechanical art as it was before the time of Watt, and as it is now; and the more deeply he investigates the question, the more will he be surprised at the enormous change effected by a few simple but most ingenious modifications of a machine for utilising the power developed by subjecting water to the action of heat.

The steam-engine has indeed exerted so vast an influence on the arts, that we shall think it necessary to devote considerable space in what follows to its description in detail. We are the more strongly urged to this, because we believe that the student who can master the details of the construction and application of this apparatus, will be prepared to find his way through any branch of Practical Mechanics.

APPLICATION OF POWER.—The mere supply of forces for our various purposes would be of little benefit to us unless we had ingenuity sufficient to find modes of applying them. All work, as we have already hinted, means effecting changes of some kind or other; and all changes of matter imply motions either of masses or of parts. A most interesting and extensive branch of Practical Mechanics consists, therefore, in the discussion of the various modes of communicating and modifying motion. The two elements of which power consists—viz., the weight or mass acting, and the velocity with which it acts—are convertible terms. Having a certain power to work with, we can give up a certain amount of weight, and thereby gain in velocity, or sacrifice velocity in order to gain in weight. We cannot create any addition to the power either in weight or in velocity, nor can we annihilate any portion of it. We can, doubtless, apply the power with better effect to the work, and thereby save a loss; or we can misapply a portion of the power, and thereby render it ineffective for the purpose intended. A power applied to put in motion any part of a train of machinery, will be found acting at any other part of the same train.

If we could make our workmanship absolutely perfect, could have materials absolutely rigid and frictionless, and could remove our machinery from the influence of all extraneous existence, we should find in every part of it an equal amount of power. Some parts may move more slowly than others, but then they act with greater pressure or weight; some parts may act with less pressure, but then they move with greater velocity: in short, in every part of such a perfect machine we should find the pressure multiplied by the velocity—that is, the power or momentum, exactly the same. Even with our comparatively imperfect workmanship, we are quite safe in estimating according to this rule, without making much allowance for extraneous resistance. In the works of a clock, the wheel fixed to the barrel which carries the weight revolves so slowly, that its motion is quite imperceptible; and through the teeth of this wheel is conveyed the force which puts the whole clock-train in motion, a weight of many pounds. Again, the escapement-wheel, which sustains the motion of the pendulum, revolves with comparative rapidity, but with so little apparent power, that an opposing pressure of a few ounces might completely stop it; yet, on stopping the escapement-wheel, we stop also the barrel-wheel, and the few ounces applied to the one thus effectually oppose the many pounds acting on the other: in fact, the weight which acts on the barrel, multiplied by the velocity with which it moves, is equal to the weight necessary to stop the escapement, multiplied by the velocity with which it moves.

FRICTION.—We have alluded to resistances in machinery, the principal of which is friction, or the retardation caused by the rubbing together of imperfectly-smoothed surfaces. This is a subject about which little is known, or probably ever can be known. Some of its general laws have been successfully investigated, and a few general principles have been carried into practice; but its effects vary so much with every change of material—of speed, pressure, workmanship, and even temperature and other circumstances—that, after all, experience is the only real guide in all matters where it is to be considered. Except in a few mechanical arrangements where friction is employed as a useful resistance, as in the case of the friction-break of a locomotive or of a crane, it is generally the mechanic's object to diminish it as much as possible. The overcoming of friction is, in fact, the wasting of so much power; and as all machines are devised with a view to economy in the application of power, it becomes most important to reduce the waste to its minimum. In all devices for communicating and modifying motion, the question of friction becomes nearly as important as the question of strength; and many arrangements which are ingenious, and would be profitable, did friction not interfere, become comparatively useless, in consequence of its influence.

If one who had never made mechanics his study were introduced into a large manufactory, and had pointed out to him the steam-engines, the cranks, levers, wheels, pinions, straps, and other contrivances for communicating power throughout the building, and setting in motion each machine,—he would at first be bewildered, and inclined to believe that the art of communicating motion was intricate and complicated; but were he really to analyse the process carefully, and trace exactly the progress of the power or motion from the prime mover to the last machine, he would find the whole effected by the combination of a few simple mechanical elements; and wonder that through means so simple, results apparently so complicated could be attained.

Students of astronomy cannot help being struck by the circumstance, that the various motions of planets, satellites, and comets, and probably also of the stars and nebulæ, of the farthest and greatest, as well as of the nearest and smallest, of the heavenly bodies, all result from two simple forces, acting in various directions and with different intensities. The movements of the vast machine of the universe present, to a superficial observer, inextricable confusion and inexplicable irregularity; but to a mind like that of Newton all is skill, order, and beauty. The very disturbances to which the different parts of the grand machine are subjected are elements of stability; the irregularities are sources of permanence. In a system of machinery devised by human ingenuity and executed by human hands, there can, indeed, be no approach to this simplicity, order, and harmony; everything must be imperfect in proportion as man is imperfect, when compared with the Divine Mechanic of the Universe.

In every human work there must be elements of decay, sources of irregularity, and causes of instability; and these can only be reduced by diminishing the extent and complication of the work itself. Simplicity is, therefore, the great aim of the mechanic, especially in arrangements for communicating motion. Every wheel, every lever, every pulley that can be saved, is saved—not so much to avoid the cost of its introduction, as with a view to simplify the machinery, and thereby diminish the amount of friction and wear, and increase the permanence of the whole. To the eye of a practised mechanic, therefore, the beauty of a piece of machinery seems to depend more on its simplicity than on any other principle. The fewer the parts required in any apparatus to render it effective, the more ingenious is its contrivance, and the less is it liable to derangement, irregularity, and decay.

GOVERNING POWER.—Next in order to contrivances for communicating power or motion, may be studied those for regulating and governing it, so as to secure uniformity of action. All the forces we employ, with the exception of gravity, are subject to continual variations of intensity; and even the most uniformly regulated forces, when transmitted through trains of machinery necessarily imperfect, are subjected to considerable variations. Further, the forces we employ are chiefly used for effecting changes on materials; and as the qualities and conditions of the materials vary, so the quantities of force required to do the work upon them differ. It becomes, therefore, most important that arrangements should be devised for compensating all these variations of force; and accordingly, great ingenuity has been exhibited in contrivances for that purpose. We may quote a very beautiful specimen of mechanical skill applied for a purpose of this kind, in order to illustrate the great use of such arrangements. Wind-power is used to a great extent for putting machinery in motion; and yet, as we all know, nothing is more variable than the force of wind, both in direction and intensity. In former times, wind-mills were made so that the miller, watching the direction of the wind, could turn round the sails of his mill to face it, and furl or unfurl those sails as he found the breeze too strong or too light to give the velocity of movement he might require. But in modern wind-mills, the wind itself is made to regulate the machinery by simple but ingenious arrangements. In the first place, if the wind change in direction, it blows upon a small subsidiary set of sails placed so that they can be acted on by a wind that does not directly blow upon the main arms; by a little simple machinery, this side action of the wind is made to turn round the head of the mill until it brings the great sails into the proper position to receive its direct impulse—just as the wind acting on a weathercock brings the arrow-point round to face it, by its pressure on the broad feather at the other end. Again, should the force of the wind increase, this very increased force is made to act upon a regulating apparatus so as to furl the different divisions of the sails, or to turn the surfaces of which they are made up edgeways to its impulse, and thereby to diminish the surface on which it acts, proportionally to its increase of intensity. The consequence of these contrivances is, that from whatever quarter the wind may blow, the sails of the mill are always directly opposed to it so as to receive its full action; and whatever be its force, whether a gentle gale or a stiff breeze, the power communicated to the machinery does not greatly vary. Perhaps the most ingenious devices for regulating power and velocity are those employed in apparatus for the measurement of time—clocks, watches, and the like, which form one most interesting branch of mechanical art, Horology.

NATURE OF MACHINES.—Having obtained the power necessary for our purposes, and having found the means of communicating it to our machines, and of regulating its intensity so as to suit the work to be done, we have next to inquire into the nature of the machines themselves, or the contrivances through which the power is made to act on the inert material subjected to it.

We can scarcely venture to offer a very distinct classification of machines; nor, indeed, in a work of limited compass like the present, could we pretend to discuss in detail, all the different classes of machinery now in use. The subject is so extensive, and demands so minute a knowledge of what has been done by thousands of ingenious mechanics, that even the professed machinist cannot pretend to an intimate acquaintance with every branch of it. But the qualities of mind and the experimental training which render a man skilful and adept in one or two of these branches, make it easy for him to take up intelligently, any other branch that may be brought under his notice. The same general mechanical principles pervade all kinds of machinery, the modes of applying them being varied according to the nature of the material subjected to their operations, or to the kind of work to be done. With the exception of certain special apparatus, we believe almost all the machinery used in modern times may be classed under some of the following heads:—

I. *Machinery for raising Weights and giving Pressure.*—Among these we may notice especially the simple mechanical powers, the lever, wheel and axle, pulley, inclined plane, wedge, and screw.* Next, in order of complication, may be mentioned such machines as cranes, crabs, capstans and windlasses, slips, tackle and travellers, jacks, screw and lever presses, printing presses, and the like.

II. *Machinery for effecting Transit and Communication.*—This branch has of late years attained immense importance by the extended use of railways and steam vessels; and under the head of transit, it embraces the consideration of vehicles for land transport, and vessels for water carriage, and the various modes of putting them in motion. For the communication of intelligence, we now practise an art unknown in former times, and one deserving of detailed consideration from its marvellous nature and the important influences it is likely to exercise upon human civilisation. We allude to the electric-telegraph, to which perhaps greater ingenuity has been devoted within a few years than has been displayed in any other branch of mechanical art during preceding ages.

III. *Machinery for Moving Fluids.*—This branch naturally includes hydraulic apparatus, such as pumps, fire-engines, hydraulic presses and lifts; and also machinery for moving air, such as bellows, blowing-cylinders, fanners, and the like.

IV. *Machinery for changing the forms of Solid Materials.*—This is perhaps the most extensive branch of mechanical art, as it includes all apparatus for cutting, piercing, moulding, bending, crushing, and such like operations. It may be subdivided, according to the materials on which the operations are to be effected, as follows:—

1. Machinery for preparing animal and vegetable products; as oil, tallow, leather, flour, sugar, vegetable oils and extracts, caoutchouc, and gutta-percha.
2. Machinery for preparing mineral products; as stones, bricks, cements, ores, pottery-ware, glass, pigments, and the like.
3. Machinery for sawing, planing, moulding, bending, and carving timber.
4. Machinery for working metals; as in the operations of moulding and casting, forging, rolling, and wire-drawing; bending, shearing, punching, and rivetting; drilling, turning, and boring; planing, shaping, and the like.
5. Agricultural implements; or machinery for opening and triturating the soil, for sowing and reaping, for thrashing, grinding, and otherwise preparing produce.

V. *Machinery used in the manufacture of Textile Fabrics.*—This is likewise a most extensive and interesting branch of mechanical art, and one of the highest importance to us as a nation, as well as to the world at large. It includes directly the apparatus and processes employed in preparing the crude materials, such as wool, flax, cotton, and silk; the various operations of dressing, carding, spinning, weaving, dyeing, bleaching, calico-printing, and the like. Under the same head may also be classed the machinery for making ropes and cordage, and for the manufacture of paper.

VI. *Machinery for Measuring and Calculating.*—The apparatus included in this class are mostly of that exact character required for philosophical experiment and observation, such as indicators, dynamometers, gauges, balances, and mathematical and optical instruments; but there is one extensive and interesting branch, horology, devoted to apparatus for the measurement and division of time, which deserves especial consideration, as well from its usefulness as from the great ingenuity displayed in it. In this class we may include some other apparatus, which, though not distinctly falling within the scope of its title, yet present in some respects considerable similarity to some of those included; we mean automata and musical instruments.

VII. *Implements of War.*—It is lamentable to think how much mechanical skill has, in all ages, been devoted to the cruel purposes of destruction. In the present age, perhaps no branch of applied mechanics has called forth so much ingenuity as the contrivance of means of offence and defence. And so vast and costly have these contrivances become, that we may almost hope to see wars cease upon the earth because of the very perfection to which its implements have attained.

These seven classes, we believe, include the greater part of the machinery used in modern times. In what follows, we will not pretend to give detailed descriptions of the different machines included in these classes; we shall endeavour rather to select a few of a general character, involving in their construction the principles which are applied, in a modified form, to most of the others.

MECHANICAL EDUCATION.—While improved education and extended acquaintance with principles, have placed those who direct mechanical labour in a better position as to knowledge of their art, the division of labour and the extensive use of mechanical contrivances, instead of manual labour, have certainly lowered the position of the workmen as to general knowledge of their trade. Formerly, the millwright knew all about the machinery he made, and could turn his hand to all the operations required in its construction; now, there are mechanics who can only turn, others who can only file, and only very few who, to skill of hand, unite a knowledge of the machinery of which they execute portions. We are convinced that this state of things is injurious both to workman and to master; for a man can never labour with hearty good-will at work which he does not understand, and in which he, therefore, takes no intelligent interest; he can only act as the machine at which he works, and he is thus morally and intellectually degraded. We would have every workman understand the character and tendency of his operations, and take an interest in them. He would thus be relieved from much of that monotonous drudgery which his ignorance forces him to undergo; he would be prepared for emergencies; he would see modes of economising labour, and of improving the work on which he might be engaged; and he would be provided with a source of rational amusement in his leisure hours.

But not to the mechanical workman alone do we think that a general knowledge of practical mechanics should be supplied; we think that it should form part of the education of every one, whatever be his position and his prospects. We have seen of late years deplorable instances of want of contrivance in military affairs, and of sacrifices of blood and treasure in consequence. We are eminently a commercial, manufacturing, agricultural, and colonising nation; our commerce is conducted by means of railways, steam and sailing vessels, and requires warehouses, docks, and quays; our manufactures are all the product of mechanical contrivances; our agriculture is now rising to its just position as a mechanical and chemical art; and our colonies have been successful from the energy displayed by our emigrants, in giving scope to their natural genius for mechanical adaptation of the means to the end. Of late, we have assumed the position of a warlike nation, and we have sadly asked ourselves why there has not been employed in war any of that mechanical skill and ingenuity which characterise our peaceful arts.

Notwithstanding all this, practical mechanics have never yet been cultivated as a branch of general education; and consequently, every man, whatever be the walk of life in which he chooses to tread, has to begin his real education after he leaves school. We think this evil should be remedied—that every man should have instilled into his mind in his early years, a thorough knowledge of common things, so that when he advances in life he may enter more readily on any of the professions or trades practised at home, and be the better prepared for the emergencies of commerce, colonisation, or warlike expeditions abroad. Among the population of the land there lies dormant a vast amount of talent and ingenuity, which at present is so much loss of capital to our country and to the world. Let some opening be made for its cultivation, and we doubt not that a few years would bring about a more astonishing development of our resources, extension of our commerce, and improvement in our arts, than all the marvellous advance of the last thirty years. While we fully admit the high importance of other branches of mental and moral training, we would also strongly urge the advantages of insight into the mechanical arts, because through their extended cultivation we expect to secure a great increase of our material prosperity and comforts, a great diminution of labour, improvement of health and strength, and wide diffusion of intelligence among all classes.

CHAPTER II.

MECHANICAL DRAWING.

Contents.—USE OF DRAWING—PLANE SURFACES—DRAWING CUBES—DRAWING CYLINDERS—PROJECTION—SECTIONS—PERSPECTIVE—PROJECTION OF CURVES—UNFOLDED SURFACES—INTERSECTIONS—HATCHING—CENTRAL LINES—SHADOWS AND SHADES—INSTRUMENTS—SCALE OF DRAWINGS.

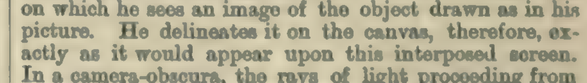
USE OF DRAWING.—In the actual practice of mechanical art, drawings are invaluable; they show the true forms, dimensions, and arrangements of machinery, to those accustomed to their use, with greater clearness than models or even the full-sized works themselves. The draughtsman devises the arrangement of his machinery; sketches it on paper; calculates the strength and proportion of the parts; draws them out full-size or to some suitable scale; studies their combinations on paper; improves this part, strengthens that part; modifies the forms so as to save complication, material, or cost of workmanship; traces the action of the whole; provides safeguards against accident or undue wear and strain; and having at length fully embodied his ideas on his plans, sections, and elevations, places them before the workman for execution. The workman has, in general, no need to study any of those details which fall within the province of the draughtsman; he has only to put his rule to the drawing, and measuring every dimension there indicated, shape the material with which he deals in exact accordance with it. Without drawings it would be impossible to make any advance in mechanical art. The paper, pencil, ink, and colours, are cheap materials; and the time and labour occupied in making a drawing are as nothing compared with the work in fashioning the solid material. To scheme on paper is, therefore, most advantageous in every point of view, as by that process only can be secured that economy of material and labour, harmony of action and justness of proportion, which constitute the beauty of a mechanical device. To scheme in the solid materials, is a most expensive as well as unsatisfactory process, and one that seldom leads to successful results. We know of no circumstance that can warrant its adoption, except in cases where there is no practical experience to guide the mechanic as to the power required, or the mode of operation suited to the work he has in hand. Even in such cases it is generally possible, by the exercise of a little judgment and ingenuity, to arrange some simple and inexpensive experiment, which may give to a practical man, a tolerable notion of the kind and scale of machinery that will be required.

A system of mechanical notation was proposed some years ago by the ingenious Mr. Babbage. In devising his calculating machinery, which consisted of a great number of parts, many of them merely repetitions, he found it difficult to imagine all their simultaneous movements without an excessive and painful exercise of that mental power which has to deal with such matters. He therefore attempted, and with considerable success, to trace by written symbols the flow of motion through a train of machinery. We are not aware that his system of notation has been adopted by practical men. Indeed, most of the complex machinery with which the engineer has to deal, is of a kind similar in many respects to works previously executed, embodying improvements that may have been from time to time effected in them; his mind is, therefore, in a manner prepared for the conception of the various motions and connections by his practice in watching those in machines in action, and he has comparatively little difficulty in fully imagining the intended action of the work on which he may be engaged. It will, therefore, be our first duty to offer a few practical suggestions on drawing, as applied to machines.

PLANE SURFACES.—When we have to draw a triangle, square, circle, or any other superficial figure, upon paper, we find no difficulty in giving a full and accurate delineation of it in respect of form and dimensions. The paper on which we draw is itself a plane surface; and so long as we are not limited in length and breadth, we can delineate any plane form whatever upon it. In the same manner, we can describe any of the flat faces of any solid object presented to us, such as a circle, pyramid, or prism; and give an accurate representation of any two of its dimensions, whether we call these by the names of length and breadth, or height and width. But when we have to delineate a solid body which has three dimensions, length, breadth, and thickness, we must either cut our paper to pieces, shape it so as to correspond with the different faces of the body, and put them together in similar order, so as to form a model of it; or we must have recourse to some device that shall enable us to comprehend for ourselves, and to communicate to others, an accurate notion of the solid body we propose to delineate on a flat surface. When the painter draws a portrait, or executes a landscape, he has to imagine, that between his eye and the object which he draws, there is interposed a surface or sheet of some kind on which he sees an image of the object drawn as in his picture. He delineates it on the canvas, therefore, exactly as it would appear upon this interposed screen. In a camera-obscura, the rays of light proceeding from every point of objects presented to it, are concentrated or gathered together by a lens, into a particular place or focus behind it. A piece of frosted glass in this focus offers a surface for these rays to illuminate, with their respective lights, shades, and colours; and an observer looking on the frosted glass, sees a perfect miniature picture of the objects. A plate of prepared metal or glass placed in the focus, receives exactly the same picture; and certain substances spread over its surface, rendered sensitive to chemical properties of rays of light, which the eye cannot appreciate, undergo changes in their constitution, which can be rendered permanently visible in photography.

DRAWING CUBES.—Pictures are thus produced by hand and by photography, which present, upon flat surfaces, delineations of solid bodies as they appear to the eye. But, if we were to apply a compass or a rule to the measurement of the bodies represented in these pictures, and also measure the objects themselves, we should find the angles, dimensions, and proportions of the picture, totally different from those of the real bodies.

Fig. 3.



Thus, a cube, such as a die, which has six equal square faces, marked by dots, as in Fig. 3, when represented on a picture, might present such an appearance as in Fig. 4, where only three sides are visible, none of them squares, and no two alike: not a single angle or dimension equal to those in he die itself. And yet the picture may be a perfectly true delineation of the die as it appears to the eye of an observer. Now, if a workman were furnished with such a picture, and required to make a die according to it, he could have no conception of its form and dimensions. For instance, he might cut a piece of plate to the shape of an irregular six-sided figure, with three lines engraved on it, meeting at a point near its middle, and certain dots marked at the distances indicated on the picture. He would then have made a solid body, which, viewed in one direction, would certainly present the appearance of the picture. Even if the picture were shaded, and marked by dotted lines, indicating the invisible edges of the die, as in Fig. 5, he could not, without further information as to its meaning, construct a solid body such as would answer to it. He would have to be told that it was a solid, having six equal flat sides, which, viewed in a certain direction, and at a certain distance from the eye, under light falling upon it at a certain angle, presented the appearance of the picture. He would then either model all conceivable kinds of six equal-sided bodies, and try each in the given aspect, or he would work out, geometrically, some other properties of the body, such as might enable him to construct it. If, on the other hand, instead of having such a perspective picture presented to him, he had a drawing like Fig. 3 placed before him, and were told to make a piece of ivory of such a shape that each of its six sides should be exactly of the form drawn, and either of its dimensions, or of some given multiple or fraction of these dimensions—as for instance, for every inch on the drawing, three inches in the die itself—he would at once comprehend and execute the work required of him.

Fig. 4.

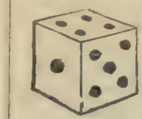


Fig. 5.

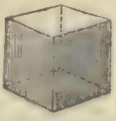
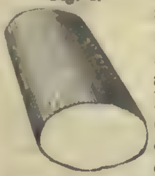


DRAWING CYLINDERS.—In like manner, if a cylinder, or roller, were pictured as it appears to the eye, with its light and shadow, as in Fig. 6, the workman might guess at its form, but could ascertain nothing as to its dimensions. But if he were told to make a thing of which Fig. 7 is the drawing, one-quarter of the full size, he could at once form his material to its proper diameter and length, by measuring the drawing, and allowing an inch in his work for every quarter of an inch on the drawing.

Fig. 6.



PROJECTION.—The object of mechanical drawing is, therefore, not to present a delineation of any object as it appears to the eye, but to furnish the exact figures and dimensions of its parts, in such an intelligible manner, that solid materials may be fashioned into shapes, whose parts shall have similar forms and proportions. The principle on which mechanical drawing is founded, is that of projection on plane surfaces, which we shall now endeavour to explain.

Fig. 7.

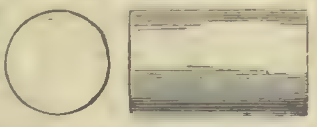


Fig. 8.

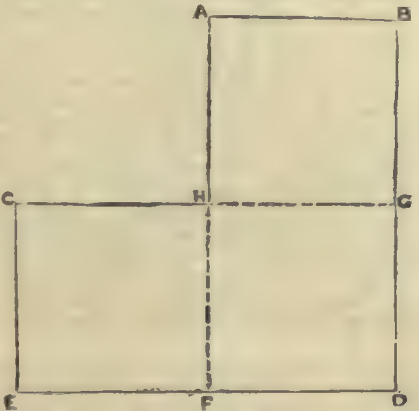

Suppose a sheet of paper were cut to the form A B D E C H (Fig. 8), and folded across where marked by the dotted lines H G and H F, the two parts A B G H and C H F E being turned up so as to stand at right angles or square to H G D F, and to one another as in Fig. 9, forming, as it were, three sides of a square box; then each of these three portions of the paper becomes what is called a "plane of projection," for receiving the representation of one of the sides of a solid body placed somewhere within the imaginary box, of which they form the sides. Let us suppose, for instance, that a die were suspended within the box (Fig. 10), and that from every point in each of the surfaces of the die exposed to the three sides of the box, lines were supposed to be drawn perpendicular or square to those sides as indicated by the dotted lines;—then the lines joining the intersections of the dotted lines, with the upright and horizontal surfaces, would enclose figures accurately representing, in form and dimensions, the respective sides of the die presented to them. The paper being then unfolded, would contain a mechanical drawing of the die (Fig. 11), exhibiting accurately the forms and dimensions of three of its sides. In order to get a drawing of the other three sides, the other sides of the imaginary box might have similar figures projected or thrown upon them. It is evident that whatever be the situation of the die, as to distance from either of three planes of projection, there will be no difference in the drawing; the form delineated will be the same, though it may appear on a different part of the paper.

Fig. 9.

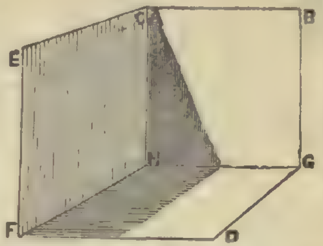

Fig. 10.

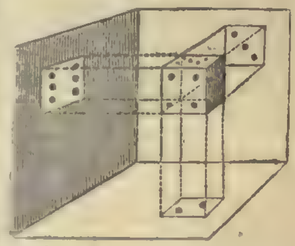
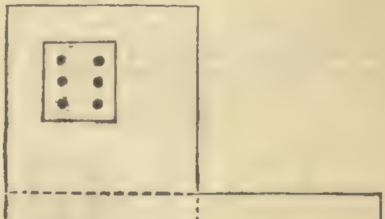


The names usually given to the three drawings of an object are these:—The projection on the horizontal plane or bottom of the box, is called the *plan:* and the projections on the vertical planes or upright sides, are called *elevations*. One of the elevations may be called the side elevation, or side view; and the other the end elevation, or end view; while the plan, when projected upwards, or on the top of the box, is sometimes called the bird's-

Fig. 11.



eye view, having nearly the form which an object would present to the eye of a bird soaring above it.

SECTIONS.—For drawing the exteriors of all solid bodies, bounded by straight lines and flat surfaces, these projections are generally sufficient. But it is often necessary to make such drawings as shall give a correct notion of the interior construction of bodies.

Suppose, for instance, we wished to have a cubical box constructed of wood, having a certain thickness, and fitted with a vertical partition of a certain height, and at a certain distance from the ends. In order to indicate this by a drawing, we must show its internal construction. To effect this, we may still use the three planes of projection; but as these planes are imaginary surfaces, we may easily conceive some of them to pass directly through the substance of the box: in other words, we may conceive the box to be sawn or cut across in any direction, and the form presented by the parts so cut, to be projected on the planes (Fig. 12). Thus, if a horizontal and a vertical cut were made, as indicated by the dotted lines, A A and B B, we should have a plan and a side elevation of the cut surface, in which the thickness of the wood, and the position and height of the partition, would be clearly shown. These views would be called *sections*, or the drawings of cuttings. The horizontal projection would be a sectional plan, and one of the vertical projections would be a longitudinal or transverse section, while the other would still remain as an end or side elevation. The dotted lines A A and D D, on the end elevation and section, correspond with the horizontal plane of section; and the lines B B and C C, on the end elevation and plan, correspond with the vertical plane of section. In a drawing, then, of a box, such as in Fig. 13, which would be seen on unfolding the paper of projection, enough of the form, thickness, position, and height of the partition would be represented to enable a workman to construct the box.

Fig. 12.

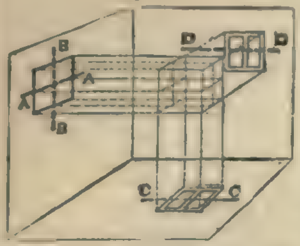


Fig. 13.

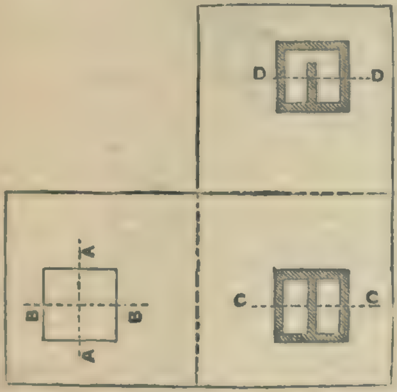

Fig. 14.

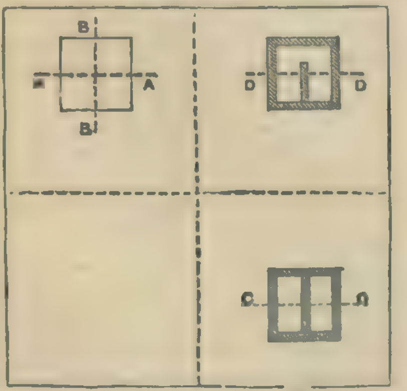
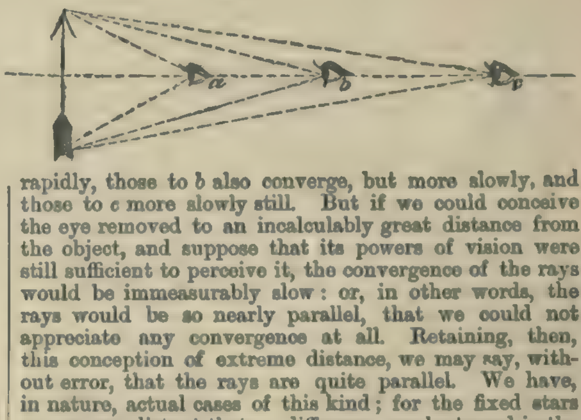


Now, if the part of the paper containing the end elevation were cut away from the rest, and turned round, so as to bring the letters on it into a more convenient position for reading them, as in Fig. 14, the accuracy of the drawing would in no respect be altered, provided always, that it were clearly understood what elevations, plans, or sections, the different parts of the drawing were intended to represent.

PERSPECTIVE.—There is another mode of considering this question. The rays of light by which the eye is enabled to perceive the form of an object, proceed from every point of the object, in straight lines to the eye. Suppose, then, one face of a die were presented directly to the eye, as in Fig. 15, the rays of reflected light, proceeding from every point in the surface of the die to the eye, would all converge or draw together towards the small opening which the pupil presents; and entering there, would produce the image which enables the spectator to see the object. This would be the case however far off, or however near, the eye were to the die; but the greater the distance, the less the convergence of the rays, or the more nearly are they parallel to each other, as may be clearly seen by the diagram, Fig. 16, where an arrow is supposed to be the object, and the rays of light proceeding from its extremities are indicated by the dotted lines, to an eye at the various positions, *a*, *b*, and *c*. While those to the eye, at *a*, converge very rapidly, those to *b* also converge, but more slowly, and those to *c* more slowly still. But if we could conceive the eye removed to an incalculably great distance from the object, and suppose that its powers of vision were still sufficient to perceive it, the convergence of the rays would be immeasurably slow: or, in other words, the rays would be so nearly parallel, that we could not appreciate any convergence at all. Retaining, then, this conception of extreme distance, we may say, without error, that the rays are quite parallel. We have, in nature, actual cases of this kind; for the fixed stars are so very distant that no difference can be traced in the direction of rays of light coming from them to the earth, at different parts of her orbit, although the distance across that orbit is nearly two hundred millions of miles.

Fig. 15.

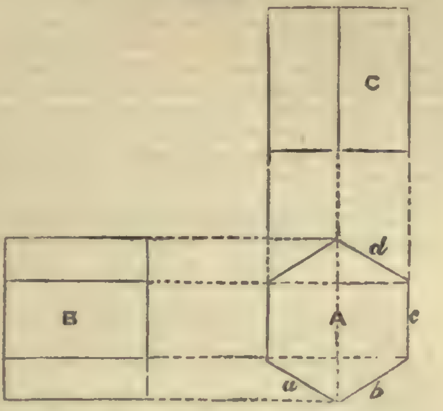
Fig. 16.



Now, we have already shown that the different projections of an object are formed by supposing parallel lines to be drawn from the different points of it to certain planes; and if we suppose these parallel lines to be rays of light, such as we have described, proceeding to an immeasurably distant eye, we attain a mode of understanding what these projections mean. According to this notion, the plan or horizontal projection is the view which an object would present when we look directly down on it, or directly up to it, from a great distance; the side and end elevations are the direct views of the side and end respectively; and sections are the direct views of the object when cut or sliced across in any direction. Bearing this in mind, we may then be prepared to make mechanical drawings of most objects with facility.

Suppose, for example, we had to draw an object such as mathematicians would call a hexagonal prism—that is to say, a solid figure having six equal oblong sides and two six-sided ends. Supposing it to stand on one of these ends, and that we looked directly down upon it, we should see its plan, which is a hexagon (A, Fig. 17).

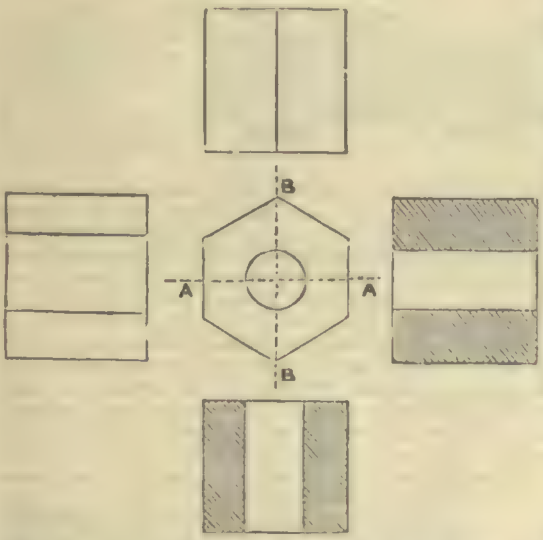
Fig. 17.



Again, looking directly on the angle formed by the two sides *a* and *b*, we should see the elevation C, showing the two retreating sides *a* and *b*; and looking direct on the side *c*, we should see the elevation B, showing the full front view of *c*, and views also of the two retreating sides *b* and *d*. The dotted lines represent portions of the supposed parallel rays of light proceeding from the angles of the object, and prolonged to form lines, projections, or drawings of the two views, the position of the top and bottom lines of these projections being determined by the height of the prism, which we suppose to be given.

Let us now suppose that the same prism is to be made with a circular hole passing through its centre from end to end, we may show the same views as before, and in addition to them two sections, as in Fig. 18.

Fig. 18.

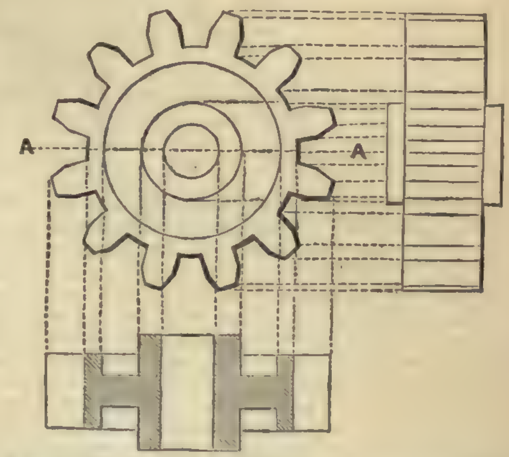


The lines A A and B B, through which the sections or cuttings are supposed to be made, are marked on the plan, and the sections are formed exactly like the elevations, by tracing the different points of the object where the section lines cut it. We have hatched or drawn diagonal lines across the solid parts which are supposed to have been cut asunder, in order to distinguish them, by a sort of shading, from the open circular part where no solid material is supposed to have been cut through.

We will now take a somewhat more complicated drawing as an illustration—for instance, a toothed wheel (Fig. 19), in front elevation, sectional plan on the line A A, and elevation as seen edgeways, which we shall call side elevation.

In this case, as in the former, the dotted lines are drawn parallel to each other from the different visible points or edges, and furnish us with the positions of these in the side elevation and plan; the width of the teeth and thickness of the material being supposed to be known independently.

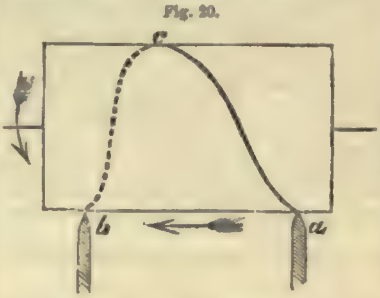
Fig. 19.



PROJECTION OF CURVES.—By the same method, drawings of curved surfaces may be made, some consideration being given in each case to the mode most suitable. Let us take for an example a drawing of a screw. In the first place, we must understand what a screw is. Suppose a cylinder or roller were revolving round its axis, and that while it was so revolving a pencil or sharp point were held against it. If the point were at rest while the roller revolved, a simple circle would be described on the surface of the latter. But suppose that while the roller revolved, the point were made to traverse lengthways along it, then a screw-line would be drawn on the surface (Fig. 20).

The pencil having begun to mark the roller at *a*, and having advanced to *b*, while the roller has made one complete turn, the screw line *a c b* would be marked on its surface. As we could not see both sides of the roller at once, we can only draw the part *a c* of the screw as visible, the other part *c b* being marked by a dotted line to show that it exists, and would be seen were the roller transparent. The whole line *a c b* would be called a thread or complete turn of the screw; and the distance *a b* would be called the pitch, or distance between two adjacent threads. It is clear that were the roller to continue to turn, and the pencil to advance, the thread would continue to be marked as far as the surface of the roller might extend. The screw marked in the figure would be technically called a "drunken thread," or be said to be of irregular pitch, as the relation between the velocities with which the roller revolved, and the pencil advanced respectively, is not of a fixed or constant character.

Fig. 20.



But if, while the roller revolved uniformly or with regular and equal velocity, the pencil also advanced uniformly, a thread would be traced perfectly regular and equal in all its parts, or a true screw, such as is used in mechanics, would be formed. We will now draw such a screw. Let A (Fig. 21) be the end-view or section of the roller, which is merely a circle, and let B be a side elevation; *a* being the position of the pencil when it began to mark the thread, *b* its position after one complete turn, and *c* its position after two turns; it is our object to find the shape of the line, or at least its drawing or projection on the elevation B, connecting the points a and b, and b and c, respectively. Now recollecting that a regular screw implies that while the roller makes any part of a turn, the pencil must make an advance through the same part of its pitch, we will divide the circumference of A into four equal parts by the points d, e, f, g, and also the two pitches $a\,b$ and $b\,c$ into four equal parts, marked by the points h, k, l, m, n, p. Then we know that while the roller has turned one quarter round, so as to bring the part of its surface e to the pencil, the pencil itself has moved one quarter of its pitch along, so as to be at the point h. If then we trace a line of projection from e along the elevation, and a line square to it from h, the point e_1, where these lines cross, must be a point in the projection of the thread. In the same manner, tracing lines from f and g and from k and l crossing them, we get other points, f_1 and g_1, in the thread; and repeating the process for the next thread, we get the points e_2, f_2, and g_2, similarly situated in it. But though we might, between the points d_1, e_1, f_1, &c., draw any sort of lines straight or crooked, we should not be warranted in assuming them to be the proper representations of the screw. We can, however, again subdivide the circumference of A and the pitch on B, and thus get a number of other points, as indicated in part on Fig. 22, which must be in the projection of half the screw. A curved line traced through these points, will then be a correct representation of half the thread; and as the thread is perfectly regular, the same form of curve will be repeated at the equal intervals of pitch, from d_1 to f_1, and d_2 to f_2. The intermediate parts of the thread from f_1 to d_2, and from f_2 to d_3, being traced on the side of the roller where g is, cannot be visible at the same time as the other portions: but if they could be seen, as in the case of a transparent roller, they would be symmetrical with the visible parts, but inverted, as indicated by the dotted lines in Fig. 23.

Fig. 21.

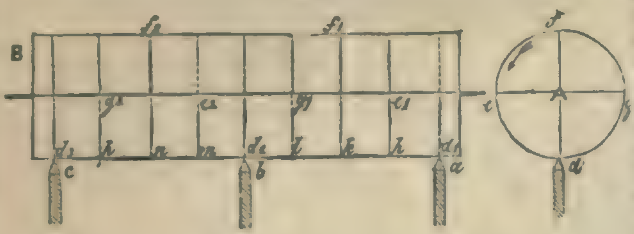


Fig. 22.

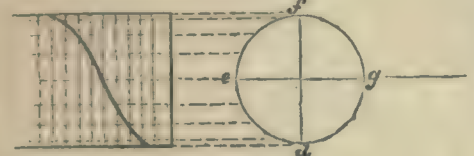
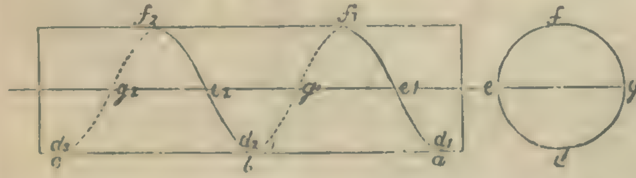


Next let us suppose that two pencils were held against the roller a little distance apart, so as to trace two screw-threads parallel with each other; the side elevation of this, as in Fig. 24, presents merely a repetition of the proper curved lines at the proper distance apart—that is to say, if any number of straight lines were drawn parallel to the axis or sides of the roller, the portions of those straight lines intercepted by the screw-curves, viz., $a\,b$, $a_1\,b_1$, $a_2\,b_2$, &c., also $c\,d$, $c_1\,d_1$, $c_2\,d_2$, &c., &c., would be all equal to one another. The ordinary practical mode of making such a drawing would be to set out the points of one portion of the curve, such as $a\ a_4$, by the method indicated on Fig. 22, to shape a piece of card-board or thin wood to fit it, and then marking out the proper distances $a\,b$, $a_1\,b_1$, $a_2\,b_2$, $b\,c$, $b_1\,c_1$, $b_2\,c_2$, $c\,d$, $e_1\,d_1$, $e_2\,d_2$, &c., and applying the shaped card to these points successively, trace by a pen or pencil as many repetitions of the curve as might be required. By a similar process, inverting the card, the elevation of the curves as they would appear through the roller were it transparent, as indicated by the dotted line in Fig. 23, could be repeated.

Fig. 23.



Recurring to Fig. 24, let us now suppose that all that part of the surface of the roller contained between the double threads were cut down to a certain depth, so as to leave a real solid screw-thread prominent, such as would be produced by winding a square wire obliquely round a cylinder. Our method of drawing this would be as follows (Fig. 25):—The transverse section shows two circles, one the boundary of the outside of the prominent thread, and the other the roller on which it is wound, or the bottom of the cutting made in the solid roller. Let half of both these circles be divided into any number of equal parts, and let the length $a\,b$, which the thread traverses during half a turn, be divided into the same number of equal parts; then, by drawing the vertical lines from the points where $a\,b$ is divided, representing the distances traversed by the describing point along the roller in equal portions of a half revolution; and by drawing horizontal lines from the points into which the half circumferences of the inner and outer circles are divided, representing the equal portions of the half revolution; the points, at which these vertical and horizontal lines cross each other, are points in the two screw curves respectively. A card shaped to each of these can be used to repeat them at equal intervals along the roller, so as to represent the continuation of the thread. A little consideration will show what portions of these lines would be visible in a side-view, and what parts would be concealed. It is usual to show, by full lines only, the visible portions, the invisible parts being marked, when necessary, by dotted lines.

Fig. 24.

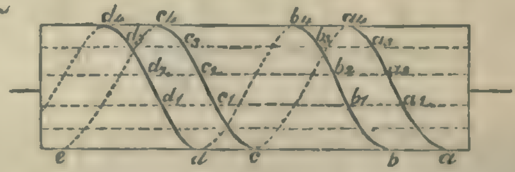


Fig. 25.

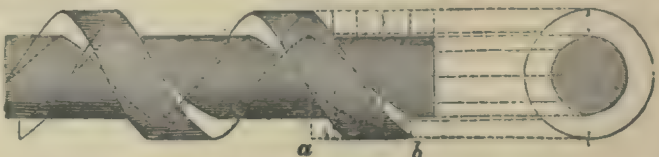

Other curves can be treated in the same way as screw-curves, the general principle being the same to all—namely, finding the projection of a number of points through which the curve must pass, and tracing through those points, a continuous curved line as nearly as the eye can judge or the hand execute. The greater the number of points projected, the more nearly accurate will be the drawing of the curve. But a little practice in drawing, and careful observation, soon enable a draughtsman to trace projections of curves with sufficient accuracy without requiring very many points for their determination. The drawing of a screw-curve, such as we have described, is as difficult as any of the projections that ordinarily occur in mechanical drawing. We have, therefore, dwelt upon it at some length, being convinced that the student who sees his way clearly through this example, will master most others without great difficulty.

UNFOLDED SURFACES.—Besides the method of drawing objects by projection, it is sometimes useful to represent surfaces developed or unfolded. This may be clearly understood by conceiving that a pattern of some kind—say a series of squares, as *a* in Fig. 26, is wrapped or folded round the roller *b*. We shall suppose that the piece of a flat paper, or fabric, containing the pattern, will fold exactly round the roller so that the edges meet. The projection of this pattern, as it would appear in a side elevation of the roller, may be drawn as in Fig. 27. Observing that the pattern is divided into three parts in height and five in width, we draw an elevation and a plan of the roller, as in Fig. 27, dividing the elevation into three equal parts in height, and dividing the circumference of the circular plan into five equal parts by the points *a*, *b*, *c*, *d*, *e*. Tracing up lines from such of these points as would be visible, looking on one side of the roller, viz., *a* and *b*, so as to cross the horizontal lines on the elevation, we get at once the elevation of the pattern as it would appear in projection when folded round the roller. This would really be a process of envelopment, for we have first drawn the pattern on a flat surface and then enveloped the roller in it. The process of development is just the converse; for it consists in developing or unfolding a surface already on the body, and then spreading it out flat. Suppose, for instance, that we had the elevation of a roller, such as Fig. 28, and we desired to develop the pattern which is represented in projection on its surface. We draw any required number of horizontal lines, at *a*, *b*, *c*, *d*, *e*, through the marked points of the pattern, and trace perpendicular lines from the same points till they meet the circumference of the circular plan in the points *f*, *g*, *h*, *k*, *l*. We then draw a straight line of the length of half the circumference of the circle, and make it the base of an oblong of the same height as the roller. Dividing the base by the points $f_3 g_3 h_3$, into parts of the same lengths respectively as the parts of the half circumference separated by *f g h* in the plan, and dividing the height, *a e*, by the points b_1 c_1 d_1, into parts corresponding with the divisions of the roller in height; and through all these points, drawing parallels and perpendiculars to the base; we get the positions of the different points f_1 g_1 h_1, &c., in the elevation, as they should be in the development, and can trace, through these points, the lines of the pattern. Should the pattern be complex, or made up of curved lines, we should have to trace the development of a greater number of points in order to get a correct drawing of it as it would appear when unfolded.

Fig. 26.

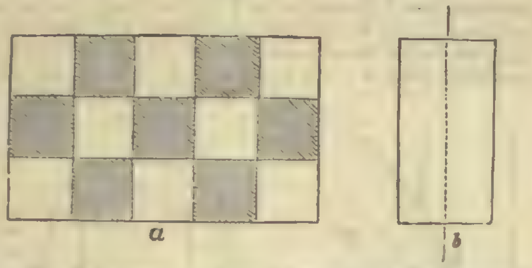

Fig. 27.

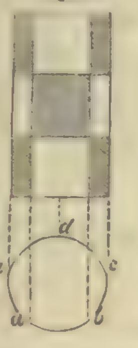

Fig. 28.

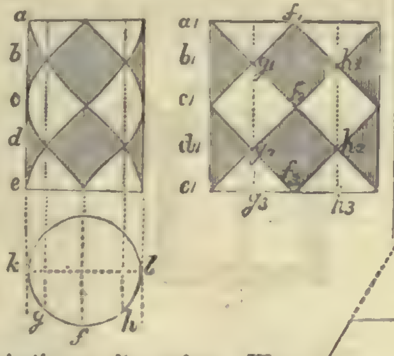
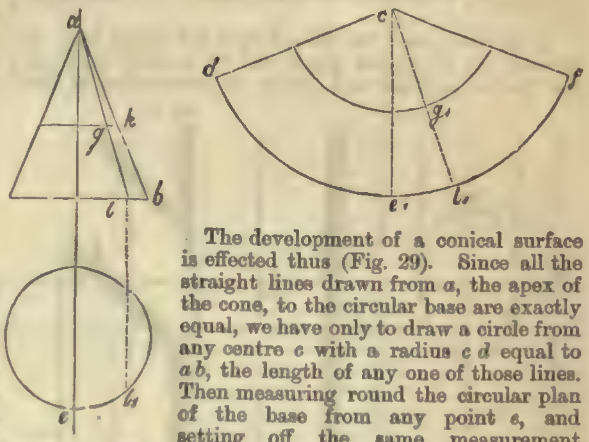


We may here observe that a conical surface is developable as well as that of a cylinder or roller; and the mechanical draughtsman has seldom occasion to deal with the development of any surfaces except these.

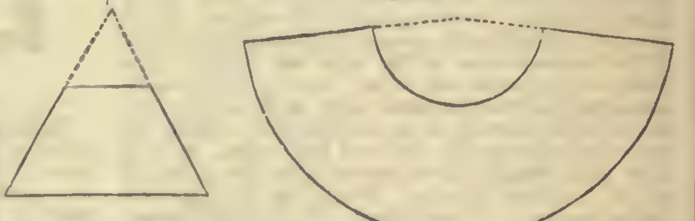
Fig. 29.



The development of a conical surface is effected thus (Fig. 29). Since all the straight lines drawn from *a*, the apex of the cone, to the circular base are exactly equal, we have only to draw a circle from any centre *c* with a radius *c d* equal to *a b*, the length of any one of those lines. Then measuring round the circular plan of the base from any point *e*, and setting off the same measurement from a point *d* to *f* on the circle we have described from the centre *c*, and drawing the straight lines *c d* and *c f*, we get the development of the conical surface. A piece of paper cut to the shape of the circular sector *c d f* would exactly fold round the cone, the edges *c d* and *c f* meeting. To develop any pattern, we should proceed, as in the case of the cylindrical surface, to find the development of a number of points. We shall show the method of proceeding with one point marked *g* in the elevation. Through the point *g* draw a parallel to the base *g k*, and a line *a g* from the apex meeting the base in *l*. Project *l* down to l_1 on the plan, and measuring round the circumference from *e* to l_1, set off the same measurement from e_1 to l_1 on the development, and draw the line $c\, l_1$, which will be the development of the line *a l*. Then from the centre *c* with a radius *a k*, draw a portion of the circle cutting $c\, l_1$ in g_1, and g_1 will be the development of the point *g*, for it is in the developed line $c\, l_1$, and at the proper distance from the apex. A similar process may be adopted with respect to any other points, and thus a pattern of any kind might be developed.

To develop the frustrum of a cone—that is, a cone with a portion of it towards the apex cut off, as in Fig. 30—we imagine the cone completed, as indicated by the dotted lines in the elevation, and have only to develop the complete cone and cut off the wanting part, leaving the development of the actual surface of the frustrum.

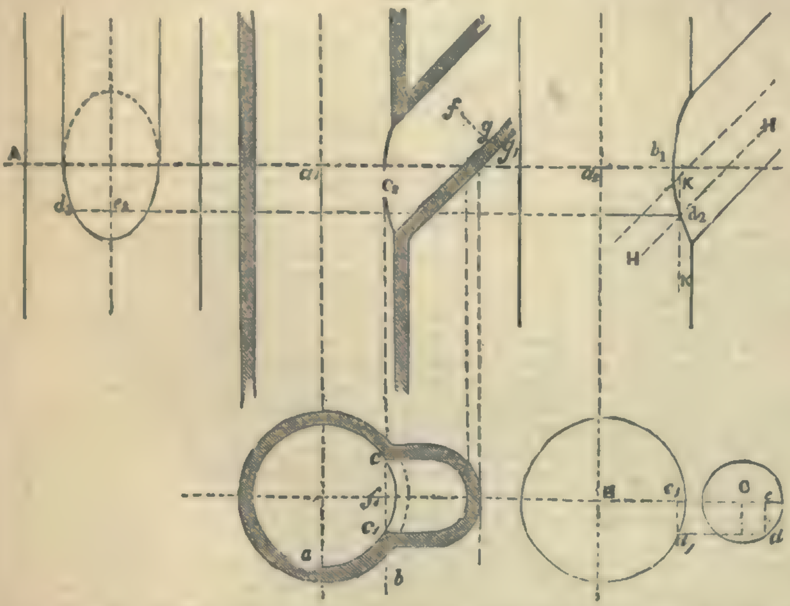
Fig. 30.



INTERSECTIONS.—In consequence of the facility with which materials can be shaped into cones, cylinders, or any forms which have circular sections, and for other reasons connected with strength and fitness, these forms are generally used in practical mechanics. It is therefore most important for the draughtsman to be expert in the projections and developments of such forms. Among the numerous problems in drawing them, there is an interesting, and often useful, class depending on the various intersections of one curved surface with another. We shall give one example of this to illustrate the method that may be very generally applied in most of them. Let us suppose that a pipe of a certain diameter branches out from another of a larger diameter at a certain angle, as indicated on the longitudinal section in Fig. 31; and that we have to draw two elevations and a transverse section of this, so as to show the form of the joint, or intersection of the branch with the main-pipe.

In the first place, we should draw the centre lines or axes of the cylindrical pipes, and then easily mark off the general outlines and points of intersection in the two elevations. The points c, c_1 in the transverse section, would be determined by setting off from f_1 on the centre line, the inside radius of the small pipe, as determined by the line $f\,g$ in the longitudinal section. These points would determine c_2 in the longitudinal section, by tracing the vertical line upwards till it meets the oblique centre line $f\,c_2$ in the longitudinal section. And in a similar manner, by tracing up a line from b on the transverse section, we should find a point immediately below b_1 on the side elevation, where the outsides of the two pipes intersect on the oblique centre line of the branch. There still remains for us to determine the particular curves of the intersection lying between the points so fixed; and this we must do by finding a number of other points in the different projections, which shall be the proper representations of points in the circumferences of the large and smaller pipes where they intersect each other. Let us, for instance, endeavour to determine some point in the curve of intersection represented on the side elevation; and as this must be a point on the outside of both pipes, we shall draw their outside circumferences from the centres B and C, connected by a line. Taking any point d in the circumference of C, and tracing on to d_1 on the circumference of B, and drawing the perpendiculars $d\,e$ and $d_1\,e_1$, we draw on the side elevation H H parallel to the axis of the small pipe at the distance C e from that axis, and K K parallel to the axis of the large pipe, at the distance B e_1. The point d_2, where these lines H H and K K intersect, is the projection of a point in the intersection of the circles on the side elevation. Tracing this across by a horizontal line to the front elevation, cutting its centre line at e_2, and setting off e_2 d_3 equal to e d_1, we get d_3 as the projection of the same point on the front elevation. And thus, by projecting a number of points, we should be enabled to trace through them a correct projection of the curves of intersection in their different aspects.

Fig. 31.



Hitherto we have only treated of the mode of drawing outlines; we may now proceed to discuss the various modes of rendering mechanical drawings distinct and more easily intelligible. These may be said to consist chiefly in hatching or section-lining, colouring, shading, and shadowing.

HATCHING.—Hatching is merely drawing parallel lines across the parts of any section, and are supposed to be cut through the solid material. Fig. 32 is the mere outline of the section of a hollow hexagonal prism; the lines convey no particular meaning, and they would apply as well to the end elevation of a prism with another projection from it; but if the section through the solid matter be hatched, as in Fig. 33, as if to indicate the appearance of the fibres of the cut material, it is understood that the drawing represents a section.

Fig. 32.

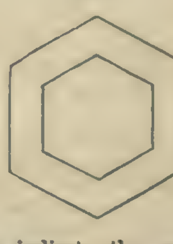


Fig. 33.

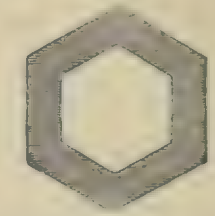
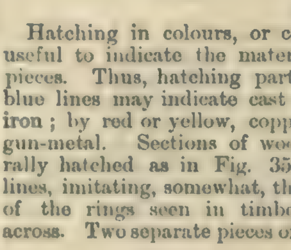


Hatching is also useful in some cases for distinguishing the different pieces of which the body drawn in section consists. This is effected by hatching one of the pieces by oblique lines lying in one direction, and an adjacent piece by lines lying in another direction. Thus, Fig. 34 may represent a section of a vessel with a separate cover fitted to it, and one of the bolts and nuts used for holding the cover in its place. The hatching lines of the vessel and its cover are oblique in opposite directions, and those of the bolt and its nut are vertical and horizontal respectively, so that all the separate pieces are distinguished.

Fig. 34.



Hatching in colours, or coloured lines, is sometimes useful to indicate the material as well as the separate pieces. Thus, hatching parts of a section by black or blue lines may indicate cast or wrought-iron; by red or yellow, copper, brass, or gun-metal. Sections of wood are generally hatched as in Fig. 35, by curved lines, imitating, somewhat, the appearance of the rings seen in timber when cut across. Two separate pieces of timber seen in cross section, side by side, may be hatched by these lines lying in opposite directions (Fig. 36); while timber in longitudinal section, may be hatched by crooked discontinuous lines, lying generally lengthways.

Fig. 35.

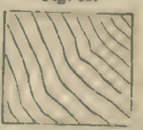


Fig. 36.

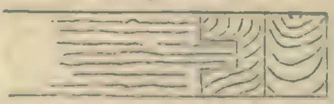


In working-drawings—that is to say, projections showing the parts in their proper dimensions, so that a workman can measure and transfer them to the solid material—colours are usefully employed to distinguish the different materials. Thus, parts tinted dark blue might represent cast-iron; while a pale blue might indicate wrought-iron or steel; yellow would mark brass or gun-metal; brownish-yellow, wood; brownish-red, copper; and so on. When any special material is to be used, its name is generally written on such part of the drawing as represents it.

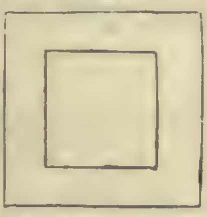
CENTRAL LINES.—In almost all mechanical works, or at least in their details, there is necessarily symmetry, or repetition of equal parts on different sides of some central points. For instance, a cylinder, cone, column, and such-like bodies, are symmetrical round their axes. The teeth of a wheel are symmetrical round its centre; and so with almost all the forms suited to machinery.

It is, therefore, most important in mechanical drawings, to mark the central or axial lines of the different parts. As these lines do not necessarily appear on the material, they are generally distinguished from those that mark outlines of actual form, by the use of a different-coloured ink; for instance, if the lines of the drawing generally be in black, as they usually are, the central lines may be ruled in red or blue. They should always be fine but distinct lines, because they serve as a starting-point for numerous dimensions. As an illustration, we may refer to Fig. 34, which we may suppose to be the section of a round or cylindrical box, the centre or axis of which is marked by the dotted line *a*. One of the bolts for fixing the cover is also shown; and as this bolt is also cylindrical, it has an axis or central line *b*, and the position of the bolt is sufficiently indicated on the section by figuring the distance of its axis from that of the cylinder, as it is marked, 10, on the figure. We have indicated the central lines *a* and *b* by dotted lines, to distinguish them from the outlines and hatchings; on a drawing they would probably be marked in blue or red, not dotted, but plain, fine, and distinct.

SHADOWS AND SHADES.—In order to render mechanical drawings more intelligible than they otherwise would be, recourse is had to shadowing and shading. The projections which constitute mechanical drawings are not representations of the actual appearances of the objects to the eye; they are merely the traces of their outlines formed by parallel lines drawn from all parts of them, to certain imaginary planes or flat surfaces, which are supposed to be transferred to the paper. In like manner, in the shadowing and shading of mechanical drawings, we must not attempt to give the natural appearance of the lights and shades visible on the objects. We must concert some system of illuminating their surfaces, in accordance with our system of projecting their outlines. The object of such light and shade is to make up for the deficiency of one of the dimensions of solid objects, depth, thickness, or distance, when we represent them on paper or any flat surface.

These outlines, however accurate, can never show more than two dimensions—length and breadth; and can convey no idea of parts projecting or receding from any surface represented. Nor can light and shade, applied to these outlines, give the other dimensions, so that they can be measured; but they can be applied with very good effect to indicate which parts are supposed to project or recede from the general surface, and the comparative amount of such superficial variations. If we have, for instance, the outline elevation of a square block of some material (Fig. 37), we cannot judge whether the outline is intended to represent a prominence or a hollow in the general surface of the block; but by a little shadowing we can give the effect of either, as in Fig. 38. In *a* we see that the inner part must project beyond the outer, in order to cast a shadow upon it; while in *b* the outer part of the surface must project beyond the inner for the same reason.

Fig. 37.



Again, shading may be very serviceable in giving a just idea of the form of an object seen in elevation. Thus *a* (Fig. 39) is the bare outline elevation of a roller standing on one end; but it gives no notion of the roundness of the object. *b* is the elevation shaded, and at once conveying the idea of roundness.

Fig. 38.

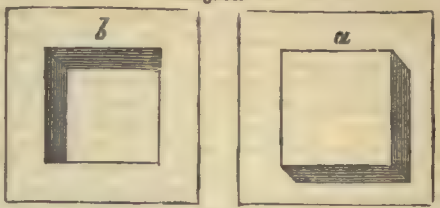


Fig. 39.

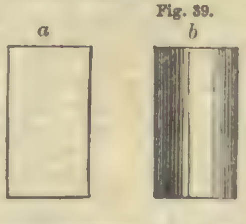

Fig. 40.

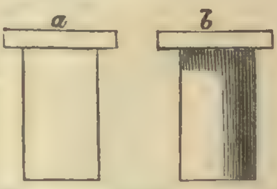
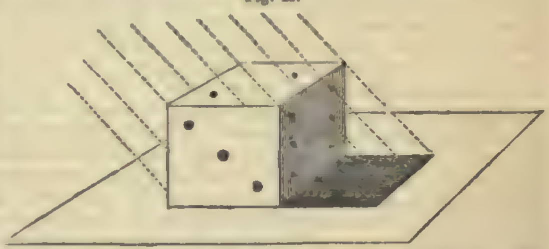


When the lights, shades, and shadows are all introduced in their proper places, as in Fig. 40, the notion of solid form is rendered very distinct, and a very clear conception of the object represented is conveyed to the mind.

The mode in which shadows are drawn is very similar to the system of projecting the outlines themselves. If we suppose a body, such as a die, to stand on a table, and numerous parallel rays of light, indicated by the dotted lines, to strike on it at an angle, some of them would be intercepted by the die, and thus all the surface of the table and the die would be illuminated, with the exception of the portions from which the light is kept by the interposition of the solid body. The dark surface thus left on the table, is a shadow of the die; and the unilluminated side of the die is a shade on the die. It appears, then, that the shadow is merely a projection of the figure made on a plane, by tracing oblique parallel lines from all the points in the outline of the body, to that plane.

Fig. 41.



But as this projection may, like the projection of the object itself, be effected on more than one plane, and as we are at liberty to suppose the object placed in light coming in any convenient direction, we can select such an obliquity of the rays as may at the same time furnish us with most distinct shadows, and with those most easily drawn. In selecting, then, the angle at which the rays of light shall strike, we can assume any that is not coincident with the planes of projection on which our drawing is made. But as these planes are at right angles, or square to one another, it seems natural to select half a right angle, 45°, or what is generally termed by workmen a *mitre-angle*, as the direction of the rays. Again, as a line drawn at such an angle may extend either from below upwards, or from the right towards the left, or from a distant point towards us, we must select the most suitable of these courses for giving us distinct shadows. As we are generally accustomed to see objects illuminated by light coming from above, it is natural that we should determine on employing rays coming from above downwards. Further, as our drawings are intended to represent the visible surfaces of objects, we must suppose those sides that are exposed to be illuminated; and therefore select rays, coming from behind us, and striking on and past the objects. As to whether these rays shall come in a direction from left towards right, or from right towards left, is a matter of indifference. The only circumstance which can affect our choice in this last respect is, that draughtsmen generally sit with their left side towards the light, and therefore are more likely to select rays coming in the direction to which they are accustomed: that is, from left towards right. Now, in order to see clearly the effect of rays supposed to come in the chosen direction, in illuminating certain surfaces, and in producing shades and shadows, we shall suppose a piece of paper, cut to the form of Fig. 42, consisting of three equal squares, and that portions of the diagonals of these squares are drawn, lying at mitre-angles, or angles of 45°, with the sides of the squares. Now, let us suppose that the paper is folded along the two lines $a\,b$ and $a\,c$, so as to turn up the two squares perpendicular to the third, and to each other, as in Fig. 43, forming three sides of a square box, with the diagonal lines drawn upon them. If the lines of projection upwards, towards the right and towards the front from the extremities of these three diagonal lines respectively, be drawn till they meet, as indicated by the dotted lines, we get a line $d\,e$ lying obliquely to each of three sides, of which line the diagonal lines are correct projections. Now, this line $d\,e$ would represent a portion of one of the rays of light which, as we suppose, illuminate the objects, and all the other rays would be parallel to it. The shades and shadows, therefore, of plans, elevations, and sections, projected on the three planes, will all be determined by lines lying at angles of 45° to the boundaries of those planes. As an example of the mode of correctly delineating shadows according to this law, we may explain the mode of defining the shadows in Fig. 44.

Fig. 42.

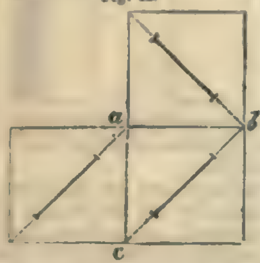


Fig. 43.

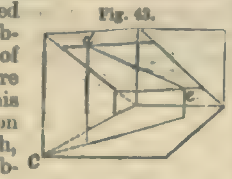
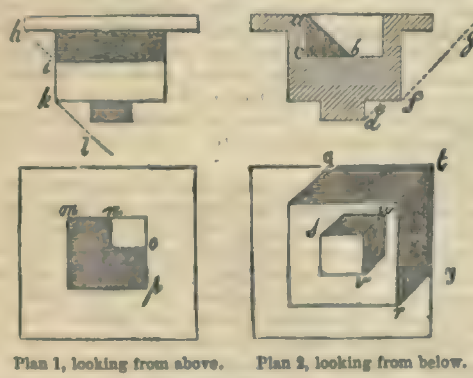


1. The line $a\,b$ drawn at 45° from the edge of the section, gives the breadth $c\,b$ of the bottom, over which the shadow of the side extends; we therefore set off $m\,n$ and $p\,o$ in the Plan 1, each equal to $c\,b$; and drawing lines from n and o parallel to the edges, we have the outline of that shadow.

Fig. 44.



Plan 1, looking from above. Plan 2, looking from below.

2. Drawing $d\,e$ and $f\,g$ at 45° from two lower edges of the section, we get the extent of the shadows observable in Plan 2, the inner shadow $s\,w\,v$ of the projecting part of the bottom being limited, because the line $d\,e$ falls within the edge of the bottom in section, while the shadow $q\,t\,y$ extends as far as the edges of the Plan 2, and would extend further if there were any surface to catch the shadow, because the line $f\,g$ in section extends beyond the edge of the body.

3. Again, in the elevation, $h\,i$ gives the point i as the limit of the shadow of the upper projection, while $k\,l$, extending beyond the projecting part of the bottom, shows that all its surface must be within the shadow.

For drawings of bodies, whose boundaries are plane surfaces, and whose edges are straight lines, the shadowing is very simple; and the proper inclinations and boundaries of the shadows almost suggest themselves, without the necessity for their actual projection. But when the bodies are bounded by curved surfaces, such as cylinders, cones, spheres, and the like, the projection of the shadows is somewhat more difficult. A little consideration, however, will in most of these cases enable the draughtsman to give a sufficiently faithful representation of the desired effect. It must not be supposed that the shadowing of mechanical drawings is intended to give them any merit in an artistic point of view; for, as they are not real perspective representations of objects, but only imaginary projections, so the shadows tinted on them are not the representations of shadows actually seen on the objects themselves, but geometrical projections of shadows, that would occur on certain suppositions as to the direction of illuminating rays. The only purpose of the shadowing is to give a clearer conception of the solid form intended to be shown; and the draughtsman should, therefore, take care to make these shadows geometrically accurate. After having solved a few problems by actual projection, he will find it easy to give tolerably faithful views of shadows by the eye. We will work out two problems in circular shadowing as examples of projection; and we have selected two kinds of shadows most commonly occurring in mechanical drawing for this purpose.

Fig. 45.

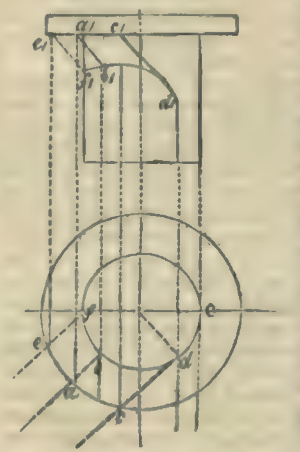


Fig. 46.

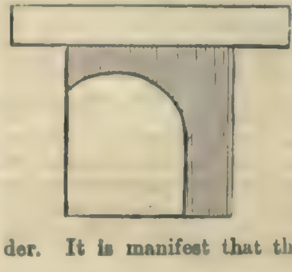
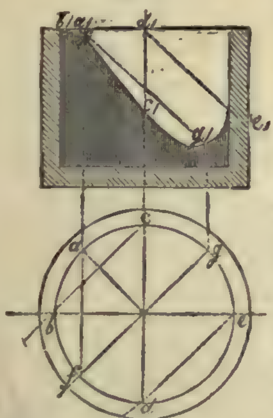


First, in Fig. 45, we have an elevation, and a plan looking from below, of a cylindrical body, with a flange or projecting rim round its upper end. The plan and elevation have a common centre line, corresponding with the axis. It is evident that the shadow of the lower edge of the flange is the boundary of the shadow of the flange on the elevation. If, then, we take any point, such as a on the plan, tracing it up to a_1 on the elevation, and drawing $a\,b$ at 45°, tracing up from b a line in elevation till it meets a line drawn at 45° from a_1, we get b_1 in the elevation as the shadow of a_1. Taking a number of points, such as a, and finding their shadows in a similar manner, we should be able to trace through them a curved line $f_1\,b_1\,d_1$ as the boundary of the shadow of the flange. The extreme point f_1 is found at once by taking f on the plan, drawing $f\,e$, tracing e up to e_1 on the elevation, and drawing $e_1\,f_1$. The line $c\,d$ on the plan is supposed to touch the inner circle in d; therefore, $d\,g$, the remainder of the visible part of that circle, must be all in shadow, as the body itself intercepts the rays. The line traced up from d to the elevation, and meeting the proper shadow line $c_1\,d_1$ in d_1, is therefore the boundary of the illuminated part of the elevation; and if the shadow part be filled in with a black tint, we have the appearance presented in Fig. 46 of the oblique projection or shadow of the flange on the cylinder. It is manifest that this shadow does not convey a proper notion of the cylindrical surfaces intended to be shown. The drawing requires shading to give the full effect; and after another example of simple shadowing, we will endeavour to show how the shading may be effected.

Referring now to Fig. 47, showing a plan and section of a cylinder open at top, we have to inquire as to the form of shadow in the section cast on the inside by the cylindrical side. Taking any points $b\ f\ d$ on the inner circle in plan, and drawing lines from them at 45° till they meet the opposite limb of the circle in the points $c\ g\ e$; tracing up these points by lines to the elevation, and also the points $b\ f\ d$ to $b_1\ f_1\ d_1$, and from the latter drawing lines at 45° to meet the others, we get the points $c_1\ g_1\ e_1$, in the boundary of the shadow. The point a, where a line at 45° touches the circle, being traced up to a_1 in the section, gives the commencement of the shadow; and the outline being filled in by a dark tint, presents the appearance of an interior cylindrical shadow. Like the exterior shadow shown in Fig. 46, shading is required in order to give the notion of a curved surface.

Fig. 47.



We shall, therefore, now proceed to discuss the question of shading; which consists in placing on a drawing, tints of various degrees of lightness or darkness, so as to represent the comparative amounts of reflected light from the different portions of the surface represented. We are not aware that the question of shading mechanical drawings has ever been discussed on geometrical grounds, like that of shadowing; it is, therefore, with considerable diffidence that we venture to offer some considerations which may furnish a clue to the proper variations of light and shade on projections. A skilful draughtsman has little difficulty in bring up a very correct, and even an artistic effect of light and shade on mechanical drawings; but we believe that it is to a practised eye and an expert hand that he owes his success. In shadowing, he trusts to the same elements of success; but as the outline of every shadow can be determined with mathematical accuracy, on the supposition of parallel rays of light proceeding at certain angles to the planes of projection, on the same supposition we think the variations of light and shade can also be determined. It must be confessed that, even if the lights and shades of a projection were determined in quantity, so that we could say such a part of a surface must have twice or thrice the darkness or the light of such another part, we should still labour under the difficulty of carrying out these dimensions of light and shade. We might, however, approach them by applying repeated dark tints to the shaded parts; making the number of equal tints laid on above one another, correspond with the degree of darkness determined on. But even without attempting any mathematically accurate mode of carrying out the theory in practice, we may at least derive useful hints from its investigation.

If we suppose the circle in Fig. 48 to be the plan of a cylinder, of which we wish to represent a shaded elevation, one half A D B would not be shown; the other half has its circumference divided into eight equal parts. We will suppose parallel rays of light R, R_1, R_2, R_3, R_4, R_5, R_6, to come at the proper angle (45°), and to be reflected from the surface of the cylinder in the directions r, r_1, r_2, r_3, r_4, r_5, r_6, respectively. These directions of the reflected rays are of course determined by drawing them so as to make the same angles with the radii C A, C 1, C 2, &c., as the incident rays make with those radii, but on opposite sides of them, according to the well-known optical principle that rays of light are reflected from a surface at the same angle as that with which they strike it. Now, of all those rays, that striking the point 3 is reflected most directly to an eye situated in the line C E, at a great distance from C, $3r_3$ being parallel to C E, and therefore the elevation of the point 3 should be the brightest. Again, the points 2 and 4 would appear equally illuminated, because the reflected rays $2\,r_2$ and $4\,r_4$ lie at equal obliquities to C E; but each of those points would appear less illuminated than the point 3, because of this obliquity. Farther, the points 1 and 5, whence the rays are reflected parallel to A B, mark the places where the illumination of the surface ceases; and were it perfectly smooth and polished, all beyond 1 towards A, and beyond 5 towards 6, would be perfectly dark. The portion 6 to B, receiving no light at all, would be represented in shadow. In the elevation then, if the points in the circumference of the plan be projected, and the surface darkened by lines or tints in accordance with the deficiency of reflected illumination at its different parts, we get a geometrically shaded representation of a cylinder.

Fig. 48.

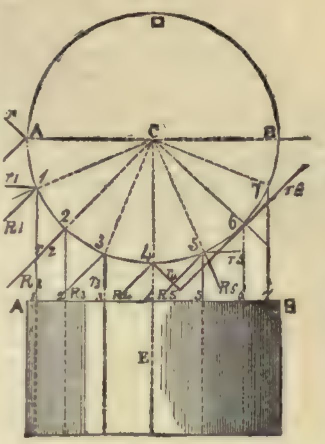


Fig. 49.

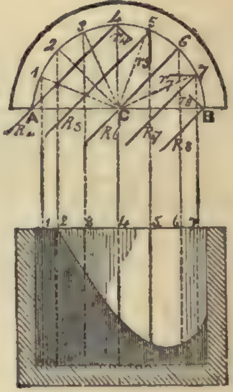


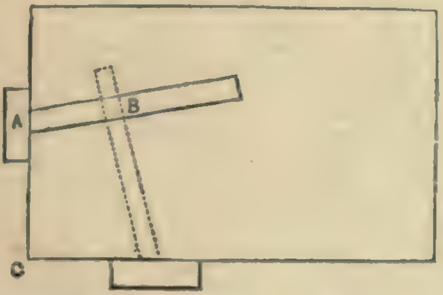
For the interior surface of a cylinder shown in section, the light and shade of the different parts may be found in a similar way, as marked in Fig. 49, where the point 5 giving the direct reflection will be the brightest, the points 4 and 6 having equal intensity of light, but each less than 5, because of the obliquity of the reflected rays; the part A 1 2 3 4 quite dark, because the light is intercepted by the edge A; the point 7, whence the ray is reflected parallel to A B, the last part of the illuminated surface; and 7 B dark, because the rays are reflected backwards. The section shows the shading in accordance with this variation of reflected lights, the lower part of the interior being completely shadowed in the form marked in Fig. 47.

The shading of other curved surfaces might be determined in a similar way; but as cylindrical surfaces are those which most commonly occur in drawings of machinery, we consider it sufficient to have pointed out the principles upon which the shading of them may be determined. A little practice will soon enable a draughtsman to give a rounded effect to drawings of such surfaces; and a little attention paid to this will often render plain and explicit a drawing, which would otherwise be comparatively obscure. The lights, shades, and shadows to complete drawings need not be determined by geometrical projections, which would often involve great labour without adequate results. A draughtsman accustomed to make drawings of machinery, forms, in his own mind, a very accurate conception of the solidity, projections, and hollows of the various parts, and throws in the shades and shadows by eye, in such a manner as to give a tolerable notion of these variations of surface. It is well, however, that the beginner should know the principles on which shading must depend, and he will then be better prepared for that success in their application, which practice of eye and hand can only give.

INSTRUMENTS.—Before concluding this part of our subject, we may say a few words respecting the instruments required by the mechanical draughtsman. The board, on which the paper is fixed, should be of well-seasoned wood, accurately right-angled, or, as it is commonly called, *square* at the angles. As wood is often apt to warp and shrink, according to changes in temperature and moisture, it is often necessary to have the edges of the board adjusted by the carpenter's plane, especially if the wood be new. Where great accuracy of drawing is required, this is a matter which should always be carefully looked to. A sheet of drawing-paper gently wetted by a sponge and clean water, will, if stretched and fastened on the drawing-board whilst moist, afford a surface as level as that of the board, and quite free from creases, when dry.

The drawing square, or ⊤ square, consists of a stock, with a projecting lip, which can slide along the edge of the drawing-board, and a blade, having the edges accurately straight and parallel. The edges of the blade should be at right angles to the face of the stock; but this is not of very great importance, for even if the blade made any other than a right angle with the stock, provided the angle C (Fig. 50) of the drawing-board be a right angle, the lines drawn by the square applied to both edges of the board would be at right angles to one another. Indeed, the blade and stock are often made so that the angle can be varied at pleasure, a screw being fitted in the stock in such a manner as to hold the blade fast at the angle required. This form of instrument is called the bevel ⊤ square, and is useful when there are to be drawn numerous lines parallel and at right angles to one another, but oblique to the edges of the board.

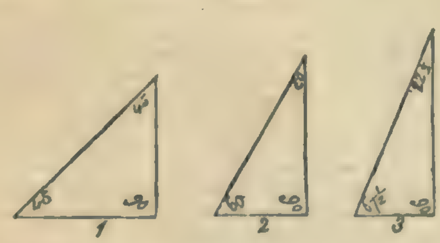
Fig. 50.



Set-squares are triangular pieces of wood having their sides accurately straight, and making particular angles with each other.

The most useful set-squares are the three shown in Fig. 51.

Fig. 51.



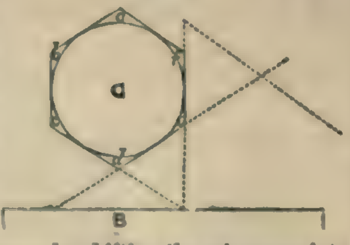
No. 1 is a triangle, having one angle a right angle, or 90°; and the other two each 45°, or half a right angle.

No. 2 has one angle 90°; another 30°, or one-third of a right angle; and the third 60°, or two-thirds of a right angle.

No. 3 has an angle 90°; another 22½°, or one-fourth of a right angle; and the third 67½°, or three-fourths of a right angle.

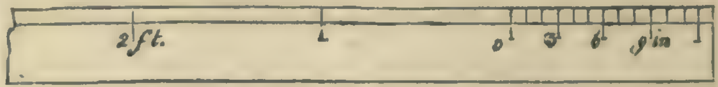
As an example of the use of these set-squares, we will suppose that we have to describe a hexagon round a given circle (Fig. 52). The circle being described round the centre G, the blade B of the ⊤ square being brought into any convenient position, the set-square No. 2 is applied to its edge in the different positions marked by the dotted lines, and the sides *f e*, *e d*, and *d c* of the hexagon drawn, touching the circle; the other sides, *c b*, *b a*, *a f*, being similarly drawn by shifting the set-square into suitable positions, which are not marked in the figure, to avoid confusion.

Fig. 52.



Scales are blades of ivory, boxwood, metal, or cardboard, having straight edges divided into equal parts, which are generally fractions of a foot or inch. In making drawings of machinery it is generally necessary to represent the parts, not of the real sizes to which they are made, but to some known scale, so that all the proportions of the parts are accurately maintained. For instance, had we to make drawings of a steam-engine, we should select some convenient size for the drawings; we might, for example, represent the engine one-eighth of its real size, and should form a scale every inch of which should stand for eight inches of the real work, every foot for eight feet, and every inch and a-half for one foot. This would be called a scale of one-eighth real size, or a scale of an inch and a-half to a foot, because an inch and a-half is the eighth part of a foot. Now, in making the drawing, or measuring from it when made, it would be troublesome and tedious to calculate what should be the size drawn of each dimension of the work; but having first formed a scale, such as Fig. 53, every inch and a half of which represents a foot, one of these feet being divided into twelve inches, we can at once apply it to the drawing, and set off any required dimension in feet and inches.

Fig. 53.



The most convenient scales for mechanical drawings are those of

6 in. to 1 foot, or $\frac{1}{2}$ real size.	1 in. to 1 foot, or $\frac{1}{12}$ real size.
3 „ 1 „ $\frac{1}{4}$ „	$\frac{1}{2}$ „ 1 „ $\frac{1}{24}$ „
2 „ 1 „ $\frac{1}{6}$ „	$\frac{1}{4}$ „ 1 „ $\frac{1}{48}$ „
1½ „ 1 „ $\frac{1}{8}$ „	$\frac{1}{8}$ „ 1 „ $\frac{1}{96}$ „

For architectural drawings, and drawings of large works generally, the following scales will be found convenient, in addition to the above:—

1 in. to 10 ft., or $\frac{1}{120}$ real size.	1 in. to 50 ft., or $\frac{1}{600}$ real size.
1 „ 20 „ $\frac{1}{240}$ „	1 „ 80 „ $\frac{1}{960}$ „
1 „ 40 „ $\frac{1}{480}$ „	1 „ 100 „ $\frac{1}{1200}$ „

For drawings of land-surveys, it is usual to employ chains as units of measurement; and scales are therefore made in terms of them, such as ten chains to one inch, and the like.

In plans of railway or canal works it is often necessary to measure various curves; and as the curves are generally made portions of circles for ease of setting out and execution, circular scales, divided equally round their circumference, are sometimes employed.

Offsets are short scales which act as set-squares as well as scales.

The annexed plate represents some of the most useful instruments required for mechanical drawing.

Fig. 1 is the Protractor, for setting off any desired angle. The instrument is placed on the paper, with the central point C at the point or vertex of the angle, and with its edge A B coinciding with one of the lines which has to contain the angle. If the angle were 40°, for

Mechanical Drawing

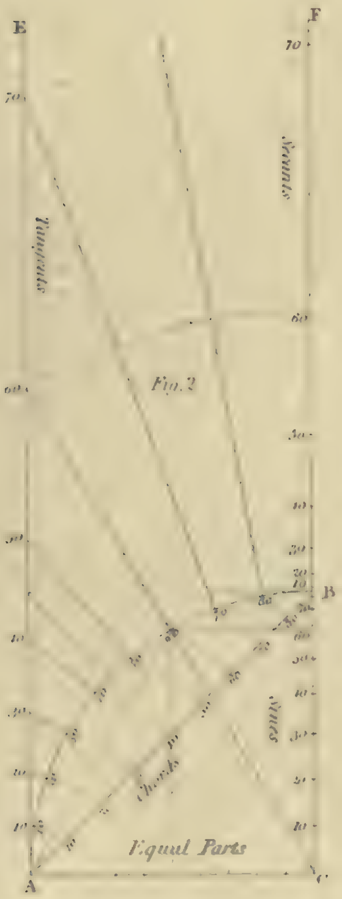

Fig. 2

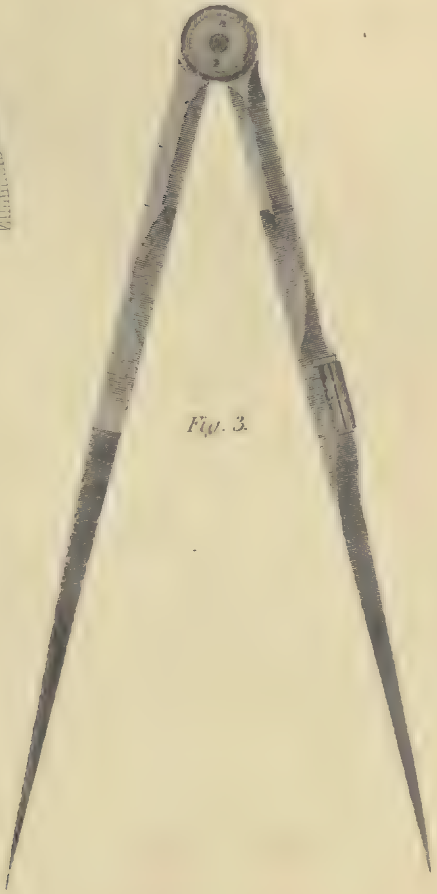

Fig. 3.

Fig. 4.

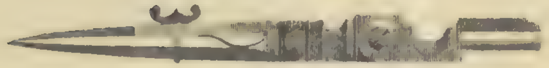

Fig. 5.

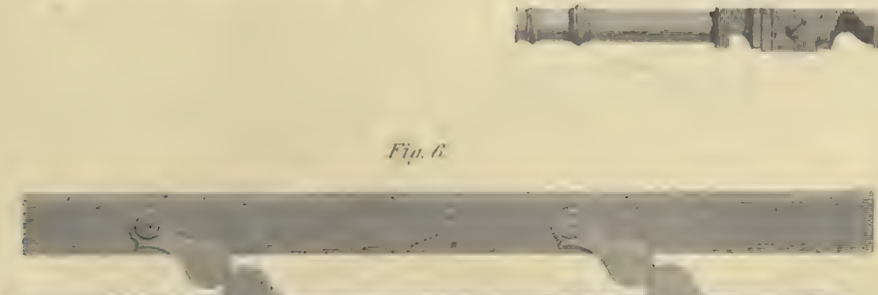
Fig. 6.



instance, the point D, corresponding to the 40° division of the Protractor, would be marked on the paper; and the instrument being removed, a straight line drawn through C and D would lie at 40° to the line C B, or at 140° to the line C A. The Protractor, being semicircular, contains two quadrants, each of 90°, making up 180°, and the arcs, or angles, are numbered, from 0° up to 180°, from each of its extremities.

Fig. 2 represents a Trigonometrical Scale, which is easily made, and is very useful in mapping or spherical projection. A quadrant, or arc of 90°, A B, is divided equally into arcs, each of 10°, or into smaller divisions, if required. The chords of those arcs are struck by circles drawn from the centre A, cutting the line A B. The base A C, or horizontal radius, is equally divided. The vertical radius C B is divided by lines, squared across from the divisions of the quadrant, and thus forms a scale of sines. The vertical line A E being cut by lines, or radii, drawn from C, and produced through the divisions of the quadrant, forms a scale of tangents; and the length of those extended radii, being laid down by describing circles from the centre C, upon the vertical line C F, forms a scale of secants. For drawing the meridians and parallels upon the projections of a sphere, either for geographical or for astronomical problems, these divisions are essential.

Fig. 3 represents the ordinary Compasses, or Dividers; and Fig. 4 and 5 show the Pen and Pencil-holders, which are substituted for one of the legs of the Compasses when circles are to be drawn on paper.

Fig. 6 represents the Parallel Ruler, consisting of two straight rulers, connected together by two equal and equally inclined radii. The edges of the two rulers being parallel to one another in any one position, maintain their parallelism when they are opened or closed; and thus, the one edge being laid to any line already drawn, another line can be drawn along the other edge, parallel to the first line at any required distance from it.

For remarks as to the use of those instruments, the reader may be referred to the Chapter on Practical Geometry. It may be farther observed here, that in laying down dimensions on paper, whether full size or to any scale, they should be always pointed off directly from the rule or scale on the drawing. The Compasses should be used only for dividing circular curves, to which straight scales cannot be applied. When they are used for straight dimensions, errors are introduced which do not occur when the draughtsman restricts himself to the scale. First is the chance of error in setting the points of the Compasses to the divisions of the scale. Secondly, the spring of the Compasses themselves. Thirdly, the uncertainty in the pricking of the paper. And lastly, the inaccuracy in drawing through the prick marks; to say nothing of the tear and wear of the scales, arising from the application of the sharp points to them, and the unseemly appearance of the drawing when full of prick marks.

SCALE OF DRAWING.—For the draughtsman employed in devising, on paper, work to be executed in solid materials, we strongly recommend that he should, as much as possible, endeavour to draw all details of their full size. Scale-drawings, especially of large works, are absolutely required to show the combination of all the parts in one machine or engine, full-sized drawings of which would be of most inconvenient size. But, in addition to the scale-drawings of the whole, it is the practice of the best engineers to execute full-sized drawings of details. One great advantage of this is, that the draughtsman sees better on the full size what should be the best forms, dimensions, and combinations of the parts in respect of strength, efficiency, and economy of material and labour; and another advantage consists in the facility with which the workman can read off the drawings, or transfer to the solid materials he labours on, the dimensions and forms marked out: he has only to apply his rule to the drawing and to his work, and make them agree. Farther, as it is customary for workmen to use rules divided into inches, and these again into halves, quarters, eighths, and sixteenths, the draughtsman should make his dimensions such as can be measured in those fractions. We have known numerous workmen who perfectly comprehended the eighth or sixteenth part of an inch, but had not the remotest conception of what was meant by the tenth or the twentieth part. Were the dimensions even figured by tenths, the workman would read it in quarters, eighths, or sixteenths, and would most probably err in reducing it from the one denomination to the other. It is, therefore, preferable, in the first instance, to draw or figure the dimensions in a denomination which the workman will employ; and thus a fruitful source of error will be avoided.

CHAPTER III.

STRENGTH OF MATERIALS.

Contents.—MATERIALS AND STRAINS—TENSION AND INTERNAL PRESSURE—COMPRESSION—TRANSVERSE STRAIN—DEFLECTION AND DISPOSAL OF MATERIALS—RULES FOR CALCULATING—TORSION—SHAFTS—CLIPPING OR SHEARING STRAIN.

MATERIALS AND STRAINS.—The materials with which the practical mechanic has principally to deal are metals, such as steel, wrought-iron, cast-iron, copper, brass and gun-metal, lead, tin, and zinc; timber, such as oak, teak, ash, beech, and other hard woods; fir, pine, cedar, and other soft woods; stones, bricks, mortars, and cements; cordage, straps and bands, and the like. The strains to which these materials may be subjected, may be classed under five heads:—

1. Tension, or a strain applied in the direction of the fibres of the body, so as to pull it asunder, as in the case of ropes, bands, tie-rods, and chains. The strength of a body to resist a strain of this kind, is called its cohesion, or the force with which its parts are held or knitted together.

2. Compression, or a strain applied also in the direction of the fibres so as to crush a body, as in the case of a column. Compressive strain is exactly opposite to tensive strain; and the power of a body to resist it seems to depend chiefly on its elasticity.

3. Transverse strain, or force applied perpendicularly to the fibres so as to break the body across, as in a beam loaded in the middle. In resisting a strain of this kind, the cohesion and elasticity of a body are both exercised.

4. Torsion or twisting, or a force applied at the end of a lever so as to turn one end of the body round its axis, while the other end is fixed, as in a shaft or axle.

5. Clipping or shearing, or a power applied to divide or cut a body across its fibres.

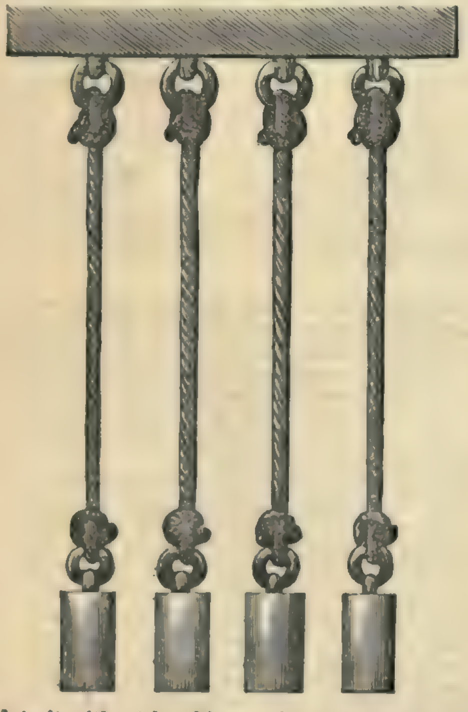
All the possible strains to which materials, whatever be their forms and arrangements, can be subjected, are of one or more of these classes. We therefore propose to consider them separately, and endeavour to apply the results of experiment and observation to their discussion, endeavouring to avoid, as far as possible, mere abstract mathematical investigations. We cannot, however, altogether dispense with mathematical aid, but shall endeavour to place the reasoning as much as possible on such a footing, that a student having a moderate acquaintance with the general principles of mathematics, may have little difficulty in following it. We must premise that the whole subject is as yet in an unsettled condition in some respects, for it has happened that very few writers have discussed it as a whole. Of those who have discussed portions of it, some may be said to have done so, with too little regard to its practical application; while others have erred in the opposite direction, giving mere empirical rules without theoretical reasons for their establishment. We shall endeavour to steer a middle course between these extremes, trying to show, as clearly as possible, the reasons for conclusions that have been arrived at, and quoting from the best authorities the results of experiments in a form that may render them conveniently applicable in practice.

1. TENSION.—We may consider that every body subjected to tension consists of numerous fibres laid side by side, and extending over the whole length of the body. Even if the body be not of a fibrous constitution, we may conceive its particles to be arranged in longitudinal rows, each particle being held to the next by some force which we call attraction of cohesion. A row of particles so held together, exactly corresponds with our notion of a fibre; and we are therefore warranted in treating all bodies as fibrous while we discuss their strength to resist tension.

Let us suppose that we have a rope capable of sustaining a hundredweight, and no more, without breaking. We should call the absolute cohesive strength of that rope one hundredweight, or 112 lbs. The length of the rope by which the weight is suspended has evidently no influence on its strength; for if any one part of its length be capable of sustaining the strain, and if it be uniform, every other part will be equally capable of sustaining it. It is true that were it hanging vertically, additions to its length would increase the weight, stretching its upper portion, because each portion of added length becomes an added weight. But considering the weight of the rope itself as part of the stretching force, we say that the given rope has an absolute cohesive strength of 112 lbs., whatever be its length.

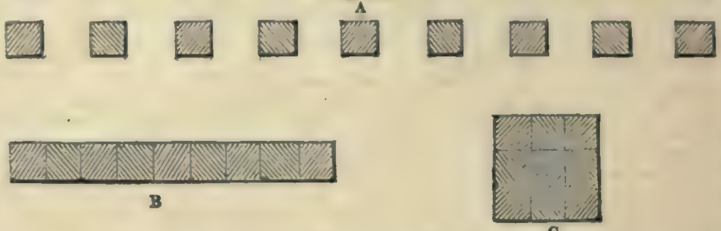
Now, if any number of such ropes were suspended in a row (Fig. 54), each might have a hundredweight attached to it without breaking, and the absolute cohesive strength of all together would be expressed by the number of hundredweights sustained; that is, by the number of ropes, reckoning each as having the strength of a hundredweight. Whether we deal with ropes, however, of hemp, or rods of wood or of iron, or of any other material, if we know the strength of one such rod, and the number of them sustaining equal weights, we know the total weight sustained by them all; that is to say, their combined strength. Let us assume, instead of ropes, that we experiment with square bars of iron measuring an inch each way, or having a square inch of sectional area. Whether a number of these bars, such as nine of them, be suspended in a row, of which A (Fig. 55) is the plan, with intervals between them; or in a close row with no intervals as in B, and forming a bar nine inches wide by one thick; or in a square, C, measuring three inches each way; there can be no difference in their combined strength, or in the total weight carried by the whole number of bars, however they may be arranged.

Fig. 54.



If, then, we know the weight sustained by a bar or rod of any material having a sectional area of one square inch, we can estimate the weight that can be sustained by any other bar of the same material, by calculating the number of square inches in its sectional area, and allowing the known strength for each square inch. For example: let us suppose that we find by experiment the average strength of a bar of wrought-iron, 1 square inch in section, to be 30 tons, or 67,200 lbs.; let us ascertain the strength of a bar 10 inches wide and 10 inches thick. Since the sectional area is 10 in. × 10 in., or 100 square inches, the strength is 30 tons × 100 sq. in., or 3,000 tons; or 67,200 lbs. × 100 sq. in., viz., 6,720,000 lbs. The strength of a round bar 1 inch in diameter would be estimated in the same way; for as the area of a circle 1 inch in diameter is 0·7854 sq. in., the strength of the round bar 1 inch in diameter would be 30 tons × 0·7854 sq. in., about 23½ tons; or 67,200 lbs. × 0·7854 sq. in., about 52,780 lbs.

Fig. 55.



Farther, as the areas of circles are in proportion to the squares of their respective diameters, the strength of a round bar of iron of any diameter is 23½ tons, or 52,780 lbs., multiplied by the square of the diameter in inches. Thus, a round bar of 10 inches in diameter has a strength of 23½ tons × 100 = 2,350 tons; for the area of a circle 10 inches in diameter is 100 times that of a circle 1 inch in diameter. All this mode of calculation manifestly proceeds on the simple principle, that every equal fibre or row of particles is supposed to act equally in resisting strain; and that as the number of such fibres or rows is proportional to the area of section, the strength of different bars or rods is therefore proportional to their areas of section.

So far the theoretical principle of cohesive strength appears very simple, and easily applicable in practice. It now becomes our business to inquire how far practical results agree with the theoretical principle. Many engineers have devoted great care to experiments on this subject; and although the results present considerable differences, yet all of them seem to bear out the principle we have laid down. As an example of the near approach which practical results make to the theoretical law, we may select some experiments made on round copper bars, as shown in the following table. The first column contains the diameters of the bars in inches; the second the sectional areas in square inches, or decimal parts of a square inch; the third contains the weights in tons, and decimal parts of tons, which were required to break the bars; and the fourth column contains the weights in tons per square inch of sectional area required to break or tear the bars asunder. The numbers in the last column are calculated by a simple proportion; thus, taking the bar 1 inch in diameter, the area of which is 0·7854 square inches, and the breaking-weight 17 tons, we say—

Sq. in.		Sq. in.		Tons.		Tons.
0·7854	:	1	: :	17	:	21·645;

the weight that would be required to break the bar were it one inch square.

TABLE I.—*Experiments on Cohesive Strength of Cylindrical Copper Bars.*

Diameter of bar: inches.	Area: sq. inches.	Breaking-weight: tons.	Breaking-weight reduced to 1 sq. inch: tons.
1⅛	0·9940	22	22·133
1	0 7854	17	21·645
⅞	0·6013	12·8	21·287
¾	0·4417	9	20·376
			Mean 21·36 tons.

It will be seen that, although the sectional areas of the bars differ very considerably, the breaking-weights, reduced to one square inch of area, do not vary greatly from their mean value.

Table II. contains the results of experiments on best hempen bower cables used in the navy. The first column contains the circumferences, or girths, of the cables in inches (the dimensions of cables being generally stated in terms of their girths); the second column contains their sectional areas in square inches; the third expresses the number of threads in each; the fourth column marks the actual breaking-weights; the fifth the breaking-weights per square inch of sectional area; and the sixth the breaking-weights per thread.

TABLE II.—*Experiments on the Cohesive Strengths of Best Hempen Bower Cables.*

Circ.: inchs.	Sect. area: sq. inchs.	No. of threads.	Breaking-weight: tons.	Break. wght. per sq. inch: tons.	Break. wght per thread: lbs.
23	42	2736	114	2·714	93⅓
18	26	1656	63	2 423	85¼
14½	17	1080	40	2·353	83
				Mean 2·5 nearly	87

The strengths in these cases also are very nearly as the sectional areas or numbers of threads. We shall finally quote the results of some experiments on the strength of wrought-iron bars of various qualities, as marked in Table III., where the breaking-weights per square inch are given as calculated from the experiments. The first column contains the description of bar, the second contains the dimensions, the third gives the amounts in inches which each foot of the bars stretched, and the fourth gives the breaking-weights per square inch of sectional area.

TABLE III.—*Experiments on the Cohesive Strengths and Extension of Wrought Iron Bars.*

By numerous experiments, such as those quoted, data have been determined from which we can readily calculate the dimensions of a bar of any material required to carry a given weight, or conversely, the weight which a given bar of material will carry. These data have been determined by the actual breakage of the bars tested; but in practice, where durability and adequate strength to meet contingencies of strain are required, it is necessary to give the materials we employ, considerably greater dimensions than such as would merely preserve them from breakage, or to load them with considerably less weights than those which would tear them asunder. Farther, it is found in practice, that materials subjected to considerable strains for long periods of time gradually lose their tenacity; and this degradation of quality must be provided against when permanence and stability are required.

In the case of metal bars, it is advisable not to load them beyond one-third of their actual breaking strain; or, in other words, to provide them of three times the strength sufficient to resist tearing asunder. In the case of ropes, timber, and such other materials as are of less uniform consistency than metals generally are, or are more liable to degradation, it is advisable to provide at least four times the breaking strength.

Table IV. contains data for the strength of a number of materials on which experiments have been made; and the numbers given may be safely used in calculation, as they are reduced to one-third or one-fourth of the breaking strength.

TABLE IV.—*Data for Calculating the Cohesive Strength of Bars of different Materials, determined from the Averages of numerous experiments. The numbers are given roundly, as no material error will arise in practice from their use.*

The strengths are given in square inches, and also in circular inches for convenience of calculation; and the following are the rules for calculating the strength of a given bar, or the dimensions required to bear a given load.

I. Given, the dimensions of a bar of any material to find its cohesive strength, or the constant load it will safely bear in the direction of its length.

1. When the bar is square.

Rule.—Multiply the number of inches in the side by itself: that is, square the number, and then multiply by the number opposite the given material in column 2 of Table IV.

Example 1.—Required the cohesive strength of a square bar of English wrought-iron of which each side measures 2¼ inches.

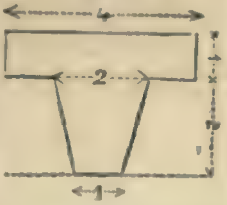
2¼ expressed decimally .	2·25
Multiplied by itself .	2·25
	1125
	450
	450
	5·0625
Multiply by tons in table .	8·3
	151875
	405000
	42·01875

Neglecting the decimal fraction, we find that we may safely load the bar with a weight of 42 tons.

2. When the bar is oblong, or of some other form having straight sides.

Rule.—Multiply the width by the thickness, or generally, find the sectional area in square inches, and multiply by the number in column 2 of the table.

Fig. 56.



Example 2.—Required the cohesive strength of a bar of wrought copper of the form and dimensions given in Fig. 56.

The upper part of the figure is an oblong or rectangle, of which the width is 4 inches and the thickness is 1 inch; its area is therefore 4 × 1, or 4 square inches.

The lower part of the figure is a trapezoid, of which the thickness at one edge is 2 inches, and at the other 1; the mean thickness is therefore 1½ inch, and the width being 2 inches, its area is 1½ × 2, or 3 square inches. The total area of the section is therefore 7 square inches: and 7 multiplied by 5 tons, the strength of wrought copper in column 2 of table, gives the strength of the bar 35 tons.

3. When the bar is cylindrical.

Rule.—Multiply the diameter in inches by itself, and by the number in column 3.

Example 3.—Required the cohesive strength of a fir pole 4 inches in diameter. 4 × 4 × 1·26 give 20·16, say 20 tons.

4. When the bar is of elliptical section.

Rule.—Multiply the greater diameter by the less, and by the number in column 3.

Example 4.—Required the cohesive strength of an elliptical lead bar, of which the greater diameter is 2 inches and the less 1½ inch: 2 × 1½ × 500 give 1500 lbs.

5. When the bar is cylindrical and hollow like a pipe.

Rule.—Multiply the outer diameter by itself, and also the inner by itself; subtract the one product from the other, and multiply the remainder by the number in column 3.

Example 5.—Required the cohesive strength of a brass tube 2 inches diameter outside, and 1½ diameter inside.

2 × 2 = 4
1½ × 1½ = 2¼

1¾ × 2·12 = 3·7 tons.

6. As a general rule, whatever be the form of section, find the area either in square inches or circular inches, and use as a multiplier the number in column 2 in the one case, and that in column 3 in the other. Or, find the strengths due to the several parts of the section, and add them together for the total strength.

Example 5.—Required the cohesive strength of a cast-iron bar of the form and dimensions given in Fig. 57.

Taking first the hollow semicircular part,

Outer dia. 5 in. × 5 = 25
Inner dia. 3 in. × 3 = 9

Take ½ for semicir.) 16

8 circ. in. × 2·12 tns. (col. 3) = 16·96 tns.

Two upright sides each
2 in. by 1 in. have an
area 2 × 1 × 2 . = 4 sq. ins.
Two lower flanges each
2½ in. by 1 in. have an
area 2 × 2½ × 1 . = 5

Square inches 9 × 2·7 tons (col. 2) = 24·3 tns.

Total cohesive strength 41·26 tns.
say 41 tons.

II. The converse operations are for calculating the dimensions of a bar required to carry a given load.

7. When the bar is square or oblong.

Rule.—Multiply the number in column 4, by the given number of tons, and the product gives the number of square inches of sectional area.

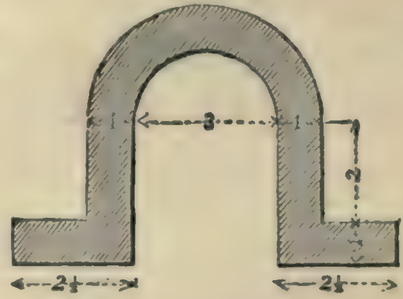
Example 7.—Required the area of a bar of wrought-iron capable of sustaining 10 tons.

Number from col. 4 . . . 0·120
Multiply by 10

1·2 square inch.

This sectional area may be attained by making the bar square about $1\frac{1}{10}$ inch of a side; or making it oblong, such as 2 inches by ⅝ inch thick, or any dimensions such that their product is at least 1·2 square inch.

Fig. 57.



8. When the bar is cylindrical.

Rule.—Multiply the number in col. 5 by the weight in tons, and take the square root of the product; it will be the diameter in inches.

Example 8.—Required the diameter of a cylindrical bar of wrought copper to carry 35 tons.

Number from col. 5 . . . 0·255
Multiply by 35

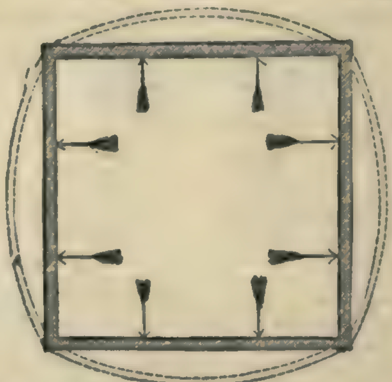
9· nearly.

The square root of 9 is 3 inches, the diameter of the bar.

9. For bars having sections of various forms and proportions, the calculations must be trials to a certain extent. The number of square inches required is found as in Example 7, and these may be disposed in any suitable form that may be required.

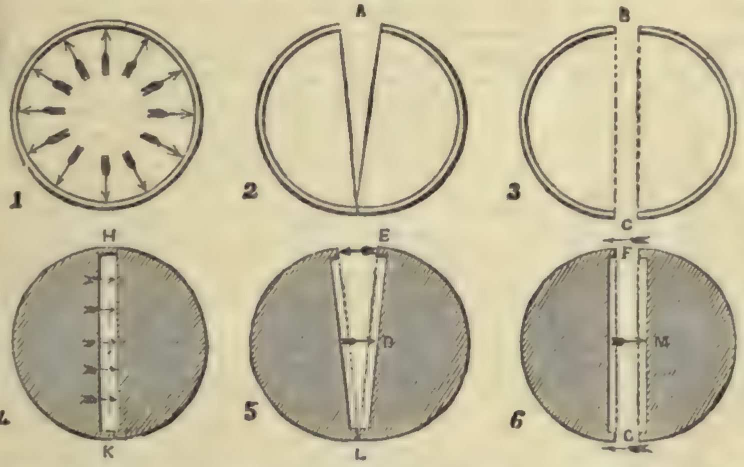
Before we leave the subject of tensive strength, we will discuss a case which frequently occurs in practice, and where the cohesive force of materials is employed in a vessel to resist a bursting or exploding strain arising from the pressure of a fluid within it. Were a boiler, pipe, or other vessel, intended to contain a fluid exerting considerable pressure, made of any form except circular in section, the internal pressure would change the form of section. Thus, suppose the section were of a square form, as in Fig. 58, the internal pressure acting equally on every part of the casing, as marked by the arrows, would bulge the flat sides, as indicated by the dotted lines; and, finally, were the material sufficiently pliable, would extend it into a circular form. After having attained a circular section, no farther change of form would be effected, and the pressure of the internal fluid

Fig. 58.



might be increased until it attained sufficient magnitude to burst or rend asunder the material. Vessels destined to sustain considerable internal pressure, are generally made circular in section; and a few simple considerations will enable us to ascertain the amount of strain, which the pressure in such vessels throws upon the material of the casing, and hence to compute the strength of material that should be employed in their construction in order that they may sustain a given pressure.

Fig. 59.



Let us suppose that a steam-boiler is of cylindrical form as in section 1 (Fig. 59), having pressure exerted on it equally, on every part of its surface, as indicated by the arrows. One effect of this pressure, if it exceeded the strength of the material containing it, would be to rend it asunder at some point A, section 2; or it might rend it at two opposite points, B and C, section 3, so as to force one-half of the casing away from the other. Now, if the material were of perfectly uniform consistency and strength throughout, there is no reason why one point A, or any two points B and C, should be selected for breakage more than any other points; but as, in practice, materials are never perfectly uniform, so, in theory, we may suppose the casing to be somewhat weaker at A, or at B and C, than elsewhere, and trace the influence of the pressure to effect a breakage at such points. Were we to suppose the whole of the vessel to be filled up with solid matter, except a thin film of fluid in the middle, as shown in section 4, exerting a pressure on every point of the flat side of the solid portion exposed to it, we should involve no change in the conditions, for the two points of the circumference, H and K, terminating the film of fluid, would have to resist exactly the same bursting-strain as if the rest of the casing were filled with fluid instead of solid matter. Farther, as this section would apply at any part of the length of the cylinder, we may take a belt or portion of its length, one inch in breadth, and trace the effect on it—an effect which would be repeated equally on every such belt one inch wide throughout the whole length of the cylinder, if the material were homogeneous throughout. Knowing the pressure which the internal fluid exerts on every square inch of the casing, we see, by section 4, that the bursting pressure on a belt of casing one inch wide, is to be measured by the pressure on a surface represented by the line H K—that is, on a surface having for length the diameter, and one inch in width. If this pressure burst the casing at one point E, section 5, so as to cause one-half to turn round the opposite point L as a fulcrum or centre; then, by the well-known principle of the lever, that a uniform pressure, acting at every point of the arm of a lever, has the same effect to turn it round its fulcrum, as if it were all collected into one force acting at the middle point of the arm, we see that the bursting pressure is equivalent to a force acting at D (as marked by the arrow), while the cohesive force of the casing acts at E, double the distance from the fulcrum L. Hence we conclude that the bursting force, as resisted at one point of the circumference, is half the pressure on the diameter, or the pressure on half the diameter, or on the radius. Again, if the vessel open at two points F and G, section 6, we see that the whole bursting force, marked by the central arrow, being resisted by two equal forces at F and G, each of those forces need be only half the bursting force; so that, in this case, we find that the effect to open the circumference is equal to half the pressure on the diameter as before.

To apply these considerations in practice, let us suppose that a boiler of English wrought-iron, 6 feet in diameter, has to sustain an internal pressure of 100 lbs. per square inch, and ascertain the necessary thickness of the plate to resist this force. Taking a belt of it 1 inch wide,

Half the diameter, 3 feet or	36 ins.
With a width of	1 in.
	—
Has a surface of	36 sq. ins.
Multiplying by pressure per sq. in. .	100 lbs.
	——
The pressure on half the diameter is .	3600 lbs.

which is the bursting strain on any belt of the circumference 1 inch wide.

By Table IV., English wrought-iron having 1 sq. in. area of section, sustains 18,600 lbs.; and by a simple proportion, 18,600 lbs. : 3,600 lbs. : : 1 sq. in : 0·2 sq. in. nearly. We find therefore, that the sectional area of the belt of circumference must be 0·2 sq. in.; or that, as it is 1 inch wide, its thickness must be 0·2 in., or $\frac{2}{10}$ or $\frac{1}{5}$ of an inch. In practice, boilers are made of numerous plates riveted together; and as the material is cut away by the rivet-holes, it is weaker at these places than elsewhere. It would, therefore, be advisable to make the strength of the plate at least double that calculated, which would give a thickness of about $\frac{2}{5}$ of an inch.

In the case of hydraulic presses which are made of cast-iron, and have to sustain enormous pressures, it is necessary to make the material of great thickness. There is, however, a limit to the pressure which such cylinders can sustain; for it is found that after a certain thickness of iron has been attained, the actual substance of the iron becomes compressed, so that the inner surface is considerably extended, while the outer surface sustains scarcely any bursting force. Additional thickness of metal does not therefore contribute proportional increase of strength. Indeed, the practical difficulty of casting thick masses of iron sound and solid in texture, renders it almost impossible to construct hydraulic presses of any very great force. It is doubtful whether, in any case, it is advisable to exceed a thickness of 6 or 7 inches when cast-iron is the material employed. The same remarks apply to a certain extent in the case of ordnance: but in making large guns or mortars, a considerable advantage results from the process of manufacture. The gun is cast solid, and afterwards the heart is bored out. Most of the unsound and spongy portions of the metal are thus removed, and the shell left is much sounder than it would be, were it cast hollow, as hydraulic presses generally are.

Vessels for containing fluids exerting pressure, are likewise subject to a bursting strain in the direction of their length, which is resisted by the cohesion of the casing. Taking the case of the boiler 6 feet in diam., and 0·2 in. thick, we may easily calculate what pressure it would bear before bursting in the direction of its length. The whole boiler may be taken as a hollow or tubular bar of wrought-iron, capable of sustaining a certain weight hung to it, equivalent to the pressure on one of its circular ends, tending to force or blow it to a distance from the other end.

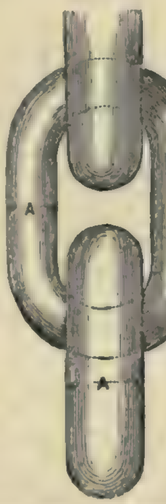
Outer diameter . . . 72·4 ins. × 72·4 =	5242 nearly
Inner diameter . . . 72·0 ins. × 72·0 =	5184
Area of ring in circ. ins.	58
Cohesive strength of 1 circ. in. wrought-iron	14600
Total strength of circumference	846800 lbs.

As the area of the end is 4,072 sq. ins., the boiler would bear a pressure of more than 200 lbs. per square inch, before parting lengthwise. Indeed, it will be found that when uniform thin material is employed, a cylindrical vessel subjected to internal fluid-pressure is almost exactly twice as strong lengthwise as it is circumferentially.[*] When the thickness is considerable, this proportion does not hold good.

It is a singular fact, that many metals, when drawn into wire, become stronger in respect of tensive strain. This may probably be owing to the wire-drawing process causing the particles to arrange themselves in continuous fibres. From numerous experiments made on iron wire less than ¼ inch in diameter, it appears that the strength of wire is about one-fourth, or 25 per cent., greater than that of iron bar; so that while the cohesive strength of wrought-iron bars may be taken at 8 tons per square inch of sectional area, that of iron wire may be taken at 10 tons; or taking bar at 6½ tons per circular inch, wire will have a strength of 8 tons per circular inch.

The following are the rules for computing the strengths of hempen ropes and chains. The dimensions of the ropes are stated in terms of girth or circumference, and those of the chains in terms of the diameters of the metal constituting the links. Thus the chain which has a diameter of ¾ inch at A (Fig. 60), is called a ¾-inch chain.

Fig. 60.



We have formed the rules so as to compute the strains at a lower rate than they are generally stated. It may be true that a new chain or rope will bear a much greater strain than that which we have allowed to it; but the chain loses strength by use—not so much from wear as from the particles of iron assuming a crystalline instead of a fibrous texture; and the rope loses strength by wear as well as by the gradual decay of its fibres. It is preferable, therefore, to err rather on the safe side, especially when it is considered that great damage may often result from the breaking of a chain or rope, and, what is still more carefully to be guarded against, serious injury to life and limb.

1. To find the diameter of a chain to carry a given weight.

Rule.—Multiply the weight (tons) to be carried by 30; the product will be the square of the diameter of the chain reckoned in 16ths of an inch.

Example.—Required the diameter of a chain to carry 10 tons. 10 × 30 = 300, which is near 324, the square of 18; therefore the diameter of the chain must be $\frac{18}{16}$ inch, or 1⅛ inch.

2. To find the weight which a chain of given diameter will carry.

Rule.—Divide the square of the diameter (reckoned in 16ths of an inch) by 30; the quotient will be the number of tons carried.

Example.—Required the strength of an inch chain: 1 inch is $\frac{16}{16}$ of an inch, and 16 × 16 = 256; dividing by 30 we have about 8½ tons.

3. To find the circumference of a rope to carry a given weight.

Rule.—Multiply the weight (tons) by 11; the product will be the square of the circumference in inches.

Example.—Required the size of a rope to carry 18 tons: 18 × 11 = 198, which is near 196 the square of 14 inches, the circumference required.

4. To find the weight which a given rope will carry.

Rule.—Divide the square of the circumference in inches by 11; the quotient will be the weight carried in tons.

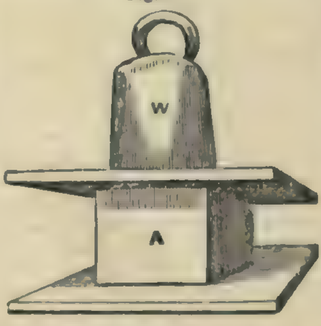
Example.—Required the strength of a 4-inch rope: 4 × 4 = 16, and 16 divided by 11 gives 1½ tons.

2. COMPRESSION.—The strength of materials to resist compressive strains, appears to depend chiefly upon some forces among their particles acting in the opposite direction to cohesive attraction. Indeed, the particles of every solid body appear to be ranged in such positions with respect to one another, and so balanced by cohesive attraction keeping them together on the one side, and by some repulsion resisting their nearer approach on the other, that considerable force is generally required to alter their relative distances. The intensity with which these forces act in any body, appears to be measured by their hardness, or their strength to resist external forces. But while cohesive attraction seems to follow a simple and regular law in any material—the amount of attraction or the strength to resist a tensive strain being proportional to the sectional area, or, in other words, to the number of particles upon which the attraction is exerted—experiments have as yet shown no very regular law as to strength of materials to resist compression. Fortunately, in practice, the other strains to which materials are subjected are generally so much more likely to affect them than mere compressive strain, that when we make the parts of our work sufficiently strong to resist the former, we are tolerably safe in respect of the latter.

Some valuable experiments have been made upon the strengths of building materials—wood and iron—to resist compression; and attempts to deduce laws from these experiments have not been wanting. We are not aware, however, that any satisfactory results have attended those efforts; and we fear that any rules founded on our present scanty information in respect of this subject, would tend rather to mislead than to assist the practical mechanic.

If we suppose that a cubical piece of any material A (Fig. 61) be loaded by a certain weight W, which it is just able to bear without being crushed, we may readily imagine that a number of such cubes—say nine, for instance—would bear nine times the weight which the one bears; and if these cubes were arranged either in a row (Fig. 55) at intervals, or close together, or in a square, they should still all together bear nine times the weight that one of them can bear. When the material we deal with is of uniform consistency, we are therefore warranted in reckoning, that its strength to resist compression, precisely as that to resist tension, is proportional to the area over which the compressive force is spread. Thus, a block of stone 4 feet long and 3 feet broad, should be able to sustain six times the compressing force which a block 2 feet long and 1 foot broad can sustain; because 4 × 3 = 12, the area of the one, is six times 2 × 1 = 2, the area of the other.

Fig. 61.



---

[*] Let r = radius, t = thickness, a = cohesive strength of 1 square inch of casing, p = pressure to burst at circumference, and P = pressure to divide the casing lengthwise.

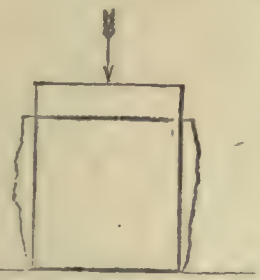
$$pr = at \therefore p = \frac{at}{r}$$

When t is small compared with r, the sectional area of casing is nearly $2\pi rt$; and as πr^2 = area of end,

$$\pi r^2 P = 2\pi rat \therefore P = 2\frac{at}{r} = 2p.$$

But if we endeavour to trace the practical effect of crushing any material, we shall find it difficult to establish the truth of this simple law, without making great allowances for irregularities in the consistency of the material, and in the application of the compressive force. Some materials of a soft consistence, such as clay or lead, on being subjected to vertical compression, merely spread out sideways. Thus, a piece of lead compressed by a heavy weight bulges in width, and thickness, to the form marked by the dotted lines (Fig. 62). Other materials of a fibrous texture, such as wood, become splintered by compression, owing to some of the fibres being driven or wedged into the interstices between others, and thus bursting them asunder. Hard and brittle materials, such as cast-iron, glass, stones, or bricks, are riven and splintered in most irregular and unexpected ways, some portions being actually pulverised in the process, or cracking away and occasionally flying off with considerable force from the rest.

Fig. 62.



These results, however, occur when the compressive strain is carried beyond what the material is capable of sustaining without disintegration; for all practical purposes, where we make the strength more than adequate to meet the load, we may very safely follow the simple law, and reckon the strength to be very nearly as the area of section at the weakest part. This, however, only holds good when we pay no regard to the height of the mass pressed upon. As we increase the height we must increase the strength, for several reasons, which we shall endeavour to illustrate. Suppose we take a cylindrical piece of cast-iron one inch in diameter and six inches high, and placing it upright, load it on the end until it will bear no more. As we place more and more weight upon it, the particles become pressed closer and closer together, and the mass yields or subsides a little in the direction of its length. After being compressed to a certain extent, the particles cannot get into closer contact; but some of them must insinuate or wedge themselves into the interstices between others, and thus the mass will tend to bulge sideways; or, being of a hard unpliable consistency, the sides will become fractured, and burst away. The mass thus weakened will finally all crumble under the pressure. Now let us take a cylindrical piece of the same material, and of the same diameter; but, instead of being six inches high, let it be merely a thin disc one-eighth or one-sixteenth of an inch thick. Here, although the area of section pressed upon be the same as before, yet the height being so much less, the number of particles that can be forced to one side or the other is much less, the number of interstices to receive pressed particles is less, the amount of bulging is diminished, and the whole resistance is enormously greater. As an example of the effect of increased height in diminishing strength to resist vertical pressure, we may quote some experiments made on pieces of cast-iron, all having square bases, a quarter of an inch each way, and various heights; whence it appears that as the height was increased, the strength to resist compression was diminished, so much, that the force to crush the piece $\frac{8}{8}$ inch, or 1 inch high, was little more than two-thirds of that required to crush the piece $\frac{3}{8}$ inch high.

Height. in.	Crushing Force. lbs.
$\frac{3}{8}$	9006
$\frac{4}{8}$	8845
$\frac{6}{8}$	8362
$\frac{7}{8}$	6430
$\frac{8}{8}$	6321

Farther, when the height is considerable, as in the case of columns, a slight want of uniformity in the material, or a slight want of equality in the distribution of the load, will cause one side to be affected more than the other, and thus produce flexure in the case of pliable materials, such as wood or wrought iron, or oblique separation in the case of stone. An extreme load pressing on a column just tottering on the verge of ruin, will certainly find out the weakest place, and there begin the demolition; and having once begun it, will very rapidly complete it. Thus, a knot in a wooden post, or a vein in a marble pillar, may become important elements in determining the mode of their fracture, and the amount of compression required to effect it. It appears, from some experiments made with wooden columns, that when the height is more than eight times the diameter, there is considerable risk of the column bending under an excessive load. With timber of uniform strength, and a load well balanced upon the column, when its height does not exceed this proportion, the wood will generally splinter under a crushing force. In columns of stone or brickwork, destined to sustain a heavy load, the ratio of height to diameter may be increased considerably above that of eight times, without the danger of their breaking by a sloping fracture. In such cases, however, the eye seems instinctively to judge of proportion; for a very tall slender column conveys a notion of instability, and is consequently wanting in that grace which depends, mainly, on the fitness of the object for the work it has to perform.

Cast-iron is found to be capable of supporting a very considerable vertical load without flexure or crushing; and columns of this material are, therefore, with safety made of tall and slender proportions. Even here, however, there is a limit beyond which the eye becomes dissatisfied; and accordingly, when the column is required to be of considerable height, it is generally made of greater diameter, the inside being hollowed out to save weight and material, without sensibly affecting the strength. Where, from inequalities of the load, there is any risk of unequal pressure on the summit of a cast-iron column, and of consequent tendency to bend, the material used in constructing the column is much more advantageously applied in the shell of a hollow column, or in the ribs of one, the section of which is a cross, than in one solid. We only advert to this now, as we shall have an opportunity of recurring to it when we discuss the question of transverse strain.

Some very valuable experiments have been made upon the crushing of building materials, such as stones and bricks. The compressive forces in most of them have been applied to cubical pieces of 1 inch or 2 inches. In some, where the pieces had a square base 1 inch broad, and a height of 2 inches, the force required to crush, has been found less than two-thirds of that required for the pieces only 1 inch in height. The increase of height, therefore, considerably diminishes the strength to resist compressive force. In connection with this subject, it may be interesting to inquire how high a brick building might be carried without becoming crushed by its own weight. We may suppose a massive brick pier or column divided into numerous separate columns, each $1\frac{1}{2}$ inch square in section, and each supported along its whole height by those around it, against lateral pressure or flexure. The lowest part of each of these columns would thus have to support the vertical weight of all the column above it; and if that weight exceeded the load required to crush a brick cube of $1\frac{1}{2}$ inch, the lowest part of the column would of course give way. Now, it has been found, by experiment, that the load necessary to crush a $1\frac{1}{2}$ inch cube of brick, varies from 1,200 lbs. up to 3,000 lbs., according to the different qualities of the brick. It would perhaps be safest to take the lower number, 1,200 lbs. The weight of 1 foot of brickwork having a $1\frac{1}{2}$ inch square base, is about 2 lbs.; therefore it would require a height of 600 feet to crush the base. An architect, wishing to secure the permanence of his building, would certainly not venture to raise it one-third of this height without having recourse to the ordinary expedient of spreading the base or foundation by extensive footings, so as to diffuse the crushing pressure over a much larger surface of material.

Table V. contains the average results of experiments made on the resistance of various materials to crushing force. We would, however, caution the mechanic against placing too much reliance on these results, as we think the number of experiments made, scarcely warrants their establishment as practical data.

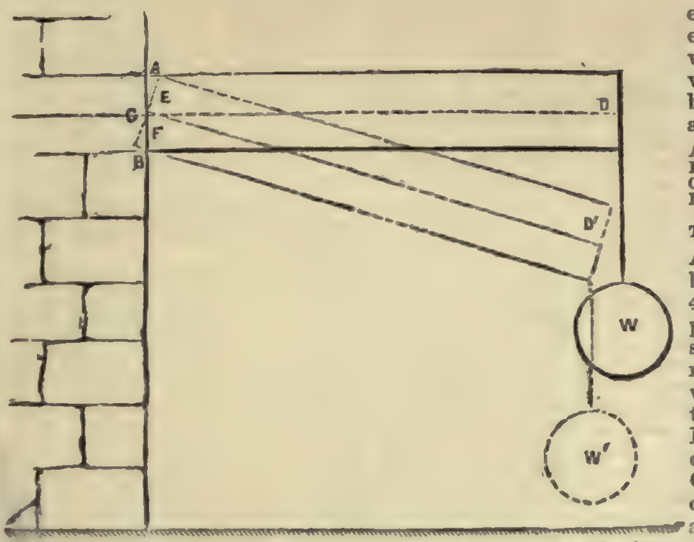
3. TRANSVERSE STRAIN.—The effect of a load on the end of a beam projecting from a wall, or on the middle of a beam supported at both ends, is to throw a transverse strain on the beam; and if the load be excessive, to break the beam transversely, or across its fibres. Of all questions respecting the strength of materials, this is certainly the most important. In architectural structures, the stability of roofs, floors, and walls supported on beams or girders; in civil engineering, the safety of girder-bridges and rails; in mechanical engineering, the strength of beams, levers, framing, and the like—all depend mainly upon the correct solution of questions relating to transverse strain. It is to this branch of the subject, therefore, that the consideration of engineers has been chiefly directed; and a vast number of experiments have been made with a view to ascertain practical data, from which the transverse strength of all useful materials may be calculated.

The theoretical investigation of transverse strain is by no means a difficult one; but the application of data in computation involves some very complicated questions, which the practical mechanic generally solves more by the eye, as he sees proportions in his drawing or model, than by any very accurate calculation. Such a mode of meeting the difficulty implies experience and observation; and without these, we fear no amount of theoretical knowledge, and no expertness in calculation, will serve for determining the strength of any structure. In machinery, especially, the strains to which parts may be subjected are so various in magnitude, owing to their respective movements, and the local qualities of materials differ so greatly, that the mere calculated strain and strength offer very little aid in guiding to the most suitable proportions. When the architect determines on the dimensions of an iron girder destined to carry a heavy wall, he can calculate, with tolerable precision, the weight to be supported, and the strength of girder required to carry it without danger. The girder is placed, the wall is built, and twenty years after, the load is the same, and the strength of the girder but little diminished.

But when the mechanic makes a pattern of a beam for a steam-engine, although he may readily calculate the strain which the pressure of steam on the piston throws upon the beam while the engine works steadily, he has little notion of the sudden though transient strain which may be thrown upon it by the sudden stoppage of some part of the machinery, or the occurrence of some slight obstacle to the movement. It not unfrequently occurs that a little water in the cylinder of a steam-engine, causes the fracture of some of the strongest parts. The machinery being all in motion, the piston descends upon a film of water which has no ready means of escape, and which being almost totally incompressible, offers as determined an obstacle as solid iron would do. In such a case, the momentum of all the moving parts must be suddenly destroyed; some of the beams, rods, or levers, through which the piston is connected with the rest of the engine, must give way; or the cylinder itself, which holds the water, must yield to the strain, and break under it. That we may form some idea of what damage such a strain as we have described may effect, we have only to reckon that in a large steam-engine there are 15 or 20 tons of iron, moving probably at an average velocity of 100 feet per minute, to be suddenly arrested. In destroying the momentum, as much force is expended as would be measured by the blow of a 68 lb. cannon-ball striking its mark at a very near range. Nor do these sudden and unexpected strains constitute the only difficulty under which the mechanic labours when he computes the strength of his work. He cannot always depend upon the internal soundness of the material with which he deals. Cast-iron is especially treacherous in this respect; and it often happens that a casting, externally sound, has some sponginess or air-bubbles under the skin, which are discovered only in the event of fracture. It is, therefore, his business not only to contrive devices for regulating the movements of his machinery, and for affording relief in cases of undue pressure, and to use every precaution against unsoundness in his materials; but also to provide such strength as shall meet the contingencies which a slight derangement may frequently bring about. It may be asked then, why, if the mechanic have to apply such excess of strength to meet contingencies, he should take any trouble in calculating or ascertaining practical data from which he may compute? The answer is plain. While he makes every part strong to excess, yet he has to maintain a proportionate strength in all. To make one part of a beam strong enough to sustain ten times its usual strain might be very proper; but to make another part of it capable of sustaining twenty times its load would be absurd, for then either the weaker part is only half as strong as it should be, or the stronger is twice as strong as required. The mechanic, then, must have a clear conception of how strains affect materials of different forms, and how far the change of one dimension or another may affect the strength, before he can venture to design or execute a machine justly proportioned in all its parts, and sufficiently strong throughout to meet the contingencies of its action, without undue waste of material and labour in its construction.

The most simple case of transverse strain is that to which a beam projecting from a wall is subjected, when a weight is suspended from its outer end. It is clear that the longer the beam, the greater the strain; and that if the beam give way anywhere, presuming it to be of uniform strength throughout, it will be at a point close to the wall where it is fixed, because at that point the weight acts with the greatest leverage. On tracing the breaking effect of the weight, we see that in bringing the end of the beam down to the position marked by the dotted lines, some action must take place among the fibres of the material at A B, where the weight acts with greatest power. This action must be that of tension among the upper fibres, and of compression among the lower ones; and there must be some point C in the beam where the extension and the compression of the fibres meet, and where there is neither of these actions. Such a point marks the position of what is called the *neutral axis*; that is, a line extending along the beam horizontally, and separating that part of the material which is extended or torn asunder, from that part which is compressed or squeezed together. It is manifest that, when the tearing asunder of the fibres commences, it must continue while the load continues to act, because the number of fibres resisting it is diminished, and those that remain, have therefore more load to bear.

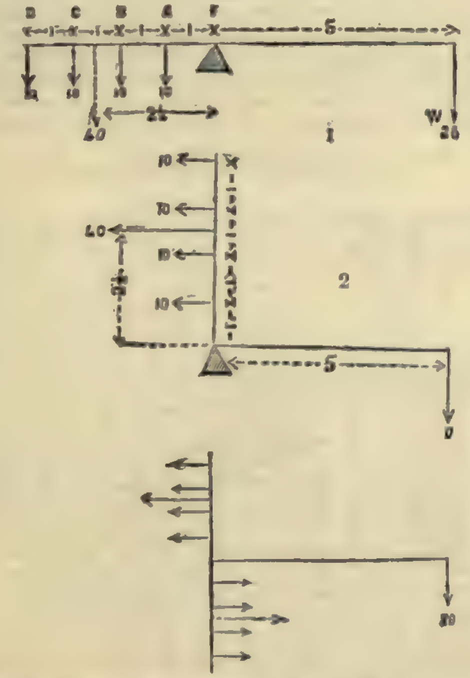
Fig. 63.



What we have to discover, however, is the strength of the beam while it is entire, or how much load W, at a certain distance from the wall, will bear without the destruction of the fibres. Supposing a horizontal line C D, drawn through the neutral axis, to form the long arm of a bent lever of which the fulcrum is C, one short arm C A, and the other C B, we have a certain power or weight W acting at the extremity of the long arm, and a number of resistances, viz., those of the fibres to extension, acting along the arm C A; also a number of resistances, viz., those of the fibres to compression, acting along the arm C B.

Now, when on one arm of a lever, a number of equal forces, equally distributed over the arm, acts against a given weight at the other end of the lever, the effect of all these forces is the same as if they were all collected into one force at the middle point of the arm on which they act (Fig. 64). This is true whether the lever be straight as 1, or bent with one arm as 2, or bent with two arms as 3. As a numerical example, let us suppose that the short arm of 1 is 4 feet long, and at each foot there hang 4 weights A, B, C, D, each of 10 lbs., as marked by the arrows; while the length of the other arm is 5 feet. A weight of 20 lbs. hung to the longer arm balances the four weights of 10 lbs. distributed along the shorter, because

Fig. 64.



A = 10 lbs. at 1 ft.	leverage is balanced by	2 lbs.	at 5 ft. lev.
B = 10 lbs. at 2 ft.	" "	4	"
C = 10 lbs. at 3 ft.	" "	6	"
D = 10 lbs. at 4 ft.	" "	8	"
Total A, B, C, D distributed . . .		20	"

And 20 lbs. at 5 feet leverage would be balanced by 40 lbs. at 2½ feet; that is, the total of the 4 weights A, B, C, D hung at their middle point, as marked by the dotted arrow. The same law will be found true, whatever the number of equally-distributed weights, and whether the lever be straight or bent. Applying this to the question of the beam, Fig. 63, let E be the middle point of A C, and F the middle of B C; then the load W acting with leverage C D has to resist the united tensive strength of the fibres along C A acting at the leverage C E, and the united compressive strength of those along C B acting with the leverage C F. Those resistances will necessarily be equal to one another, because the neutral axis C is the fulcrum, on each side of which they equalise themselves; and the tensive strength of C A, multiplied by its leverage C E, is therefore equal to the compressive strength of C B multiplied by the leverage C F; or, as C A is double of C E, and C B double of C F, and as doubles of equal things are themselves equal, the tensive strength of C A multiplied by the length C A is equal to the compressive strength of C B multiplied by the length C B; and each of those products is equal to the weight W multiplied by its leverage C D, the length of the beam, because each is double of half the effect of W to break the beam.

To show how this reasoning may be applied numerically, let us suppose that a beam of oak 1 inch thick and 6 inches deep, fixed in a wall so as to project 10 feet, is broken by a load hung at the end; and that while in the act of breaking, the neutral axis is observed to be 2 inches from the under side, and therefore 4 inches from the upper side of the beam, we may, from knowing the tensive strength of oak, estimate the weight required to break the beam. Taking this tensive force per square inch (or force required to tear asunder a square inch) at 12,000 lbs., we have in the case before us 4 square inches having a tensive force of 4 × 12,000 = 48,000 lbs., acting with leverage of 4 inches against leverage of 10 feet or 120 inches; and as 4 inches is the $\frac{1}{30}$th of 120 inches, the weight at D must be the $\frac{1}{30}$th of 48,000, viz., 1,600 lbs.

By such calculations as this we could compute the transverse strength of materials, from knowing their tensive strength, provided we knew the position of the neutral axis of fracture. The determination of this, however, is a point of very great difficulty; for it must, in the first place, depend upon the relative proportions of compressive and tensive strength: and as we are much in the dark as to the former, we cannot institute a comparison between it and the latter. In the second place, no material to which we can apply transverse strain resists completely, and then instantaneously gives way. While we add weight after weight, the extension of fibres at one side and the compression of those at the other goes on; the beam bends or becomes deflected; greater and greater strain is thrown on the outer fibres; the tensive and compressive strength of each varies as it is more and more extended or compressed; the neutral axis changes its position; fibres, which were, during part of the process, compressed, begin to be extended; and the condition of the material at and near the point of fracture becomes generally so altered as it approaches destruction, that we cannot clearly estimate its resistance, even if we were possessed of the most accurate knowledge of its strength to resist compression or extension. Owing to these circumstances, it becomes necessary to make distinct experiments on the transverse strength of bodies, and, by means of them, to establish certain data which we may apply in calculation. But while experiment and observation furnish the data or facts on which to calculate, we must still trust to reasoning for our methods of applying these facts; and fortunately the reasoning is of a simple character.

As to the neutral axis of fracture, without requiring to determine its position in any beam, we assume that, for beams of the same material, its distance from the upper or lower sides is proportional to the depth of the beam. Thus, if in a beam of ash 6 inches deep, it is 2 inches from the lower side and 4 inches from the upper; in a beam of ash 12 inches deep it will be 4 inches from the lower and 8 inches from the upper side; in one of 1 inch deep, it will be ⅓rd of an inch from the lower, and ⅔rds of an inch from the upper; and so on in regular proportion. We can see no reason why this should not be the case; and, so far as we can trace the circumstances which determine the position of the neutral axis, we see every reason for believing that it is so. This assumption greatly simplifies the rest of our reasoning; for it enables us to get rid of all calculation as to the actual position of the neutral axis, and to proceed with the comparison of beams as to transverse strength independently of it. We will suppose that we have three beams of the same material, all of equal lengths and breadths, but of the following depths: A depth 2 inches, B depth 4 inches, C depth 6 inches, and that we desire to compare their transverse strengths. Let us assume, for the sake of simplicity, that the neutral axis is midway in the depth; then in A we have, above the neutral axis, a set of fibres extending over 1 inch in depth, and acting with a leverage of 1 inch to resist the breaking load. In B we have fibres extending over 2 inches, and therefore double the number of those acting in A, acting with 2 inches leverage, or double the leverage of those in A. We see, then, that the strength of B must be twice 2, that is, 4 times the strength of A. Again, in C we have 3 inches depth of fibres and a leverage of 3 inches; therefore C has a strength of 3 times 3, or 9 times that of A. And so with any other depths, the strength being always as the depth multiplied by itself, or as the square of the depth. If we had assumed the neutral axis to be in any other position, such as ⅓rd of the depth from the lower side, we should still have found the same law to obtain; for so long as the beams we are considering are of the same material, and of similar form, the neutral axis must proportionally divide their depth, and leave proportional numbers of fibres to act with leverage proportional also to the depth.

We, therefore, have established the simple law, that in beams of the same form, length, breadth, and material, the transverse strengths are as the squares of the depths; and knowing the strength of a beam 1 inch deep, we can estimate the strength due to any other depth by multiplying that of the 1-inch beam twice, by the depth of the other in inches; that is, by the square of the depth.

Example.—An iron beam 1 inch deep breaks with a load of 2 tons: required the load that will break a similar beam 4 inches deep. The square of 4 is 16, and 2 × 16 = 32 tons, or 2 tons × 4 × 4 = 32 tons.

Now, let us ascertain what relation the transverse strengths of beams bear to their breadths. Suppose that a beam 1 inch broad carried a load of 1 ton, then another exactly like it will also carry 1 ton; a third will also carry 1 ton; and the three placed side by side, or united into one beam 3 inches broad, will of course carry 3 tons. Beams, then, of a certain material of equal lengths and depths, have transverse strengths which are proportional to their breadths; and if we know the strength of a beam 1 inch broad, we compute that of a beam having any other breadth, by multiplying the strength due to 1 inch of breadth, by the number of inches in the given breadth.

Example.—A fir beam 1 inch broad carries 10 cwt.: required the load carried by a fir beam 6 inches broad, of like length and depth. 10 cwt. × 6 ins. = 60 cwt., or 3 tons.

We may now combine the laws as to breadth and depth into one, and thus compute the transverse strength of a beam as depending on both dimensions. This law is, that the transverse strengths of beams of the same material and similar in form, are as the breadths multiplied by the squares of their depths; and if we know the strength of a beam 1 inch broad and 1 inch deep, we compute the strength of a beam having any other breadth and depth, by multiplying the strength of the 1-inch beam by the breadth in inches, and twice by the depth in inches of the other.

Example.—Suppose a beam 1 inch broad and 1 inch deep bears 5 cwt.: required the strength of a beam 4 inches broad and 6 inches deep.

5 cwt. × 4 ins. × 6 ins. × 6 ins. = 720 cwt. or 36 tons.

The strength of a beam is irrespective of its length; but the actual weight which it can carry depends upon the length, inasmuch as the leverage with which the weight acts, so as to fracture the beam, is greater, the greater the length. A weight of 12 tons hanging at the end of a beam 1 foot long, is exactly equivalent to a weight of 6 tons at 2 feet distance, of 4 tons at 3 feet, of 3 tons at 4 feet, of 2 tons at 6 feet, of 1 ton at 12 feet, of ½ ton at 24 feet, and so on—the weight multiplied by its distance being always a constant quantity. If, then, we know the load which a beam 1 foot long will carry at the end, we estimate the weight carried at any other distance by dividing that carried at 1 foot by the distance in feet; and combining this element with those of breadth and depth, we have the general rule embracing all the dimensions of a beam; *i. e.*, multiply the weight carried by a beam 1 inch broad, 1 inch deep, and 1 foot long, by the breadth in inches, and twice by the depth in inches, and divide the product by the length in feet.

Example.—A beam 1 inch square and 1 foot long, carries 5 cwt. at its end: required the load carried by a beam 4 inches broad, 6 inches deep, and 18 feet long.

$$\frac{5\text{ cwt.} \times 4\text{ ins.} \times 6\text{ ins.} \times 6\text{ ins.}}{18\text{ ft.}} = 40\text{ cwt., or 2 tons.}$$

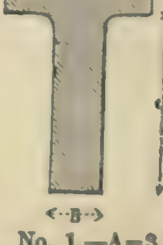
So far we have discussed the strength of beams of square or rectangular sections; but similar reasoning will apply to those of other forms. When the section is circular, the breadth being equal to the depth, we have to multiply the strength of a cylindrical beam 1 inch in diameter and 1 foot long, three times by the diameter in inches, and divide by the length in feet.

Example.—A cylindrical beam 1 inch diameter and 1 foot long, bears 3 cwt.; required the load supported by a cylindrical beam 4 inches in diameter and 8 feet long.

$$\frac{3\text{ cwt.} \times 4\text{ ins.} \times 4\text{ ins.} \times 4\text{ ins.}}{8\text{ ft.}} = 24\text{ cwt.}$$

When the section is of any form, such as the ⊤ shaped iron girder (Fig. 65), from our ignorance as to the position of the neutral axis of fracture, we are at a loss how to reckon the effect of the fibres at different parts of the section, and cannot therefore estimate the strength from any data obtained by experiments upon beams of square or rectangular section. But if we know the strength of a beam of certain dimensions, and of the form in question, we may pretty nearly estimate that of a beam of the same kind whose dimensions, as to breadth and depth respectively, are proportionally greater or less. For instance, to compare two ⊤ shaped beams of which the dimensions are as follows:—

Fig. 65.

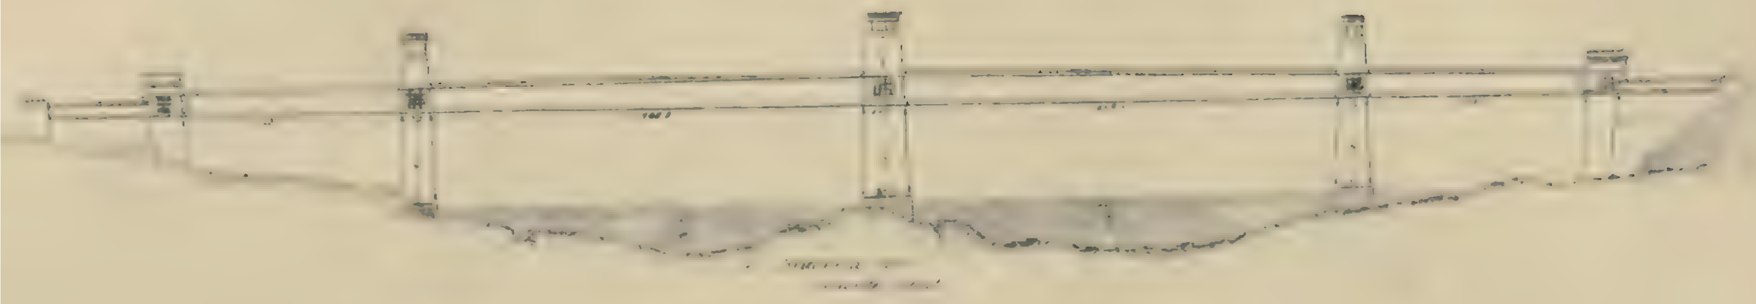


No. 1.—A=3 ins., B=1 in., C=4 ins., D=1 in., length 10 feet, is found to bear 2 tons: required the strength of No. 2, where A=6 ins., B=2 ins., C=6 ins., D=1½ in., length 15 feet.

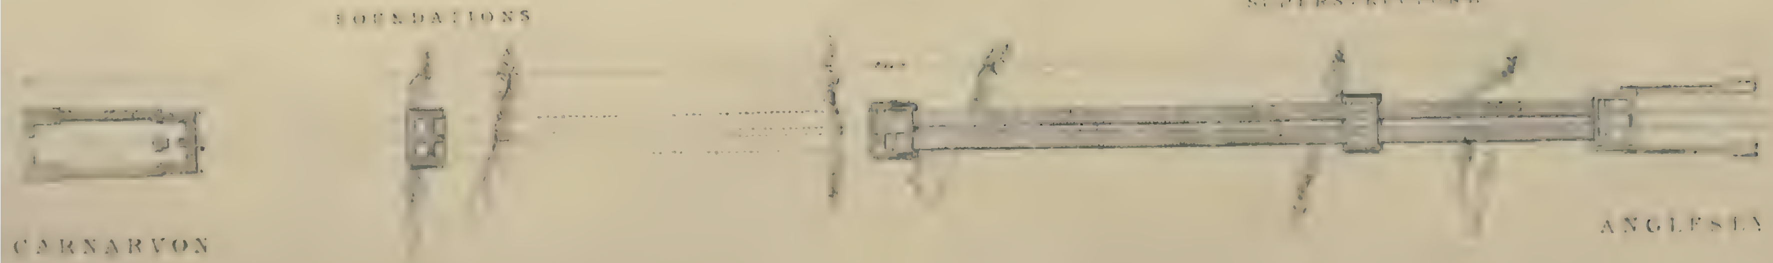
See pages 905 909

BRITANNIA TUBULAR BRIDGE.

ELEVATION



PLAN



Strength of No. 1 is as $\frac{3 \text{ ins.} \times 4 \times 4}{10} = 4{\cdot}8$

Strength of No. 2 is as $\frac{6 \text{ ins.} \times 6 \times 6}{15} = 14{\cdot}4.$

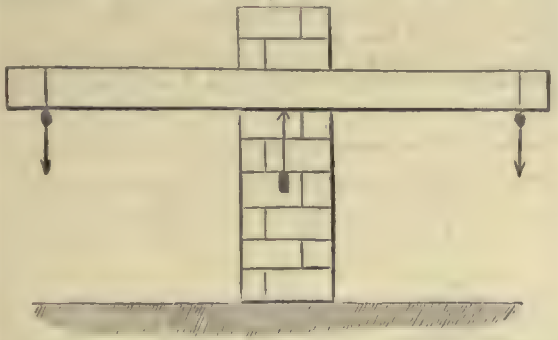
And by the simple proportion,

Strength No. 1. Strength No. 2. Tons. Tons.
4·8 : 14·4 :: 2 : 6, load carried by beam No. 2.

In the absence, then, of sufficient knowledge of the effect of material at different parts of the section in contributing to strength, for every different form of section we are under the necessity of making such experiments as shall fix data for calculation, to be applied to cases where the section is similar, but the dimensions different. A number of such experiments have been tried from time to time, and attempts have been made to settle, by theoretical reasoning as well as by practical results, the best form of section to be used; that is to say, the form which gives the greatest strength with the least material. We are not aware, however, that for any material, the subject has been so far investigated as to warrant us in laying down any absolute proportions; and the form of section must therefore be determined, in a great measure, by balancing a number of circumstances, and adopting such arrangements as shall combine the results most advantageously.

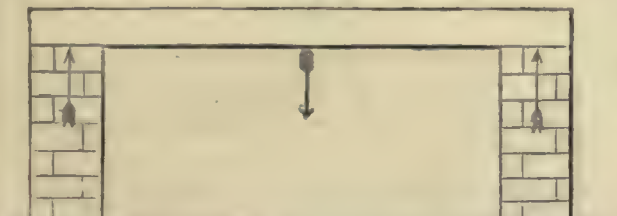
In a recent engineering work, a triumph of skill and perseverance over difficulties at first sight apparently insurmountable—we mean the Britannia Tubular Bridge across the Menai Straits—an enormous amount of preliminary investigation was conducted before the form and dimensions of the structure were finally determined. Models were made of all convenient forms, and tested against each other: one was found too weak in one place, another too weak in another place. Fresh models were made, with the weak parts strengthened by additional materials, and the mass of material in strong parts removed: the most suitable and convenient form was thus decided. A much larger model was made and tested as to deflection and fracture; and after a large comparison of results, the actual dimensions and details of construction of the full-sized structure were determined, and carried out with merited success.

Fig. 66.



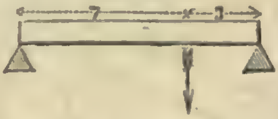
Hitherto we have referred only to the circumstance of a beam projecting and loaded at one end. This, however, is by no means the most ordinary condition under which materials are exposed to transverse strain. Beams are usually supported at both ends, and carry their load in the middle. We have, therefore, now to ascertain what relation exists between the strength of such a beam and that of a beam projecting and loaded at one end. If we suppose a beam built into a wall and projecting equally on both sides (Fig. 66), each end being loaded with an equal weight, it is clear that the wall supports double the weight suspended at each end. If we conceive the forces acting on such a beam inverted or turned upside down, we establish the conditions of a beam supported at both ends, and loaded in the middle (Fig. 67) with double the weight which each of the end supports has to bear. Now, if, in the first case, where the beam projected both ways from the wall, each end were loaded with the weight capable of breaking the beam, that is, up to its transverse strength; in the second case, the beam, which is twice the length of each projecting arm of the first, may be loaded with double the weight which hung from each end of the first, and this weight will measure its strength. We, therefore, come to the conclusion that the transverse strength of a beam, supported at both ends and loaded in the middle, is double that of a beam half the length at one end and loaded at the other. We have already shown that if we double the length of a projecting beam, we can load it with only half the weight; therefore, if each projecting arm of the beam were made equal in length to the beam supported at both ends, the former would bear only one-fourth of the weight which the latter can bear. For equal lengths, therefore, the strength of the beam supported at both ends and loaded in the middle, is just four times that of the beam fixed at one end and loaded at the other; or, conversely, the strength of the beam projecting is only one-fourth of that of the beam supported at both ends. Experiments upon transverse strain have been generally made upon beams supported on both ends; and tables of practical data founded on these experiments have been formed. Such tables generally contain the transverse strength of beams, having square and also circular sections one inch in diameter, and having a length of one foot between the supports, their load being supposed to be placed in the middle of their length. When the load is placed out of the middle it may be increased, because its leverage to break the beam, is diminished the farther it is from the middle point.

Fig. 67.



The mode of reckoning this diminution of strain may be best illustrated by an example. Suppose we found that a beam, 10 feet long, bore 42 cwt. at its middle point, and desired to ascertain how much it would bear suspended 2 feet from the middle—that is, 7 feet from one end and 3 feet from the other (Fig. 68)—we should proceed as follows:—Square half the length of the beam, or multiply 5 by itself, giving 25, and this by 42 cwt., the load sustained at the middle, product 1,050; now multiply 7 by 3 (the two portions into which the beam is divided), product 21, and divide the former product 1,050 by this, that gives a quotient 50 cwt., the load which the beam would carry 2 feet from the centre.

Fig. 68.

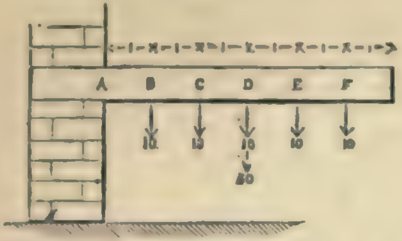


The simple principle of this computation is, that the load hung from any point of a beam, is to the load which may be hung from any other, as the product of the two lengths into which the second point divides the beam, is to the product of the two lengths into which the first point divides it. Thus, in the case we have given above, knowing that the beam bears 42 cwt. at the middle, or when it is divided into two lengths, each 5 feet, we say,

$$7 \times 3 = 21 : 5 \times 5 = 25 :: 42 : 50$$

It frequently happens, that beams have to bear a load not hung at any one point, but distributed uniformly over their length; as in the case of roofs, floors, and girder-bridges. Here, it may be readily seen, that the strain is only half that which it would be if the whole load were collected at the middle. If we suppose a beam projecting 6 feet from a wall, loaded at intervals of a foot by weights each 10 cwt. (Fig. 69), then, by the principle of the lever, the effect of each of the weights, to break the beam at A, may be reckoned as follows :—

Fig. 69.

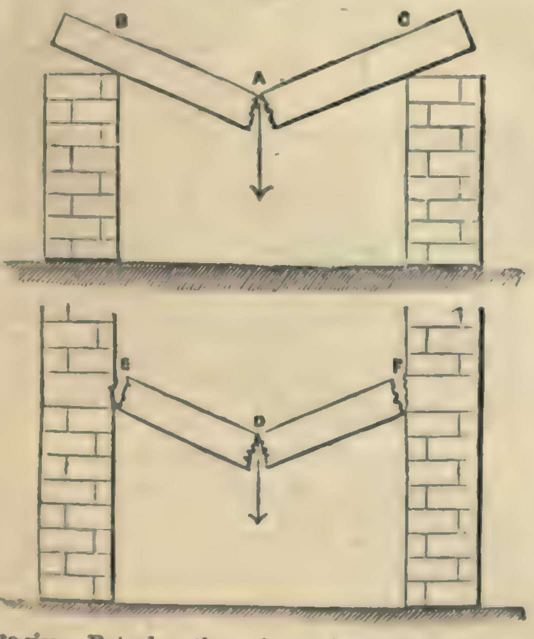


B=10 cwt.	acting	at 1	ft. from A	has the effect of	10	cwt. at	1	ft. leverage.
C=10	„	„ 2	„	„	20	„	1	„
D=10	„	„ 3	„	„	30	„	1	„
E=10	„	„ 4	„	„	40	„	1	„
F=10	„	„ 5	„	„	50	„	1	„
Total 50 cwt. distributed equally.					150	cwt. at	1	ft. leverage.

Or, as 150 cwt. at 1 foot leverage are equivalent to 50 cwt. at 3 feet, we find that the total strain is the same as if the total weight were collected at D, the middle point. Were we to assume a greater number of weights at smaller intervals, we should still find the same result; and the more numerous the weights, and smaller the intervals we assume, the more nearly do we approach to the case of a beam uniformly loaded over its whole length; whence we conclude that the effect of the distributed load is the same as if it were collected at the middle of the beam, and therefore just half of what it would be if hung at the end. Or, conversely, if the beam bear a certain load at its extreme end, it will bear double that weight distributed over its whole length. The same law applies in the case of a beam supported at both ends, and loaded uniformly throughout its length; the strain of the load is reduced to half what it would be if collected at the centre; or the beam will bear twice as much distributed weight, as it can bear at its middle point.

When a beam is not merely supported at each end, but fixed firmly there, its strength is increased by one-half. It would appear at first sight, that by fixing the ends of a beam we should double its strength, for the following reasons: when the beam is merely supported, an extreme load in the middle has only to effect one fracture at A (Fig. 70), the two ends B and C being free to rise. But when the ends are fixed, the load has not only to break the beam at the middle point D, but also at E and F; and to do this it must be double what it would be if the ends were free, as may be very simply computed thus. Suppose, in the first case, it required 12 cwt. to effect the single fracture at A, then in the second it would require likewise 12 cwt. in the middle to effect the fracture at D, and 6 cwt. in the middle to effect each of the fractures at E and F; making a total of 24 cwt. in the case of the beam with fixed ends.

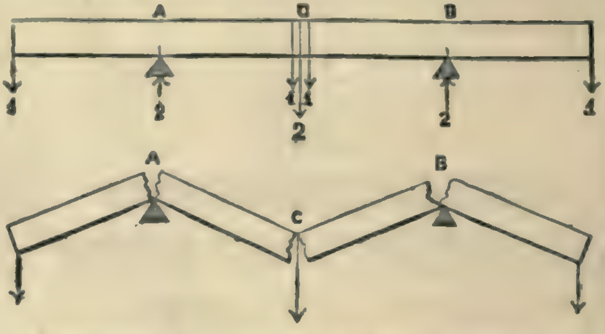
Fig. 70.



Many writers have taken this view, neglecting a circumstance which must in such cases occur, and which greatly modifies the distribution of strain on the middle and ends. A single glance at the figure shows that the amount of tension and compression on the fibres at the middle fracture must be double that at either of the end fractures; and hence each half of the weight required to produce either of the end fractures, or the total weight due to the middle fracture, must be 4 times either of those due to the end fractures. If then we supposed the total breaking-weight divided into 6 equal parts, 4 of those parts would act to break the beam in the middle, and 2 to break it at the ends. But the 4 parts required to effect the middle fracture must make up the breaking-weight due to a beam merely supported without being fixed at the ends; and the other 2 parts—that is, half as much more—make up the additional weight required when the ends are fixed. Taking the numerical example as before, if it required 12 cwt. to effect the single fracture at A, it would require as much to break the beam at D, and one-fourth, or 3 cwt., to break it at each of the points E and F, making a total of 18 cwt., which is the sum of 12 and 6, the ordinary breaking-weight increased by its half.

As this principle of computation accords better with experiment than the former, it is important that its demonstration should be clear, inasmuch as numerous theorists have adhered to the principle, that by fixing the ends of a beam its strength is doubled. According to them, the circumstances correspond with those of a beam (Fig. 71) resting on supports A and B, and projecting each way one half of its length beyond. A load of 1 at each end, balanced by two loads, each 1, in the middle, throws a breaking strain of 2 upon the beam at each prop; and an additional load of 2 in the middle will measure the breaking strain there, so that the total middle load is 4, or double the ordinary breaking strain. This is no doubt true, because if we suppose the fracture effected, the amount of compression and extension of the fibres at each of the points A, C, and B is the same; and therefore each fracture requires the same load to effect it. But in the case of the beam with ends not balanced but fixed, as we have already explained, the end fractures demand only half the amount of extension and compression due to the middle fracture.

Fig. 71.



When a load acts on a beam not perpendicularly or square to its length, but at some other angle, it throws less strain upon it, because the actual leverage of the weight is not the length of the beam as measured from A to B (Fig. 72), but the length of a line measured from A to C perpendicularly to the vertical line in which the weight acts. So when a beam is supported at both ends, but lies obliquely, the transverse strength is to be reckoned as that due to a beam of the length indicated by the horizontal line D E (Fig. 73) measured between the supports.

Fig. 72.

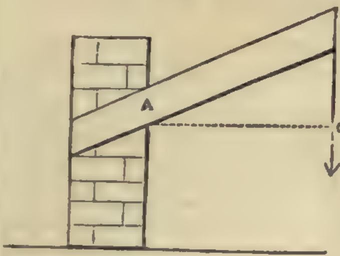


Fig. 73

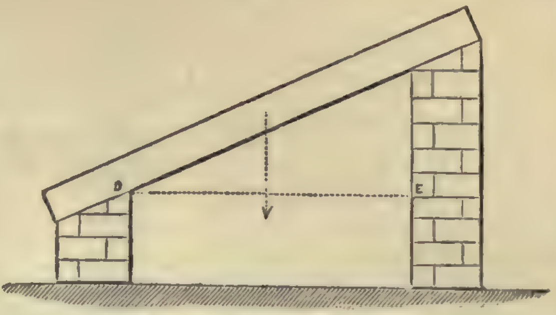
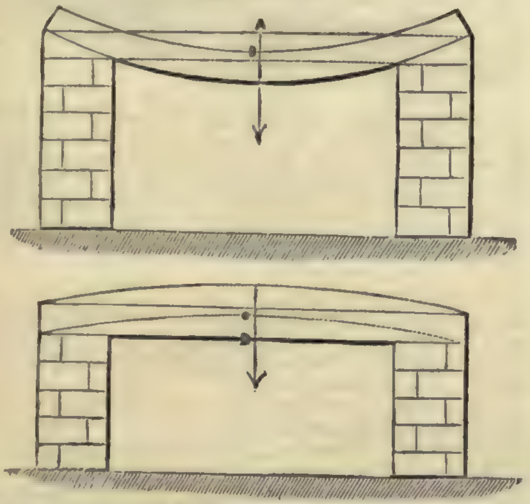


DEFLECTION.—Hitherto, for the sake of simplicity, we have discussed the question of transverse strain as applied to materials perfectly inflexible, such as break, but cannot bend. We have, however, no practical experience of materials of this character, although stones, slates, or even cast-iron, approach very nearly to it. Timber beams, and those made of wrought-iron, bend considerably before they become fractured by transverse strain; and as, in such beams, deflection from their straight or horizontal condition may be inconvenient and unsuitable, it becomes important to estimate the amount of deflection which they will exhibit under certain loads, so that they be made slightly curved in the opposite direction before the load is placed upon them. If it were found, for instance, that a beam loaded with a certain weight deflected so far from the straight line that its middle point B (Fig. 74) sunk a certain distance—say 6 inches—below the horizontal line; then if the beam, instead of being made straight, were made somewhat arched, or *cambered*, as it is technically called, the load being placed upon it would still deflect it, and thus bring its surface to a horizontal line, if the camber or amount of arching C D were properly estimated.

The complete investigation of the question of deflection would involve us in mathematical reasoning of rather a complex character, which would scarcely be in place here; and, indeed, practical results as to deflection present so many irregularities, and so many deviations from any apparent law, that it is questionable whether theory would prove a very safe guide. Some writers on this subject have determined theoretically, that the amount of deflection of a beam of certain length, increases in the same proportion as the load, and that the deflection under a certain weight varies as the square of the length. If this law were true, a beam 20 feet long, with a certain weight on it, would be deflected four times as far as one 10 feet long, because the one has twice the length of the other, and the square of 2, or 2 multiplied into itself, is 4.

Fig. 74.



This law, however, has not by any means been found to be true in practice. More accurate investigators have furnished a law which, while it appears to be theoretically correct, presents results very nearly according with those of experiment. This law is, that the deflection of a beam (having a rectangular section) varies directly as the weight and as the cube of the length (or the length multiplied 3 times into itself), and inversely as the breadth and the cube of the depth. If, then, we knew the deflection of a certain beam, we might estimate that of another of the same material, but varying in all its dimensions. Suppose, for example, that a fir batten 1 inch broad and 2 inches deep, with a load of 1 cwt., deflected $\frac{1}{16}$th of an inch in a length of 3 feet, and we desired to know the deflection of a fir beam 3 inches broad, 10 inches deep, and 15 feet long, under a weight of 1 ton, or 20 cwt. In the case of the batten, which is 2 inches deep, since $2 \times 2 \times 2 = 8$, the deflection is only $\frac{1}{8}$th of what it would be were the depth 1 inch, because it is inversely as the cube of the depth. The deflection, then, of a batten 1 inch deep, under a load of 1 cwt., would be $8 \times \frac{1}{16} = \frac{1}{2}$ inch, the length being 3 feet. Further, the cube of 3, or $3 \times 3 \times 3$, is 27; and were the batten only 1 foot long instead of 3 feet, the deflection would be $\frac{1}{27}$th; the deflection then of a batten 1 inch broad, 1 inch deep, and 1 foot long, would be $\frac{1}{27}$th of $\frac{1}{2}$ an inch, or $\frac{1}{54}$th of an inch, with a load of 1 cwt. Having thus got an estimate for a beam with all the dimensions reduced to unity, we can apply it to any other beam, according to the law we have stated. This law is arithmetically applied by multiplying the deflection found above, $\frac{1}{54}$th of an inch, by the weight 20 cwt., by the cube of the length 15 feet (or 3 times by 15 feet), and dividing the product by the breadth 3 inches and the cube of the depth 10 inches; or the deflection is

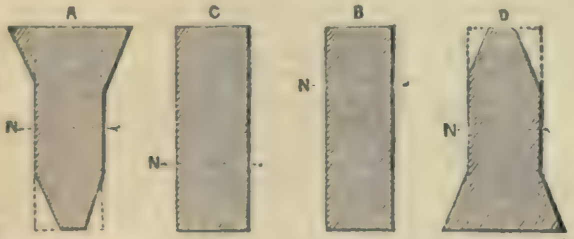
$$\frac{\frac{1}{54}\text{th in.} \times 20 \times 15 \times 15 \times 15}{3 \times 10 \times 10 \times 10} = \frac{5}{12}\text{ths of an inch,}$$

or nearly $\frac{1}{2}$ an inch.

As to the deflection of beams of various forms and materials, and subjected to strains under various conditions, although numerous experiments have been made, yet they have been conducted with too little reference to each other for us to develop any law of general application. In Barlow's *Treatise on the Strength of Materials*, the question of the deflection of wrought-iron, as applied in the construction of rails, is treated at considerable length; but the conditions of strength in malleable iron must differ very considerably from those in other materials, because their comparative tensive and compressive strengths differ very widely. Mr. Fairbairn, of Manchester, has lately conducted some extended experiments on this and allied subjects, which are well worthy of the attention of practical men. To show how cautious we ought to be in applying to any particular material the results deduced from experiments on other materials, we may instance the peculiar difference between cast and wrought-iron in respect of tensive and compressive strength. The direct cohesive strength of wrought-iron is about 3 times that of cast-iron; or, to bear a certain tensive strain, the area of section in cast, should be about 3 times that of wrought-iron. As to compressive strain, on the other hand, although it may be true that wrought-iron will sustain much greater compression than cast-iron before it becomes entirely crushed and disintegrated, yet the greater softness of the wrought-iron permits it to yield under pressure, and to become compressed to a considerable extent; while cast-iron scarcely yields perceptibly until it entirely gives way.

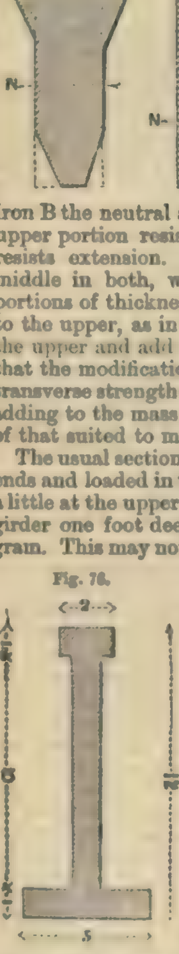
DISPOSAL OF MATERIAL.—If we apply these considerations to a beam subjected to a transverse strain, as when it is supported at both ends and loaded in the middle, we see that at the middle of the beam, just before fracture takes place, there must be a portion of the material above the neutral axis compressed, and a portion below it extended by the action of the load. If the resistance of the material to extension and to compression under those conditions be equal, the neutral axis would be in the middle of the beam; and its resistance to fracture would then be the greatest possible, because the total leverage of the compressed and extended portions on each side of it, would be greater when it is in the middle than when it is elsewhere. But if it happened that the material was more easily compressed than extended, it would be nearer the lower side; while if it were more easily fractured by extension than compression, it would be nearer the upper side. Desiring, however, in either case to secure the advantage of having it in the middle, and thereby giving both the compressed and the extended portions the greatest possible leverage, we should somewhat alter the form of transverse section, so as to increase the area of the weaker part, or add to it some fibres, diminishing the area of the stronger, and, upon the whole, not altering the quantity of material or total area of section, but only modifying it in such a way as to bring the neutral axis to the middle of the depth. In a rectangular beam of malleable iron C (Fig. 75), the neutral axis N is below the middle of the depth, because the upper portion yields more readily to compression than the lower to extension. In a beam of cast-iron B the neutral axis N is above the middle, because the upper portion resists compression more than the lower resists extension. To bring the neutral axis to the middle in both, we should for malleable iron remove portions of thickness from the lower edge, and add them to the upper, as in A; for cast-iron we should take from the upper and add to the lower, as in D. We thus find that the modification of form requisite for increasing the transverse strength of cast-iron of certain depth, without adding to the mass of material, is exactly the opposite of that suited to malleable iron.

Fig. 75.



The usual section of cast-iron girders, supported at both ends and loaded in the middle, is the inverted ⊤, swelled a little at the upper edge (Fig. 76). The dimensions of a girder one foot deep are nearly those marked in the diagram. This may not be precisely the best form for combining the greatest strength with economy of materials, but it approaches it; and, besides, it possesses practical advantages which deserve consideration. The flange, or increased width at the lower side, not only affords the additional strength required there in order to meet the tensive strain, but presents a projecting ledge for receiving the beams or arches which the girder may have to bear. The increased thickness at the upper side not only provides additional material to resist compressive strain at the greatest possible distance from the neutral axis, but serves to stiffen the girder so as to prevent it from bending or buckling sideways, either from contraction in cooling from its molten state, or from excessive strain in its place. The thickness of the metal in the middle part and in the lower flange is made as nearly equal as possible, because it is found practically that, in making iron castings, unequal thicknesses of metal cause unequal contractions or shrinkings in the metal as it cools, and thus tend to distort the work.

Fig. 76.



The best form of section for malleable iron rails is nearly the opposite of that for cast-iron girders, a ⊤ not inverted (Fig. 77). As, however, the upper part of the rail gets worn and uneven by the friction of the traffic, it is sometimes thought desirable to have the opportunity of inverting it, and thereby wearing both the upper and lower sides before the rail is rejected as worn out. The section is, therefore, made symmetrical above and below, as well as on both sides (Fig. 78).

Fig. 77.

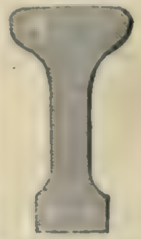


Fig. 78.

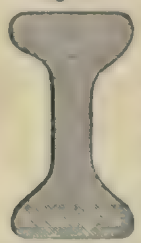

As we have shown above, the strength of any beam to resist transverse strain increases very greatly as the depth is increased. It is, therefore, of great importance in all cases of transverse strain to give as much depth as possible. This is often effected, not by increasing the total depth of the material, and thus adding greatly to its weight, but by introducing ribs or flanges, and thus dispersing a given quantity of material in a better form. If, for instance, we had to provide a square cast-iron plate, of sufficient strength to resist a great weight pressing on its middle (Fig. 79), while it is supported on two piers at the sides: instead of making the plate of solid iron, sufficiently thick to sustain the strain, we should probably make the upper part a thin flat plate (Fig. 80); and round the edges, as well as across the diagonals, provide projecting ribs of the greatest depth in the middle (Fig. 81); and thus attain sufficient strength and stiffness, while we should save a considerable quantity of material. This mode of attaining strength is particularly useful with such a material as cast-iron; for when it is formed in thick masses, the cooling of the outer crust, while the inner part of the mass remains fluid, sets or fixes the outside, and the subsequent contraction of the inside causes a sponginess or looseness of texture, which greatly diminishes strength. It is, therefore, of the utmost importance to attain the required strength without great thickness, as well for the sake of securing solidity and firmness of material, as for

Fig. 79.

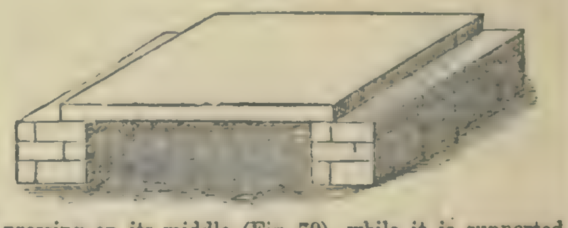

Fig. 80.

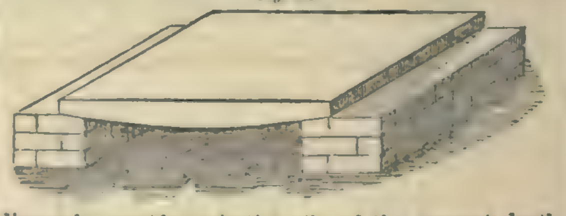

Fig. 81.

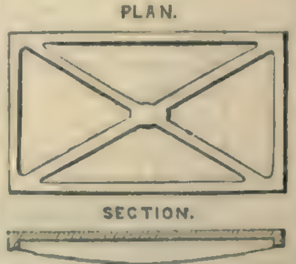

avoiding air-bubbles and flaws, which are apt to occur in thick castings; and which, if they do occur in thin castings, do not take so much from the strength, or, at all events, are more likely to be visible, and can be allowed for. In malleable iron bars, when they are required for strength and stiffness, the ⊤ form is usually employed. In plates, corrugating or wrinkling adds greatly to the stiffness, because it provides depth of material transversely.

The question of how to dispose material in order to secure the greatest strength with the least weight and cost, is indeed the main subject of mechanical contrivance as to form. We have already instanced the contrivance of the Britannia Tubular Bridge, as an example of skill in device going hand-in-hand with experiment. Were the material employed in one of the great tubes of this bridge all compressed into one solid bar, having a section of dimensions proportional to those of the tube, we question if it could support its own weight without breaking, even if the span were reduced to half that of the tube; while with one-fourth of the span, the deflection, from its own weight, would be enormous. In this tube, the material is disposed in such a manner as to attain the greatest strength with the least weight, and the most suitable form for the purposes of the traffic. The additional material required in the upper part of the section (as in the case of other wrought-iron girders), is arranged in the sides of cells or subsidiary tubes (Fig. 82); and due regard has been paid to the securing of lateral stiffness, to resist the pressure of strong winds against its immense side-surface, as well as to the attainment of vertical stiffness to resist the strain and shake of a heavy passing load. The annexed plate represents an elevation and plan of this great work, as much admired for its grandeur and simplicity as for its strength and durability.

Fig. 82.

In some other cases, where malleable iron is used in the construction of bridges, a girder has been formed of plates, disposed in a manner somewhat different. The upper part is a tube bent over to an arch-form (Fig. 83), and the lower portion forms a flange or ledge, as well for strength as for receiving the ends of the beams that carry the roadway. The upper and lower portions are connected by a longitudinal fin, with several transverse ribs for stiffening, and more firmly connecting the whole together. This ingenious arrangement of parts is due, we believe, to Mr. Brunel, the engineer.

Fig. 83.

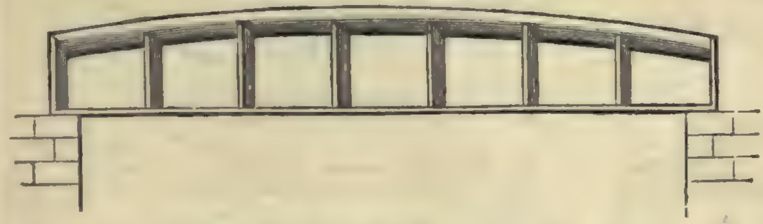

Fig. 84.

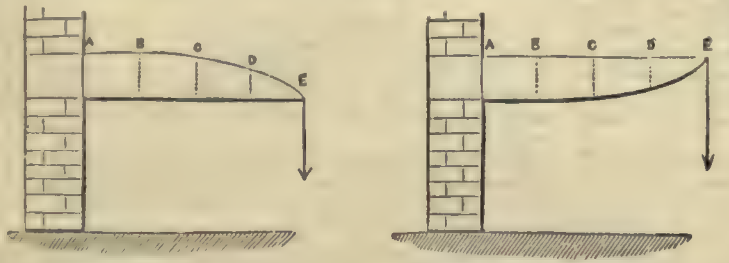
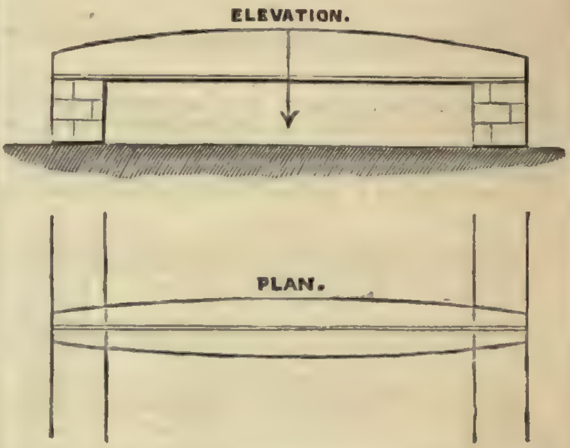


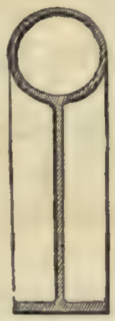
Not only, however, is there scope for modification of form of the transverse section so as to secure strength with economy of material, but the longitudinal section and a plan of a beam are also susceptible of modifications.

In the case of a beam projecting from a wall (Fig. 84), with a weight suspended at its extreme end, the strain is greatest at A, close to the support, and diminishes towards the end, because the leverage with which the weight acts to fracture the beam, diminishes. Thus, at C, midway, the strain is only half that at A; at B it is $\frac{3}{4}$ths; and at D it is $\frac{1}{4}$th. If, then, the breadth of the beam be uniform throughout its length, its depth may be with safety diminished towards the extremity. As the strength is proportioned to the square of the depth, the depths at B C D may be made such that their squares are respectively $\frac{3}{4}$, $\frac{1}{2}$, $\frac{1}{4}$ of the square of A. This may be done by removing material from the upper or lower side of the beam, so as to give it a curved outline above or below; and still the strength of the beam is maintained. The curve for such a beam is what is called a parabola, the peculiar property of which is, that a square of the length of each of the vertical lines or ordinates, A, B, C, D, is proportional to its distance from the apex or extremity E. Let us take, as an example, a beam of cast-iron projecting 12 feet, and 12 inches deep at A by 3 inches broad. The weight of such a beam of uniform depth throughout would be about 12 cwt. But by tapering it off, as we have indicated, its weight would be reduced to 8 cwt., $\frac{2}{3}$rds of what it was. Thus, not only is a saving effected in the cost of the beam, but as its own weight is an important part of the strain at A, this element of strain is considerably diminished, and the weight hanging from the end may be proportionately increased. The depths at the different points would be as follow :—

Fig. 85.



Section.

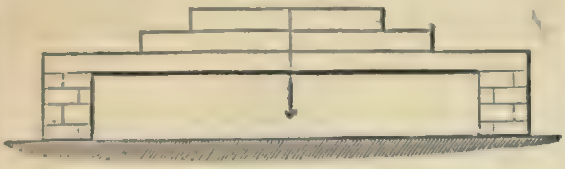


At A, close to the support, 12 inches.
" B, $\frac{3}{4}$ths of the length from A, about $10\frac{1}{2}$, because $10\frac{1}{2}$ squared is about $\frac{3}{4}$ths of 12 squared. $10\frac{1}{2} \times 10\frac{1}{2} = 110\frac{1}{4}$, and $12 \times 12 = 144$, $\frac{3}{4}$ths of which is 108.
" C, $\frac{1}{2}$ the length, or 6 feet from A, about $8\frac{1}{2}$ inches.
" D, $\frac{1}{4}$th the length, or 9 feet from A, 6 inches.

If the depth of the beam cannot conveniently be varied, the breadth may be diminished at a distance from the point of support; because the strength of a beam being at its breadth, and the leverage of the weight being lessened as we recede from the breaking-point, the breadth may be lessened in like proportion. Sometimes it is convenient to vary the depth and breadth also, and thus maintain a similar section throughout the whole length; that is, a section of like figure, but of varying dimensions.

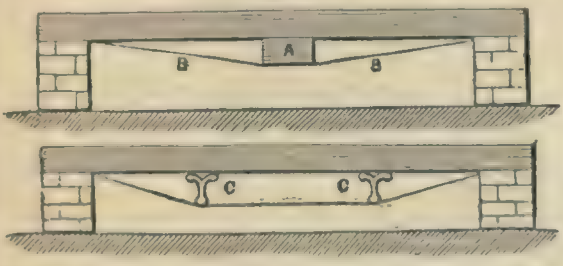
In the case of beams supported at both ends, and loaded in the middle (Fig. 85), the same principle is applied; the dimensions, in respect of depth and breadth, being made greatest in the middle, and diminished gradually towards the ends. This economy of material is easily effected in cast-iron girders, by making the pattern from which the casting is moulded of the requisite form.

Fig. 86.



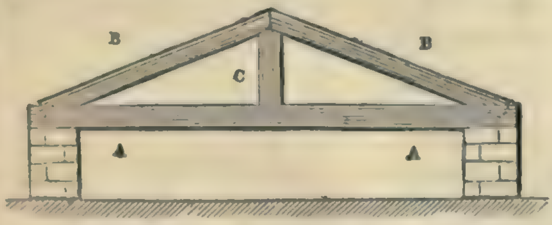
When timber beams are used, the increased depth towards the middle is attained by piling several beams on one another (Fig. 86). As the lower side of a beam resting at both ends is subject to a tensive strain, great additional transverse strength may be secured by straining a rod or chain B B (Fig. 87) from end to end of the beam, and blocking it off from the lower surface by means of one or more wooden or iron struts A or C C. By this arrangement the wooden beam, when loaded between the supports, is subjected to a compressive strain only, the whole of the tensive strain being thrown upon the rod or chain.

Fig. 87.



Again, by fixing a strut, or king-post, C (Fig. 88), upon the upper side of the beam A A, and connecting it by pieces B B to the ends, the compressive strain is thrown on B B, and the tensive strain only on A A. Indeed, there is no limit to the contrivances by means of which the direction and amount of the strain can be varied so as to economise material and secure stability. We have only instanced a few as examples of arrangements, a complete account of which would fill many volumes.

Fig. 88.



CALCULATION OF TRANSVERSE STRENGTH. The table of transverse strengths gives the load which may be safely placed on the middle of beams of different materials supported at both ends. The table applies to beams 1 foot long between the points of support. The weights are those for beams the transverse section of which in the middle is 1 inch square, or 1 inch broad and 1 inch deep; and these apply to all beams of rectangular section. The weights for beams of circular section, may be taken at two-thirds of those for square section. The following are the rules for computing the strengths of beams of various dimensions, according to the data furnished by the table:—

Table of transverse strengths of beams, 1 foot long between supports, lying loose at both ends, loaded in the middle, having a section 1 inch square.

Name of material.	Permanent load.	Name of material.	Permanent load.
Ash	250 lbs.	Oak (English)	190 lbs.
Beech	170 „	Pitch pine............	190 „
Deal	130 „	Teak	270 „
Elm	120 „	Iron (cast)	850 „
Oak (African)	230 „	Iron (wrought)......	1300 „

I. For beams supported at both ends and loaded in the middle. Given the length, breadth, and depth, to find the load.

Rule.—Multiply the number in the table by the breadth (in inches), twice by the depth (in inches), and divide by the length (in feet).

Example 1.—Required the transverse strength of a beam of teak 8 inches broad, 12 inches deep, and 14 feet between bearings.

Number from table opposite teak . .	270 lbs.
Multiply by breadth	8 ins.
	2160
Multiply by depth	12 ins.
	25920
Again by depth	12 ins.
Divide by length	14)311040
	22217 lbs.

Very nearly 10 tons, or 22,400 lbs.

Example 2.—Required the transverse strength of a wrought-iron bar $1\frac{1}{2}$ inch broad, 4 inches deep, and 6 feet long.

$$\frac{1300 \times 1\frac{1}{2} \times 4 \times 4}{6} = 5200 \text{ lbs., nearly } 46\tfrac{1}{2} \text{ cwt.}$$

For bars of circular section.

Rule.—Multiply the number in the table three times by the diameter (in inches), divide by the length (in feet), and deduct one-third of the result from itself.

Example 3.—Required the transverse strength of a beech roller, 2 inches diameter, and 4 feet long.

$$\frac{170 \times 2 \times 2 \times 2}{4} = 340$$

Deduct one-third = 113

227 lbs., about 2 cwt.

II. When the beam is fixed down at its ends.

Rule.—Find the strength as before (I.), and add to it its half.

Example 4.—Required the strength of a cast-iron bar 2 inches broad, 6 inches deep, 9 feet long, fixed at both ends.

$$\frac{850 \times 2 \times 6 \times 6}{9} = 6800 \text{ lbs., about 3 tons.}$$

And one-half 3400 „ $1\frac{1}{2}$ ton.

10200 „ $4\frac{1}{2}$ tons.

III. When the beam is supported loosely at both ends, and has the load uniformly distributed over its length.

Rule.—Find the strength as before (I.), and double it.

Example 5.—Required the strength of a deal rafter 3 inches broad, 11 inches deep, 10 feet long, loaded uniformly throughout its length.

$$\frac{130 \times 3 \times 11 \times 11}{10} \times 2 = 9438 \text{ lbs., about } 4\tfrac{1}{4} \text{ tons.}$$

IV. When the beam is fixed at both ends, and has a load uniformly distributed over its length.

Rule.—Find the strength as in I., and triple it.

Example 6.—Required the strength of a round wrought-iron bar 2 inches diameter, 10 feet long, fixed at ends, the load being uniformly distributed.

$$\frac{1300 \times 2 \times 2 \times 2}{10} = 1040$$

$$\text{Deduct one-third} = \underline{347}$$

$$693 \times 3 = 2079 \text{ lbs.}$$

V. When the beam is loaded by a weight not in the middle.

Rule.—Find the strength as before (I.), multiply twice by half the length, and divide successively by the length of each part into which the beam is divided by the point of suspension.

Example 7.—Required the strength of an ash beam 6 inches broad, 8 inches deep, 14 feet long, to carry a weight 3 feet from one end. Half the length is 7 feet, and the two parts are 11 and 3.

$$\frac{250 \times 6 \times 8 \times 8}{14} \times \frac{7 \times 7}{11 \times 3} = 10{,}182 \text{ lbs., about } 4\tfrac{1}{2} \text{ tons.}$$

VI. When the beam is fixed at one end and loaded at the other.

Rule.—Find the strength as in I., and divide it by 4.

Example 8.—Required the strength of an English oak beam 13 inches square, projecting 10 feet from a wall, to bear a load at the end.

$$\frac{190 \times 13 \times 13 \times 13}{10} = \underline{41743 \text{ lbs.}} \text{ strength by I.}$$

$$\text{Divide by 4, } \underline{10436 \text{ lbs.}}$$

These cases include most of the circumstances which occur in practice. The converse operations for finding the dimensions of a beam when we know the weight it has to bear, do not furnish us with the breadth and depth separately (except in the case of cylindrical and square beams when the depth and breadth are equal), but give us a result which is the product of the breadth by the square of the depth. We must, therefore, be guided by other circumstances in determining one of these dimensions; and having determined the one, we easily find the other. For instance, if we were required to provide a cast-iron girder of rectangular section, such that when placed on two walls 10 feet apart it should carry a load of 2 tons in the middle, we should reason thus:—By the table, a cast-iron rectangular beam 1 inch broad and 1 inch deep, and 1 foot between supports, bears 850 lbs.; one 10 feet between supports must be made ten times as strong to bear 850 lbs.; and to bear 2 tons, or 4480 lbs., it must be about five-and-a-quarter times as strong, because 4480 lbs. is about five-and-a-quarter times 850 lbs.

The strength, then, for the given length and weight must be $5\frac{1}{4} \times 10 = 52\frac{1}{2}$; or, more correctly,

$\frac{10 \times 4480}{850} = 52{\cdot}7$ times that of a beam 1 inch broad and 1 inch deep. But as the strength is as the breadth multiplied by the square of the depth, the number 52·7 must be the product of the breadth in inches, multiplied by the square of the depth, or twice by the depth; and if we determine one of these dimensions, we can easily ascertain the other: thus—

Assume breadth,	then depth,	because	nearly
1 in. . .	$7\frac{1}{4}$ in. . .	$1 \times 7\frac{1}{4} \times 7\frac{1}{4}$	$= 52{\cdot}7$
2 in. . .	$5\frac{1}{8}$ in. . .	$2 \times 5\frac{1}{8} \times 5\frac{1}{8}$	$= 52{\cdot}7$
3 in. . .	$4\frac{1}{8}$ in. . .	$3 \times 4\frac{1}{8} \times 4\frac{1}{8}$	$= 52{\cdot}7$
4 in. . .	$3\frac{5}{8}$ in. . .	$4 \times 3\frac{5}{8} \times 3\frac{5}{8}$	$= 52{\cdot}7$
5 in. . .	$3\frac{1}{4}$ in. . .	$5 \times 3\frac{1}{4} \times 3\frac{1}{4}$	$= 52{\cdot}7$

And so on, the one dimension being assumed according to circumstances of convenience, or for other reasons. When it is determined that the section of the beam shall be square, the product found as above is the cube of the breadth or depth, or it is the breadth multiplied 3 times by itself; and therefore the breadth or depth is found by taking the cube root of this product. In the case given, the cube root of 52·7 is about $3\frac{3}{4}$; and we therefore conclude that if the beam be of square section, its breadth or depth must be $3\frac{3}{4}$ inches, because $3\frac{3}{4} \times 3\frac{3}{4} \times 3\frac{3}{4} = 52{\cdot}7$ When the beam is cylindrical, the diameter is also determined. Since the strength of a cylindrical beam is about $\frac{2}{3}$ of a square one of the same material, we must make up the other $\frac{1}{3}$ by adding to its dimensions; and as $\frac{1}{3}$ is one-half of $\frac{2}{3}$, we must add to the product its half, and then take the cube root as for a square beam. In the case given, adding to 52·7 its half, or 26·35, we have 79·05, which is nearly the cube of $4\frac{1}{4}$; and we must therefore make the diameter of a cylindrical beam $4\frac{1}{4}$ inches, or more correctly 4·3 inches.

As a proof of the accuracy of our calculation, we have only to reverse the operation, and calculate the load which the beam of the dimensions we have thus determined will bear. If the result correspond with the given weight, we know that we are right. In the example we have taken, we have to find the strength of a cylindrical cast-iron beam 4·3 inches diameter and 10 feet long. By the rule for bars of circular section, case I.,

$$\frac{850 \times 4{\cdot}3 \times 4{\cdot}3 \times 4{\cdot}3}{10} = 6758 \text{ lbs.}$$

$$\text{Deduct } \tfrac{1}{3} = \underline{2253}$$

$$4505$$

Nearly 2 tons, or 4480 lbs., the load which the beam was intended to carry.

The following rules give the mode of calculating the *strength product* under various circumstances of strain, and then the method of dealing with the *strength product* when the form, proportions, or one of the sectional dimensions of the beam is given. The cases are numbered in the same order as those in the calculation of the load.

I. Beams supported at both ends and loaded in the middle: given the length and load to find the *strength product.*

Rule.—Multiply the load (in lbs.) by the length (in feet), and divide by the number in the table.

Example 9.—Required the *strength product* for a beam of teak 14 feet between bearings, to carry 10 tons in the middle.

$$10 \text{ tons} = 22{,}400 \text{ lbs.}$$

$$\frac{22{,}400 \times 14}{270} = 1161, \text{ strength product.}$$

8 ins. broad and 12 ins. deep would suit this case, because $8 \times 12 \times 12 = 1152$, nearly 1161.

II. When the beam is fixed down at the ends.

Rule.—Find the strength produced as in I., and deduct from it its $\frac{1}{3}$rd part.

Example 10.—A cast-iron bar fixed at both ends 9 feet apart has to carry 10,200 lbs.

$$\frac{10{,}200 \times 9}{850} = 108$$

$$\text{Deduct } \tfrac{1}{3} = \underline{36}$$

$$72 = \text{strength product.}$$

2 ins. broad and 6 ins. deep, for $2 \times 6 \times 6 = 72$.

III. When the beam is loosely supported, and the load uniformly distributed.

Rule.—Halve the strength product.

Example 11.—A deal rafter 10 feet long is loaded uniformly with 9438 lbs.

$$\frac{9438 \times 10}{130} \times \tfrac{1}{2} = 363$$

3 ins. broad and 11 ins. deep, for $3 \times 11 \times 11 = 363$.

IV. When the beam is fixed at both ends, and has the load uniformly distributed.

Rule.—Divide the strength product by 3.

Example 12.—A wrought-iron bar 10 feet long, fixed at its ends, is loaded with 2080 lbs., uniformly distributed.

$$\frac{2080 \times 10}{1300 \times 3} = 5.333, \text{ or } 5\tfrac{1}{3} \text{ the strength product.}$$

If the bar be round, we must increase this by one-half, making it 8; and as 8 is the cube of 2, or 2 × 2 × 2, the round bar must be 2 ins. diameter.

V. When the beam is loaded not in the middle.

Rule.—Multiply the strength product successively by the two lengths into which the weight divides the beam, and divide twice by half the total length.

Example 13.—An ash-beam 14 feet long, has 10,182 lbs. suspended from it 3 feet from one end (consequently 11 feet from the other, half the length being 7 feet).

$$\frac{10,182 \times 14}{250} \times \frac{11 \times 3}{7 \times 7} = 384.$$

6 inches broad and 8 inches deep, for 6 × 8 × 8 = 384.

VI. When the beam is fixed at one end and loaded at the other.

Rule.—Multiply the strength product by 4.

Example 14.—An English oak beam projects 10 feet, and carries 10,433 lbs. at the end.

$$\frac{10,433 \times 10}{190} \times 4 = 2196.$$

13 inches square, for 13 × 13 × 13 = 2197.

The following rules embody the methods of dealing with the strength product when found as above.

1. Given the depth to find the breadth.

Rule.—Divide the strength product twice by the depth (in inches), the quotient is the breadth (in inches).

Example 15.—Beam 6 inches deep to give strength product 72.

$$\frac{72}{6 \times 6} = 2 \text{ inches, the breadth}$$

2. Given the breadth to find the depth.

Rule.—Divide by the breadth, and take the square root of the quotient.

Example 16.—Beam 8 inches broad strength product 1161.

$\frac{1161}{8} = 145$, the square root of which is nearly 12, for 12 × 12 = 144.

3. When the beam is square in section.

Rule.—Take the cube root of the strength product.

Example 17.—Square beam, strength product 2196. Cube root of 2196 = 13 nearly, for 13 × 13 × 13 = 2197.

4. When the beam is cylindrical.

Rule.—Increase the strength product by its half, and take the cube root.

Example 18.—Cylindrical beam, strength product $5\frac{1}{3}$
Add half of $5\frac{1}{3}$ = $2\frac{2}{3}$

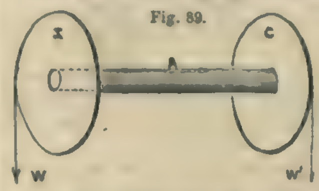
$$\overline{8}$$

Cube root of 8 = 2.

For beams of other forms than those which have square, rectangular, or circular sections, we cannot furnish any rule. Practical men, from long experience, and from a habit of observing the proportions suitable to certain strains, can form a tolerably accurate conception of the strength due to particular forms under various conditions. Before any mechanical work is executed, the appearance of the parts on the drawing recommends itself to a practised eye, or otherwise, according as the details are studied in consonance with the just proportions of strength or otherwise. In providing not only against absolute fracture, but also against deflection, vibration, and all such elements of degradation and weakness, the strength must be made very much in excess of that which the mere calculation of breaking-strain would indicate; and the different modes of providing adequate firmness and permanence without extravagant use of materials, are matters of ingenious contrivance for which no rule can be furnished.

4. TORSION.—As, in machinery, motion is generally conveyed from one part to another by means of shafts or spindles rotating on their axes, it becomes a matter of considerable importance to determine the strength of materials to resist a twisting or wrenching force. If we suppose an iron shaft fitted with a wheel at each end, one of which is driven by some prime mover, such as a steam-engine, and the other conveys the power or motion to some machinery, it is clear that the whole power so conveyed has to pass through the shaft; and the resistance of the machinery at the one end to the prime force applied at the other, subjects the shaft to a torsive or twisting strain.

Fig. 89.



That we may simplify the view which we should take of this kind of strain, we shall suppose a shaft A (Fig. 89) fitted with a wheel at each end Z and C, round the circumference of each of which, in opposite directions, a rope passes, suspending weights W W′. The wheels and weights being equal and balanced, the shaft is not caused to turn in either direction; but both weights tend to twist the shaft in itself. If instead of one of the weights W′ we were to substitute a fixed pin or hook to which the rope might be attached, the rope would still be subjected to the same strain as if it had the weight suspended from it; and as it would react on its wheel with a force precisely equal to its tension, the twisting effect on the shaft would not be altered. We may, therefore, suppose the wheel and weight entirely removed from one end of the shaft, and that end fixed firmly in such a manner that it cannot turn or revolve on its axis, while it is throughout its whole length subjected to a twisting strain from the action of the weight at the other end. The power with which this weight tends to twist the shaft, depends both on its magnitude and on the size of the wheel round which its rope passes. The radius, or half-diameter, of the wheel is the leverage of the weight; and by increasing it we increase the torsive strain in like proportion. For ease of calculation, we will suppose the radius, or half-diameter, of the wheel to be 1 foot; and if we can find the torsion of a certain weight acting at a radius of 1 foot, we can reckon that of the weight at any other radius; or having found the weight to produce a certain torsion at 1 foot radius, we can easily reckon the radius at which the same weight would produce some other amount of torsion.

Thus, by doubling or trebling the radius we double or treble the torsive strain; by doubling or trebling the weight, we have to place it at one-half or one-third the radial distance from the centre of the shaft, in order to subject it to the same torsion; and so generally in simple proportion. The torsive strain, therefore, is as the weight multiplied by its radial distance. One ton at a radial distance of 3 feet, is equivalent to 3 tons at a radial distance of 1 foot, because 1 ton × 3 feet = 3 tons × 1 foot.

We have now to inquire what effect the dimensions of the shaft, or the quantity of material in it, has in resisting a certain torsive strain; how large the shaft must be to resist a given strain, or what strain a shaft of given dimensions can resist. The replies to these questions must depend upon the form of section and the nature of the material employed; but if we can ascertain, by direct experiment, the torsive strength of a shaft of certain material, form, and dimensions, we must endeavour to find a principle on which to reckon the strength of a shaft of the same form and material, but of different dimensions. We may imagine two plates of metal or other material, placed face to face, having such corresponding projections and hollows in their surfaces, that the projections of the one fit into the hollows of the other. We may suppose these plates pressed together, and some force applied at their edges, so as to push the one along the face of the other. It is manifest, that the force for this purpose must depend upon the amount of roughened surface in contact, upon the pressure squeezing the plates together, and the peculiarities of the roughness which their surfaces present. Instead
